Such a thermal limitation does not exist in production of heat for process use where no conversion to work is involved. Except for relatively small leakages, all of the heat energy supplied to the transfer medium is capable of being utilized. This suggests that, if power and process heat could be produced together, some or all of the heat that otherwise would be wasted by heat rejection could be used, thus saving energy. This ideal is what actually occurs in cogeneration. During an industrial process, heat energy may be consumed by fluid heating, endothermic chemical reactions, or other needs, but any of the energy remaining in the form of low-level heat has potential value because it may ultimately reach the environment by, say, heating a building rather than being wasted.

In some cases, such as with industrial furnaces and kilns, the process need is for *high-level* (i.e., high-temperature) heat. Here, also, where effective uses of such large quantities of "leftover" heat are not available, cogeneration allows the option of converting heat energy that would otherwise be wasted to power. As will be explained later, when the power conversion is thermally below the heat utilization, it is called a "bottoming" cycle.

Figure 73.2 shows the energy savings with cogeneration by comparison of separate versus cogenerative plants accomplishing the same power generation and process heat duty. The typical power generation system is the same in either case—except, with cogeneration, energy that would have been rejected is used to supply the process heat.

**Figure 73.2** Energy savings with cogeneration. (After Boissenin, Y. 1992. *Cogeneration and energy savings. GEC Alstom Technical Review No. 10.* European Gas Turbines S.A., Belfort, France.)

## Units for Power and Heat Flow

The numbers shown on Fig. 73.2 for both power and heat flow are intended to be in megawatts, which would make the figure comparable in size to actual plants of this type. The classic units for heat (i.e., Btu, joules, calories, etc.) vary with the unit convention being used, but the use of watts as a basic unit for electric energy is common to most conventions. Further, the use of watts as the common unit for both heat flow and power is frequently done for simplicity. Accordingly, a thermal kilowatt ( $kW_t$ ) is understood to be 3412.14 Btu/h, 3600 kJ/h, or 859.9 kcal/h, according to the electrical equivalent of heat as expressed in three commonly used unit conventions. As shown in the Fig. 73.2 diagram,  $E$  will henceforth refer to electrical or shaft power, in  $kW_e$  or  $MW_e$ . For heat flow,  $Q_f$  will refer to heat release rate of fuel,  $Q_u$  to useful heat flow to process, and  $Q_r$  to heat flow wasted by rejection, in  $kW_t$  or  $MW_t$  unless otherwise noted.

The values for fuel heat release and efficiencies in Fig. 73.2 and elsewhere in this chapter are based on the **lower heating value (LHV)** of the fuel. LHV excludes the latent heat of water vapor formed from combustion of hydrogen in fuel compounds. It is excluded because this energy is almost always lost with the vapor in the flue gas at temperatures above 150°F, and using LHV makes comparative cycle analysis easier (independent of the fuel). Nevertheless, only *higher heating value (HHV)* can be directly measured and, therefore, is always the basis of fuel cost, so that in economic evaluations HHV must be determined. It is a good practice to show both LHV and HHV for fuel heat release and efficiencies where economics are involved, particularly if different fuels must be compared. This is a simple matter of multiplying LHV heat release and **heat rate**, or dividing thermal efficiency, by a constant (e.g., typically 1.11 for natural gas or 1.06

for diesel oil). For fuels without hydrogen (e.g., pure carbon or coke) the constant is 1.0 and LHV and HHV are identical.

## Heat Rate and Efficiency for Noncogenerative Cycles

It is important to recall relations for conventional power cycles so that corresponding parameters for cogeneration may be more easily explained. Heat rate is a standard parameter in both the power and industrial fields for sizing and rating power plants and is always expressed in classic heat units. It is closely related to thermal efficiency,  $\eta$ , which is a dimensionless ratio that can be expressed in percent. Considering the separate power generation system on the upper left in Fig. 73.2, we see that the fuel heat release,  $Q_f$ , to the system is 70 MW<sub>t</sub> (LHV). The net power,  $E_{\text{net}}$ , is 35 MW<sub>e</sub>. (The term *net* here refers to the power that is actually delivered to the utility grid, after subtracting cycle **auxiliary power** and any other electrical losses from the output at the generator terminals quoted by the equipment manufacturer.) With the foregoing established, heat rate and efficiency for the conventional power generation example on the upper left in Fig. 73.2 then become, with Btu/h units and HHV for natural gas:

$$\text{Net heat rate (LHV)} = \frac{Q_f \times 3412.14}{E_{\text{net}}} = \frac{238.85 \cdot 10^6}{35\,000} = 6824 \text{ Btu/kWh}$$

$$\text{Net heat rate (HHV)} = 1.11 \times 6824 = 7575 \text{ Btu/kWh}$$

$$\text{Thermal efficiency (LHV), } \eta = \frac{E_{\text{net}}}{Q_f} = \frac{35\,000}{70\,000} = 50\%$$

$$\eta = \frac{3412.14}{\text{Net heat rate}} = \frac{3412.14}{6824} = 50\%$$

$$\text{Thermal efficiency (HHV)} = \frac{50}{1.11} = 45\%$$

Note that heat rate is simply the reciprocal of thermal efficiency with unit conversion.

## Cogeneration Performance Criteria

The criteria of efficient performance of a cogeneration plant are quite different from that of a conventional power plant. In the latter, the object is usually to meet a demand for a single product, power, with the least amount of fuel. In a cogeneration plant there are *two* products, power and heat, which together require more fuel energy than either would require if produced separately (although less fuel energy than both would so require). Because the products and their required fuel are now intertwined, the heat rate and thermal efficiency definitions given above are no longer adequate. New definitions are required to account for the two products.

## Energy to Process

Figure 73.3 shows schematically an industrial boiler providing heat to a process, without power production, as in the lower left side of Fig. 73.2. The heat is provided in the form of steam, which is returned as condensate to a system reservoir, usually the deaerator, where dissolved oxygen is removed by a relatively small amount of deaerating (d/a) steam. The **net heat to process**,  $Q_u$ , is defined strictly based on the energy entering and leaving the process, except that frequently some or all of the steam delivered to the process does not return as condensate, and makeup water must be provided to keep up the system inventory. As shown in Fig. 73.3,  $Q_u$  is defined as the difference in total enthalpy, here in Btu/h, between that of the steam delivered to process and that of the sum of condensate returned plus makeup required.

**Figure 73.3** Net heat to process.

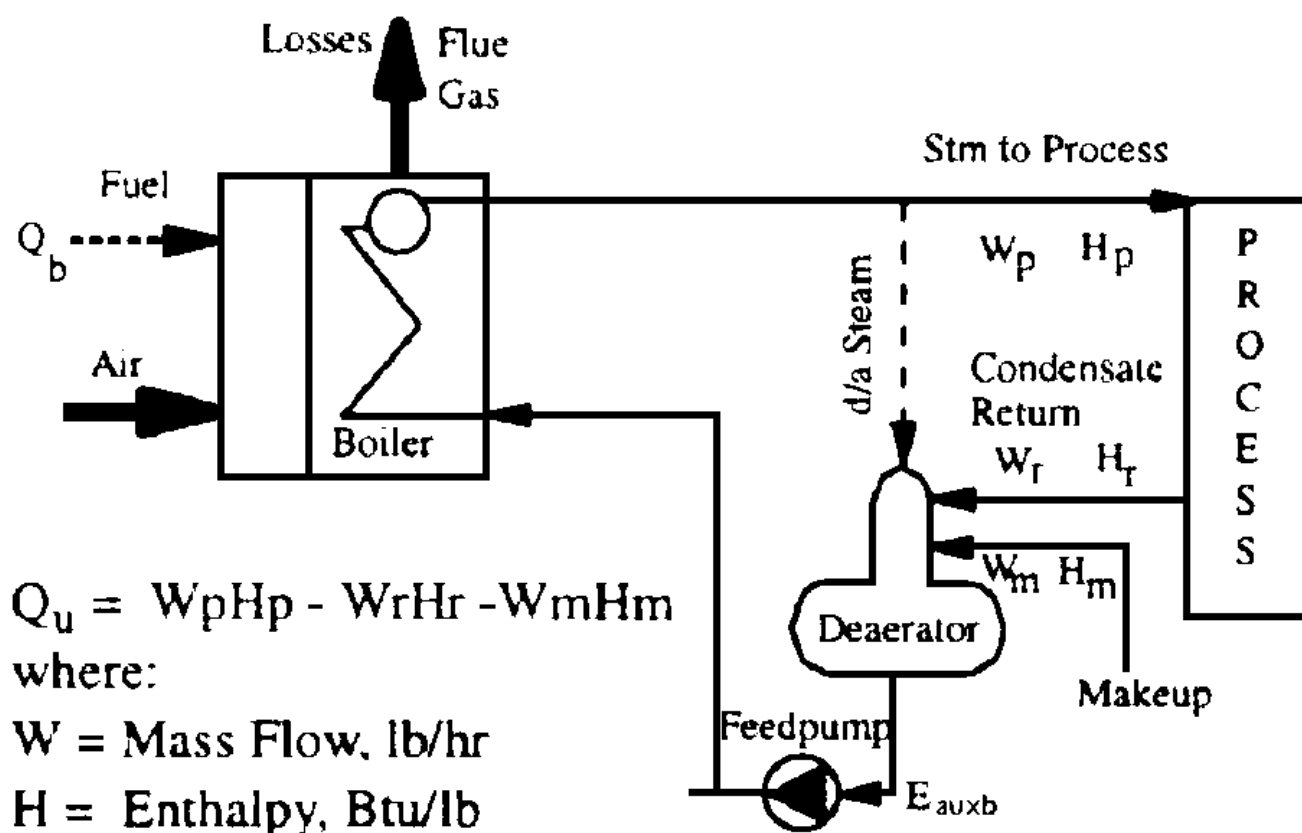

Figure 73.3 also illustrates another form of energy that is necessary in providing process heat. This is the auxiliary power necessary to run the boiler system, here represented as the electric power required to run the boiler feed pumps,  $E_{auxb}$ . This usually includes power to run boiler fans and other necessary devices and is typically less than 2% of the process heat, or about 1000 kW<sub>e</sub>, for the 50 MW<sub>t</sub> process shown in Fig. 73.2. This energy is not included in the boiler efficiency,  $\eta_b$ , which involves only the energy balance around the boiler. (Nor is any energy associated with condensing the d/a steam, since that energy does not leave the system and is present at the boiler inlet.) Further definitions for a cogenerated plant will involve  $\eta_b$  and  $E_{auxb}$  for a hypothetical heat-only plant delivering the same amount of process heat as the cogenerated plant.

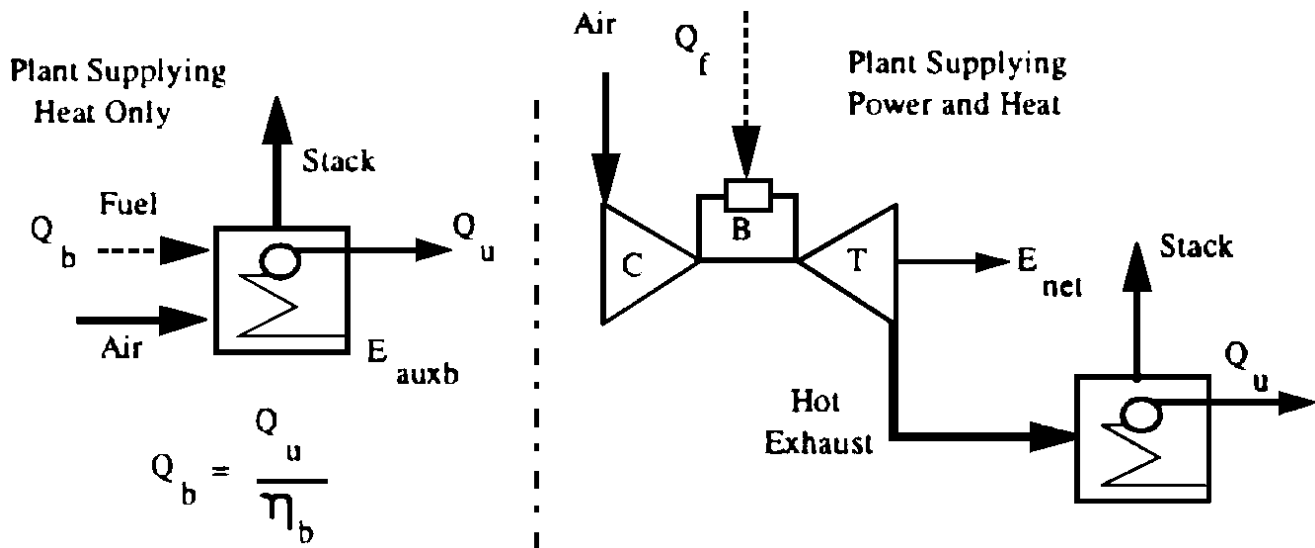

### Energy Utilization Factor (EUF) and Primary Energy Savings

These terms are defined in Fig. 73.2 as measures of the savings from cogeneration by comparing separate and combined production. However, as Horlock [1987] suggests, the EUF is not considered an efficiency, as it has been by some authors, because it mixes power and heat flow in the numerator rather than relating power to available thermal energy as in the classic thermal efficiency definition. Furthermore, it causes confusion with a more rigorous, industry-preferred, cogenerative efficiency definition that is based on noncogenerative heat rate and thermal efficiency as defined above.

### Cogenerative Efficiency

The industry-preferred cogenerative efficiency definition starts with **fuel chargeable to power (FCP)**, which is analogous to heat rate, in that it is the power related fuel required, in Btu/h, per kW<sub>e</sub> produced. Figure 73.4 shows the relations needed to define FCP. Numerical values correspond to the right side in Fig. 73.2.

**Figure 73.4** Fuel chargeable to power. (Adapted from Kovacic, J. M. 1983. *Industrial Gas Turbine Cogeneration Application Considerations*. Report No. GER-3430. Gas Turbine Reference Library, General Electric Company, Schenectady, New York.

$$\begin{aligned}
 \text{FCP} &= \frac{\text{Total fuel} - \text{Process fuel credit}}{\text{Net power} + \text{Process aux pwr. credit}} \\
 \text{FCP} &= \frac{(Q_f - Q_u/\eta_b) \times 3412.14}{E_{\text{net}} + E_{\text{auxb}}} \\
 \text{FCP} &= \frac{(100\,000 - 50\,000/0.93) \times 3412.14}{35\,000 + 1000} \\
 &= 4382.4 \text{ Btu/kWh (LHV)}
 \end{aligned}$$

By analogy with thermal efficiency, defined earlier relative to heat rate, we now can state, using Btu, **cogenerative efficiency** as

$\eta_{\text{FCP}} = (E_{\text{net}} + E_{\text{auxb}})/(Q_f - Q_u/\eta_b) = 3412.14/\text{FCP}$  [Horlock, 1987; Kovacik, 1983]. A numerical example, using Fig. 73.2 (right side), is  $3412.14 / 4382.4 = 77.9\%$ . The validity of the FCP relationship is apparent from applying it to the extremes of  $E_{\text{net}}/Q_u$ . If  $Q_u$  approaches 0,  $E_{\text{net}}/Q_u$  becomes very large and FCP reduces to the noncogenerative power heat rate. This effectively happens when  $E_{\text{net}}/Q_u$  is larger than about 5 [Boissenin, 1992]. The value  $\eta_{\text{FCP}}$  is maximized when  $Q_u$  is equal to the noncogenerative heat rejection from pure power production for the given power system. For a power system with noncogenerative thermal efficiency of 50%, this peak occurs when  $E_{\text{net}}/Q_u = 1$  and all of the erstwhile rejected heat is used to supply the process. For  $E_{\text{net}}/Q_u$  approaching zero, the system becomes "heat only," with thermal efficiency approaching that of the industrial boiler in Fig. 73.2.

### Fuel Split

The FCP does more than provide an index of energy efficiency. It also provides one means of dividing the fuel between the two products, which is necessary for allocation of fuel cost in economic evaluation. For example, again using the numbers in Fig. 73.2, the total cogenerated fuel is 100 MW<sub>t</sub> and the net power is 35 MW<sub>e</sub>. From above, the FCP is 4382.4 Btu/kWh, so that the power production share of the fuel is  $35\,000 \times 4382.4 = 153.38 \cdot 10^6$  Btu/h, or 45 MW<sub>t</sub> (dividing by 3412.14). The remainder,  $100 - 45 = 55$  MW<sub>t</sub>, would be fuel chargeable to heat, meaning chargeable to the **thermal host**.

The problem with the foregoing, as pointed out by Horlock [1987] and others, is that, strictly thermodynamically, there is no alternative to giving equal "weight" to a unit of heat and a unit of power, and, in allocating the fuel using FCP as the basis of cogenerative efficiency, *all* of the fuel savings from cogeneration are credited to the power producer. Horlock suggests a "value-weighted" efficiency and fuel allocation method that usually charges less of the fuel to the thermal host according to the ratio of the "sale value" of a kWh of heat to a kWh of power. There are several more sophisticated approaches to economic optimization beyond the scope of this article, that are given in Horlock and other references cited later.

## 73.2 Examples of Cogeneration

Cogeneration plants may be classified according to the *thermal sequence* of power and heat production, which relates to the type of industries served. Plants so classified are said to involve "topping" or "bottoming" cycles. The *fuel* is another characteristic that affects the design of the plant. The magnitude of the energy output will determine the *physical size* of the plant, which affects the type of machines used. Brief descriptions of typical plants as affected by each of these characteristics are given in the following paragraphs.

### Thermal Sequence

The topping cycle—in which the major conversion to power is thermally *above* the delivery of heat to process—is by far the most effective and economically attractive form of cogeneration. This is because, in power production, the heat most readily available for cogeneration is that which would otherwise be rejected at low temperatures. Further, conversion to power, for which demand and potential revenue are highest, is most efficient at high temperatures. Nevertheless, the temperature level of heat rejection can be high enough for many processes, and/or the temperature range of effective power and heat utilization can be shared.

Figure 73.5 shows a typical topping cycle example involving a diesel engine. For small to medium power systems up to 10 MW<sub>e</sub>, the diesel can be very economical with regard to capital and operating cost. The exhaust temperature, ranging from 1000 to 1400°F, can be used to generate hot water and/or steam through a heat recovery steam generator (HRSG).

**Figure 73.5** Small topping cycle cogeneration plant. (Source: Butler, C. H. 1984. *Cogeneration: Engineering, Design, Financing, and Regulatory Compliance*. McGraw-Hill, New York.)

In a bottoming cycle the primary energy source is first applied to a useful heating process at high temperature, and the rejected heat emerging from the process is then used for power production. It is not as effective as the topping cycle, because the Carnot/second-law principle of low-temperature heat rejection during conversion of heat into work is on the wrong side, working against effective heat recovery rather than with it. Obviously, the bottoming cycle is necessary only when the process need is for relatively large amounts of high-temperature heat, such as in industrial furnaces and kilns. [Figure 73.6](#) shows a high-temperature furnace process for production of ethylene,  $C_2H_4$ , the raw material for manufacturing plastics. Ethylene is produced by "cracking" heavier molecules such as ethane,  $C_2H_6$ , by raising the temperature of the ethane feedstock to 1600°F in a furnace maintained at 2100°F by burners firing natural gas. The feedstock flows inside a tube in a flat "cracking coil" (S-shaped dashed line in [Fig. 73.6](#)). As the molecules of ethane break into ethylene (and other compounds), it is important to quench, or rapidly cool the "cracked gas" to optimize the "yield" and prevent the cracking process from proceeding too far, forming carbon (coke). A steam generation loop (quench loop) accomplishes this by generating high-pressure steam, thus cooling the gas. The steam thus formed is superheated in the hot convective section of the furnace outlet where the stack gases are cooled, recovering the leftover heat from the furnace. The superheated steam is used in steam turbines that drive compressors for the downstream ethylene separation processes. The quench loop and the steam turbocompressors will be recognized as a bottoming cycle. Note, also, that a condenser is used, which indicates that it was impractical to recover all of the furnace heat due to the down-side location of the power cycle.

**Figure 73.6** Ethylene furnace bottoming cycle (and topping cycle). (*Source: Cooke, D. H. 1987. Combined Cycle Thermodynamic Inquiries and Options for Cogeneration Facilities in the Process Industry. ASME Paper No. 87-JPGC-Pwr-61. ASME, New York.*)

**Figure 73.6**

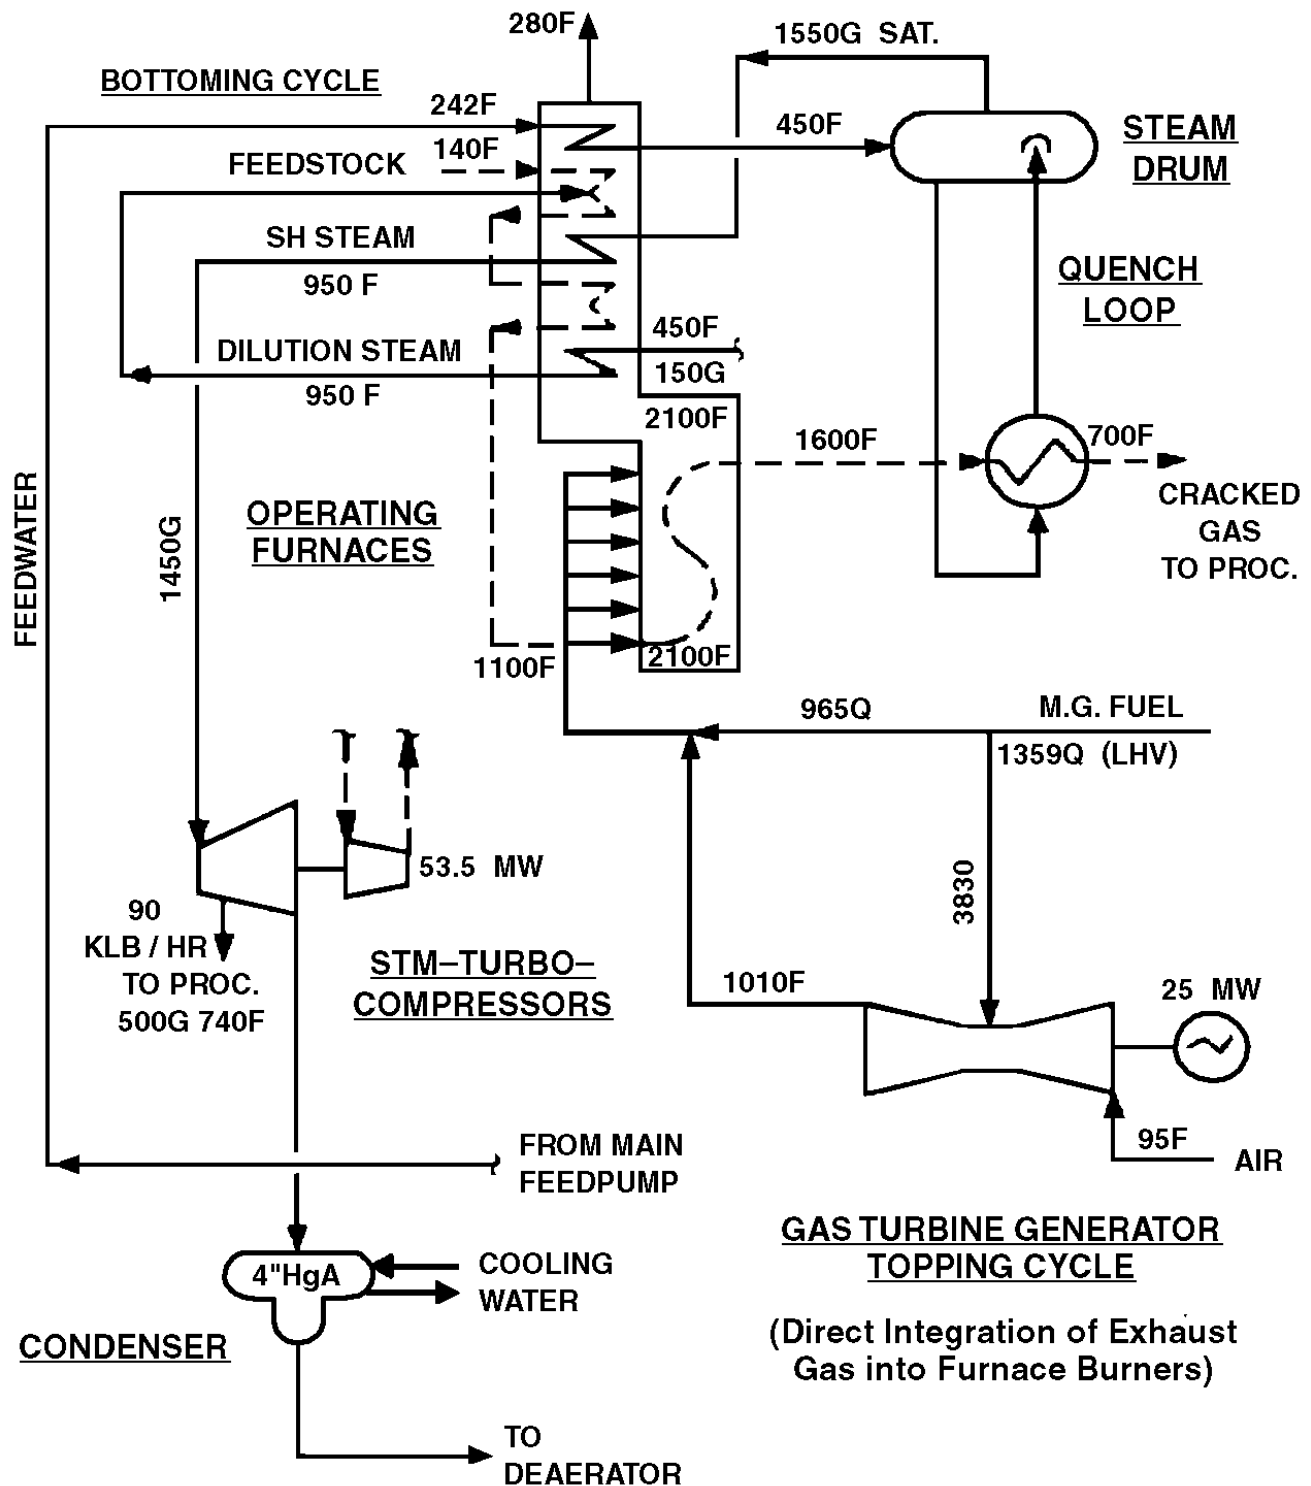

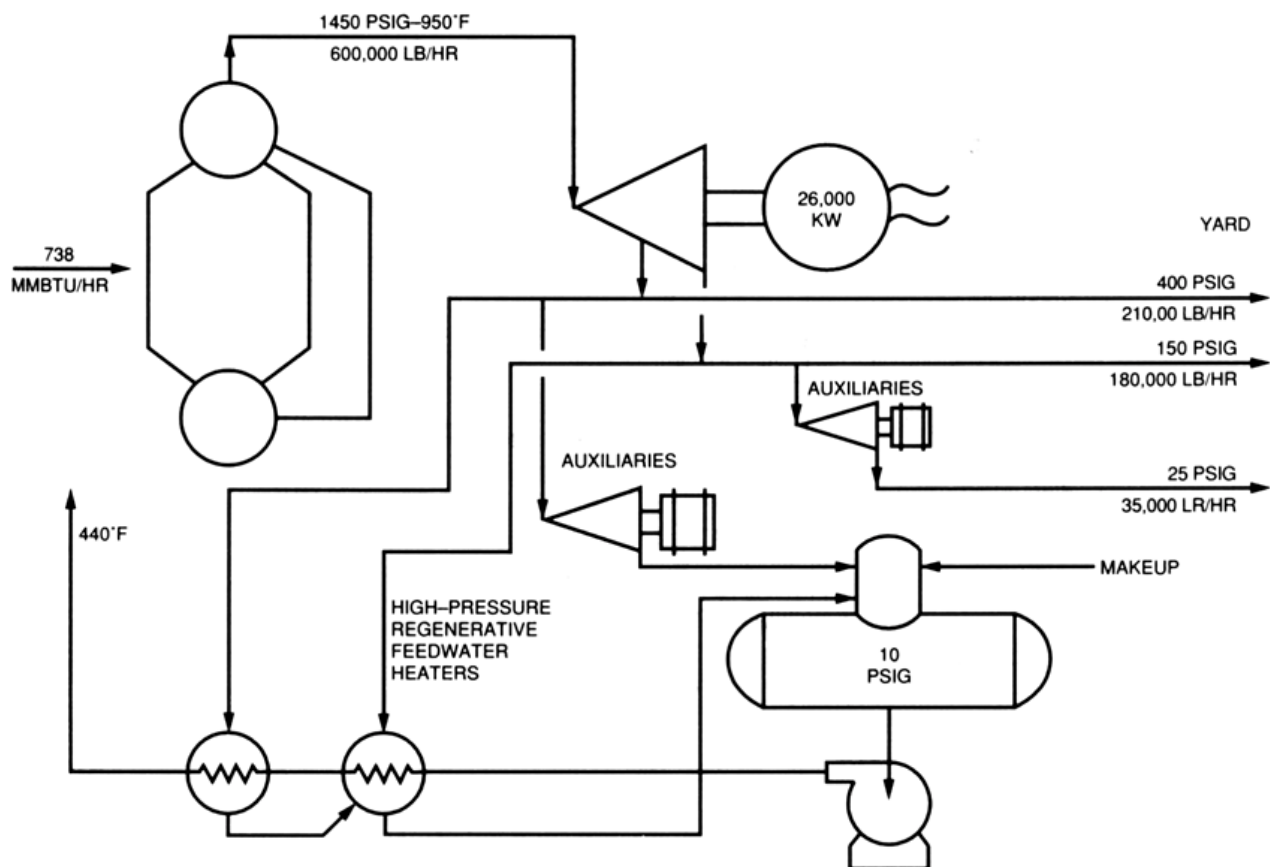

Figure 73.6 also illustrates a *topping* cycle consisting of several gas turbines generating 28 MW<sub>e</sub> of electric power each and exhausting directly into the furnace burners. There is enough residual oxygen in the gas turbine exhausts that the 1010°F exhaust gas acts as heated combustion

air, reducing the fuel required to maintain the furnaces "at temperature."

## Plants for "Difficult" Fuels

Over the years, the workhorse of utility and industrial power generation has been the steam power, or Rankine, cycle. This type of plant features a furnace type, near-stoichiometric-combustion boiler, producing steam at high pressure and temperature in a separate closed loop free of erosive particles for expansion through the turbines. In recent years, technological advances with the gas turbine have produced plants with considerably higher efficiency and lower capital cost than the pure Rankine. However, the pure Rankine still enjoys one advantage in that cheaper, and possibly more abundant, solid fuels such as coal, lignite, and coke—more difficult in terms of handling, burning, and waste disposal than gaseous or liquid fuels—can be used. Figure 73.7 shows a typical pure Rankine cycle cogeneration plant supplying steam for process heat at several pressure levels in a refinery.

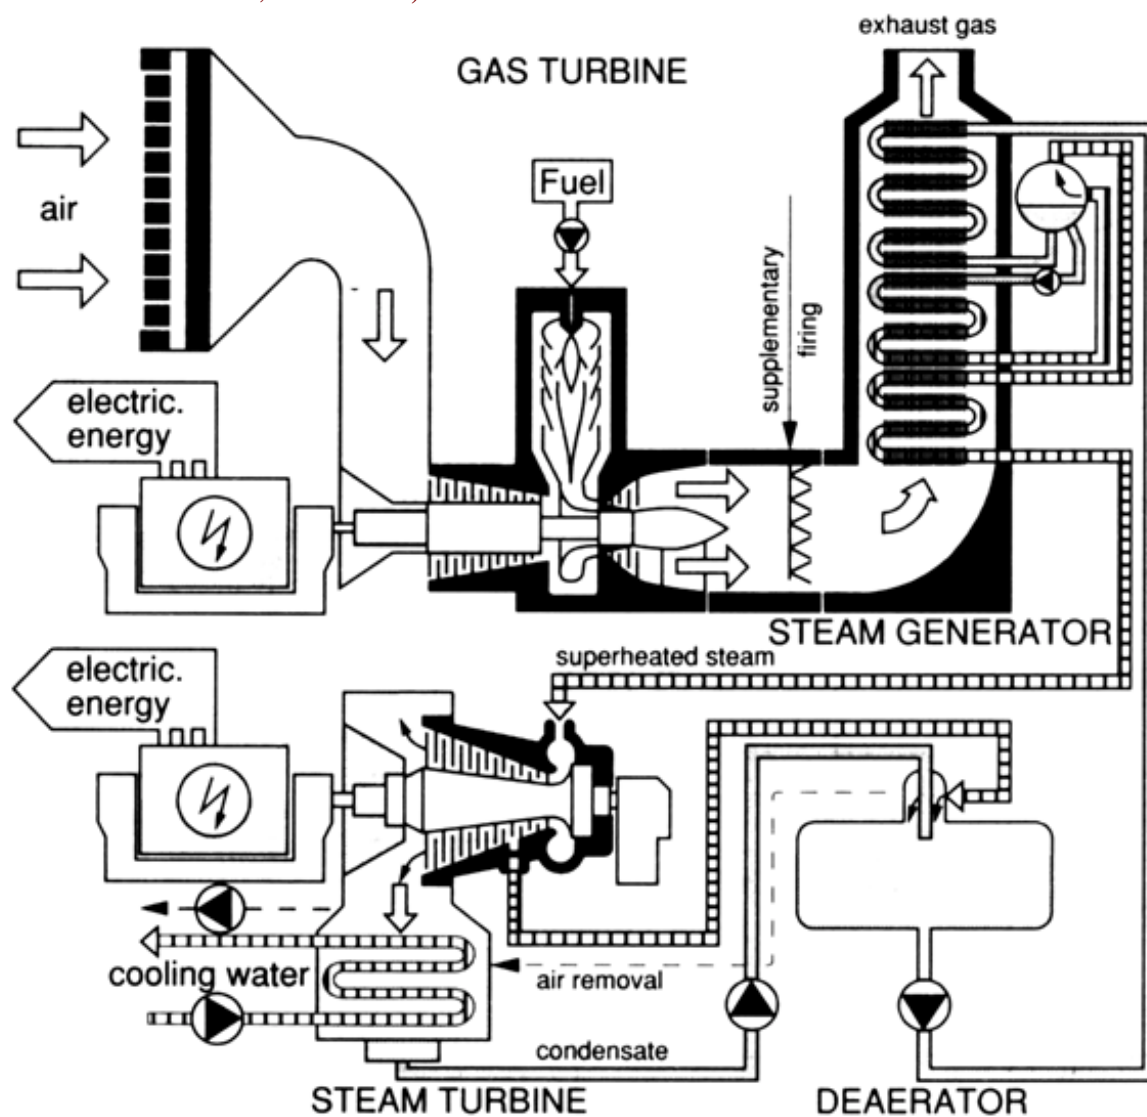

**Figure 73.7** Rankine cycle cogeneration plant. (Source: Cooke, D. H. 1987. *Combined Cycle Thermodynamic Inquiries and Options for Cogeneration Facilities in the Process Industry*. ASME Paper No. 87-JPGC-Pwr-61. ASME, New York.)

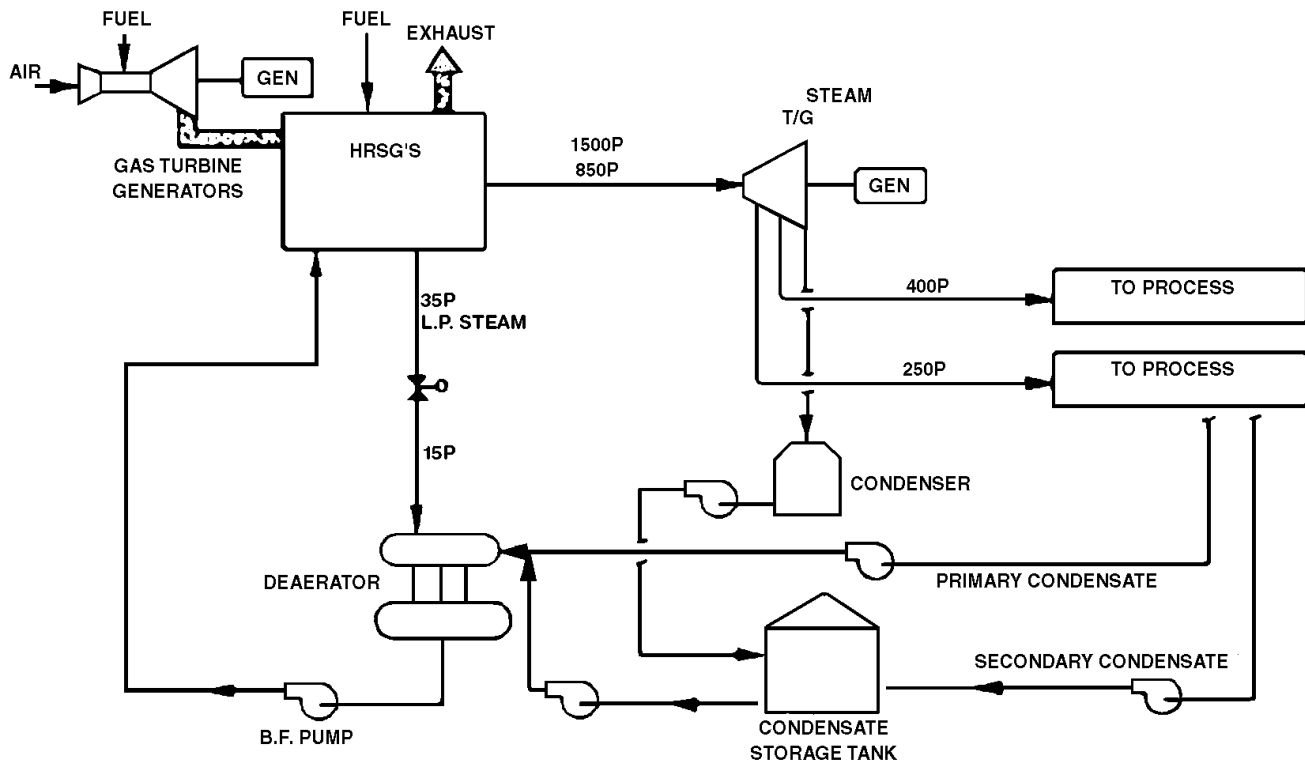

## Large-Scale Power and Cogeneration

The gas turbine, or Brayton/Joule, cycle has come into its own as the cycle of choice for large-scale power (typically up to 230 MW<sub>e</sub> with a single engine in *simple cycle*) and cogeneration systems. Using technology developed for aircraft, the gas turbine produces power very efficiently at extremely high temperatures (typically 2200°F, versus 1000°F maximum for steam), exhausting at about 1000°F, so that a complete Rankine cycle steam plant, with the gas turbine exhaust replacing the furnace boiler, can *double* the simple cycle plant output in **combined cycle**. Safe, reliable, combined cycle power systems of this type typically reach 50% net thermal efficiency, compared to 35% for the best pure Rankine plants. The combined cycle offers great flexibility for cogeneration. For example, instead of converting the high-level exhaust heat to power, the entire steam output can be used for process as shown in Fig. 73.4. A complete combined cycle power system is shown conceptually in Fig. 73.8, including provision for supplementary firing in the gas turbine exhaust duct, which gives excellent control over a wide range of increased steam production. The use of such a system in a large multilevel steam cogeneration plant is illustrated in Fig. 73.9.

**Figure 73.8** Gas turbine combined cycle. (Source: Cooke, D. H. 1987. *Combined Cycle Thermodynamic Inquiries and Options for Cogeneration Facilities in the Process Industry*. ASME Paper No. 87-JPGC-Pwr-61. ASME, New York.)

**Figure 73.9** Combined cycle cogeneration plant. (Source: Butler, C. H. 1984. *Cogeneration: Engineering, Design, Financing, and Regulatory Compliance*. McGraw-Hill, New York.)

## Defining Terms

**Auxiliary power:** Parasitic electric power necessary to operate cycle equipment that must be accounted for in computing net output to the grid from gross generated power.

**Cogeneration:** The production, from the same fuel or energy source, of electric and/or shaft power sequentially together with process heat.

**Cogenerative efficiency:** The apparent thermal efficiency of cogenerated power production, taking credit for all of the fuel energy saved by cogeneration. It is analogous to thermal efficiency in a plant producing power only and is the reciprocal of FCP with units adjusted.

**Combined cycle:** A gas turbine, separately known in *simple cycle* as the Brayton/Joule cycle, combined with a Rankine cycle, consisting of a heat recovery steam generator (HRSG) in the downstream exhaust duct and a steam turbine converting some or all of the steam energy to power.

**Fuel chargeable to power (FCP):** Cogenerative heat rate, for example, in Btu/kWh. The total fuel heat release less the process fuel credit (gross heat release required for "heat only" production of net heat to process) divided by the cogenerated net power output plus the uncogenerated process auxiliary power. It is the reciprocal of cogenerative efficiency with adjustment of units.

**Heat rate:** In a plant producing power only, the fuel heat release per unit of power, for example,

in Btu/kWh. It is the reciprocal of thermal efficiency with adjustment of units.

**Lower heating value (LHV):** The energy released by combustion of a unit mass or standard volume of a given fuel, excluding the latent heat of water vapor formed from combustion of hydrogen in fuel compounds. Must be calculated from *higher heating value (HHV)*, which includes this, as determined by calorimeter. Important for definition of comparative efficiencies and heat rates.

**Net heat to process:** The difference in total enthalpy, for example, in Btu/h, between that of the steam delivered to process and that of the sum of condensate returned plus makeup required.

**Thermal efficiency:** In plants producing power only or heat only, the dimensionless ratio of power or thermal output to fuel input. Usually expressed in percent. For power-only plants it is the reciprocal of heat rate with adjustment of units.

**Thermal host:** In a cogeneration venture, the industrial purchaser of the heat to process.

**Wheeling:** The transmission of electric power from its source in one utility's grid system to consumers in another's, sometimes passing through systems of intermediate utilities. Important for distributing cogenerated power from concentrated industrial areas.

## 74.1 Induction Machines

## 74.2 Synchronous Machines

## 74.3 DC Machines

### E. Keith Stanek

*University of Missouri, Rolla*

The study of electrical machines is important because a very significant percentage of the world's energy usage is accomplished by conversion from chemical, mechanical, or nuclear form into electrical form. The motivation for doing this is the ease of transmitting the energy and the exceptional control we have over the flow of this energy when it is in electrical form. One major disadvantage is that it is not possible to store significant energy in electrical form. Therefore, it is necessary to match electrical energy generation and consumption within a system on an instantaneous basis. When this is not accomplished, the system frequency tends to rise for an excess of generation and sag for a deficiency in generation.

The goal of this chapter will be to present equivalent circuits that can be used to perform steady state analysis of the three major types of rotating machines: three-phase induction, three-phase synchronous AC machines, and direct current machines. These models or equivalent circuits allow the calculation of performance indices such as efficiency, losses, output torque, output power, voltage or speed regulation, and so on. Space limitations will preclude transient or dynamic analysis of these devices. It is important to realize that the equivalent circuits presented are *not* sufficiently general for use in transient situations with the exception of calculating some motor-starting characteristics.

## 74.1 Induction Machines

---

Like all rotating electric machines, induction machines consist primarily of iron for magnetic paths, copper for electrical current flow, and insulation to separate the windings from the iron of the stator and rotor. The stator has a distributed three-phase winding embedded in slots. The rotor may have either a distributed three-phase winding or a series of copper or aluminum bars embedded in slots with shorting straps at each end of the rotor. In the former case the machine is a wound rotor type and in the latter case the machine is a **squirrel cage** type. Induction machines are usually used as motors. They are only occasionally used as generators. Therefore, this chapter will be limited to a discussion of motor operation.

The three-phase induction machine model is shown in [Fig. 74.1](#). All parameters in [Fig. 74.1](#) are

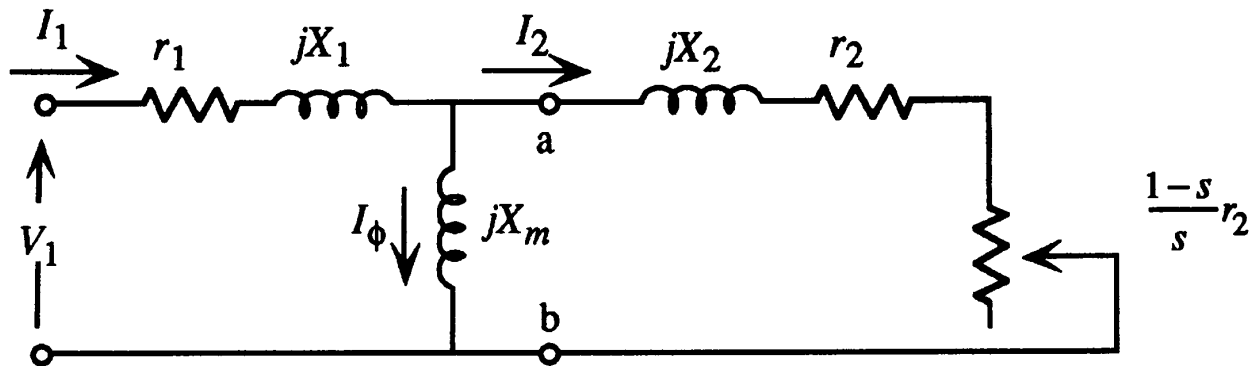

referred to the stator and are defined as follows:

- $r_1$  = Stator resistance per phase in ohms
- $r_2$  = Rotor resistance per phase in ohms
- $X_1$  = Stator leakage reactance per phase in ohms
- $X_2$  = Rotor leakage reactance per phase (ohms)
- $X_m$  = Magnetizing reactance per phase (ohms)
- $V_1$  = Line-to-neutral stator voltage (volts)
- $I_1$  = Stator current (amperes)
- $I_2$  = Rotor current (amperes)
- $s$  = Slip (per unit)  

$$= \frac{\omega_s - \omega}{\omega_s} = \frac{n_s - n}{n_s}$$
- $\omega_s$  = Synchronous rotor speed (radians per second =  $2\pi f/(P/2)$  )
- $n_s$  = Synchronous rotor speed (revolutions per minute =  $60f/(P/2)$  )
- $f$  = Stator frequency (hertz)
- $P$  = Number of stator or rotor poles
- $\omega$  = Actual rotor speed in radians per second
- $n$  = Actual rotor speed in revolutions per minute

**Figure 74.1** Basic equivalent circuit of a three-phase induction motor.

The resistor with ohmic value  $[(1 - s)/s]r_2$  is of special significance. The energy consumed in this resistor represents the energy transferred across the air gap from the stator to the rotor on a per phase basis.

This equivalent circuit is best analyzed by use of Thevenin's theorem. If this theorem is applied at terminals a-b looking toward the left, the resulting circuit is shown in Fig. 74.2. The new parameters are

$$V_{th} = \frac{jX_m}{r_1 + j(X_1 + X_m)} V_1 \quad (74.1)$$

$$r_{th} + jX_{th} = \frac{r_1 X_m (X_1 + X_m)}{r_1^2 + (X_1 + X_m)^2} + \frac{jX_1 X_m (X_1 + X_m)}{r_1^2 + (X_1 + X_m)^2} \quad (74.2)$$

**Figure 74.2** Revised equivalent circuit of a three-phase induction motor.

The current flowing in this circuit can be easily calculated if a value of slip,  $s$ , is assumed:

$$I = \frac{V_{th}}{\left( r_{th} + r_2 + \frac{1-s}{s} r_2 \right) + j(X_{th} + X_2)} \quad (74.3)$$

The power delivered across the air gap is simply

$$P_{air\ gap} = 3I^2 \frac{(1-s)}{s} r_2 \quad (74.4)$$

In this equation, the factor of 3 results from the fact that this is a per phase model and there are three phases.

Not all of the power calculated in these equations results in useful mechanical energy. The only losses accounted for in the model are stator and rotor copper losses. Other losses include core losses, friction and windage losses, and stray load losses. Generally, these losses can be approximated as being fixed or constant with varying load. This power loss,  $P_{fixed}$ , can be deducted to yield the mechanical power out,  $P_{mech}$ .

$$P_{mech} = P_{air\ gap} - P_{fixed} \quad (74.5)$$

Since power is torque times radial velocity,

$$P_{\text{mech}} = T_{\text{mech}} \omega \quad (74.6)$$

$$T_{\text{mech}} = P_{\text{mech}} / \omega \quad (74.7)$$

The stator current,  $I_1$ , can be found by using the current divider equation.

$$I_2 = I = \frac{jX_m}{r_2 + [(1-s)/s]r_2 + jX_2} I_1 = \frac{jX_m}{r_2/s + jX_2} I_1 \quad (74.8)$$

$$I_1 = \frac{r_2/s + jX_2}{jX_m} I \quad (74.9)$$

Then, it is easy to find the input power,

$$P_{\text{in}} = 3V_1 I_1 \cos \theta \quad (74.10)$$

where  $\theta$  is the angle by which  $V_1$  leads  $I_1$ .

It is now possible to analyze all aspects of induction motor performance by assuming a value of slip and calculating, in order, the rotor speed, the Thevenin voltage, Thevenin impedance, rotor current, stator current, rotor copper loss, stator copper loss, power in, air gap power, mechanical power, output torque, total losses, and efficiency.

If a number of different values of slip are assumed between 0 and 1, the performance of the induction motor from standstill to synchronous speed can be found. The torque plotted as a function of rotor speed is shown in [Fig. 74.3](#). A couple of other interesting things can be found from the equivalent circuit. One of these is the starting current. At start-up, rotor speed is zero and slip is unity (1.0). Using a value of 1.0 for slip and neglecting the small current through the exciting inductance yields the starting current in amperes

$$I_{\text{start}} = \frac{V_1}{r_1 + r_2 + j(X_1 + X_2)} \quad (74.11)$$

**Figure 74.3** Typical torque-speed curve of a three-phase induction motor.

Another quantity of interest is the maximum or pull-out torque. This quantity can be found by applying the maximum power transfer theorem to the total rotor resistance  $r_2/s$ . The slip corresponding to maximum torque is

$$s_m = \frac{r_2}{\sqrt{r_1^2 + (X_1 + X_2)^2}} \quad (74.12)$$

and the torque at this slip is (in N·m)

$$T_{\max} = \frac{3V_{\text{th}}^2}{\omega_s^2 \left( r_1 + \sqrt{r_1^2 + (X_1 + X_2)^2} \right)} \quad (74.13)$$

## 74.2 Synchronous Machines

A three-phase synchronous machine has a stator winding very similar to a three-phase induction motor. The rotor is quite different. The rotor has a single winding consisting of many turns of fine

wire that is excited by a DC voltage supply connected to the rotor via brushes and slip rings.

The equivalent circuit (see Fig. 74.4) of a synchronous machine is one of the simplest for all machine types, but there are some important subtleties involved in the analysis of this circuit that need to be discussed. Variables in Fig. 74.4 are defined as follows:

- $E$  = Internal EMF in V
- $V_t$  = Terminal voltage in V
- $I$  = Armature current in A
- $X_s$  = Synchronous reactance in ohms.

**Figure 74.4** Equivalent circuit of a synchronous generator.

Consider the operation of the synchronous machine as a generator while it is connected to a large system. In the limit the "large system" would have unlimited capacity and it is referred to as an **infinite bus**. The characteristics of an infinite bus are that it has perfectly stable voltage and frequency and the phase angle is constant. If a synchronous machine is connected to an infinite bus, the terminal voltage of the machine is forced to be equal to the infinite bus voltage in both magnitude and angle. The real power output of the generator will not cause the infinite bus frequency to either sag or rise.

With these facts in mind, consider what happens when one of the two controllable inputs to the synchronous generator—real power in and field excitation level—is varied. Assume the real power in is varied. In order to visualize what happens, assume generator resistance is negligible and the synchronous reactance is  $X_s$  in ohms. Let the generator internal voltage be  $|E|\angle\delta = \overline{E}$ . Kirchhoff's voltage law (KVL) states that

$$\overline{E} = jX_s\overline{I} + \overline{V}_t \quad (74.14)$$

This equation is represented by the phasor diagram in Fig. 74.5. Therefore,

$$\bar{I} = \frac{\bar{E} - \bar{V}_t}{jX_s} \quad (74.15)$$

**Figure 74.5** Phasor diagram of a synchronous generator.

Assume the infinite bus voltage is  $\bar{V}_t = |\bar{V}_t| \angle 0^\circ$ . Then,

$$\bar{I} = \frac{E \angle \delta - V_t \angle 0^\circ}{jX_s} = \frac{E \angle \delta - 90^\circ}{X_s} + \frac{V_t}{X_s} \angle 90^\circ \quad (74.16)$$

The real power delivered by the internal EMF is

$$P = \text{Re}(\overline{EI}^*) = \frac{EV_t}{X_s} \sin \delta \quad (74.17)$$

Therefore, the real power generated or transformed from mechanical to electrical form is dependent on  $\delta$ , the angle by which  $\overline{E}$  leads  $\overline{V}_t$ . With fixed field current, when the mechanical power is increased, the angle  $\delta$  increases to allow the electrical power out to balance mechanical power in. Clearly, there is a limit. When  $\delta = 90^\circ$  or  $\pi/2$ , the maximum power is reached. If mechanical power is increased further, synchronism will be lost. The dependence of power on  $\delta$  is illustrated by Fig. 74.6.

**Figure 74.6** Power-angle curve of a synchronous generator.

A separate analysis can be done assuming the mechanical power in is fixed and the field current (and hence the internal EMF,  $|\overline{E}|$ ) is variable. In this case it can be shown that the reactive power out of the generator is

$$Q = \frac{V_t}{X_s} (E \cos \delta - V_t) \quad (74.18)$$

In most cases, the angle  $\delta$  is small ( $15^\circ$  or less) and  $\cos \delta$  is approximately 1.0. Thus,  $E \cos \delta - V_t \approx E - V_t$ . Note that if  $E > V_t$ ,  $Q > 0$ , and if  $E < V_t$ ,  $Q < 0$ . Therefore, an

overexcited generator supplies reactive power, whereas an underexcited generator absorbs reactive power.

In summary, if a synchronous generator is supplying power to a large system, the amount of real power supplied is controlled by the power from the prime mover. The amount of reactive power supplied is controlled by the field excitation, which controls the magnitude of the internal voltage.

The equivalent circuit of Fig. 74.4 can be used for motor analysis by reversing the polarity of the current  $\bar{I}$ . Space limitations will not permit a discussion of the operation of a synchronous machine as a motor, but the analysis is quite similar to that for generator operation.

## 74.3 DC Machines

---

The construction of a DC machine is somewhat more complicated than either of the AC machine types discussed. Suffice it to say that a single winding of many turns of fine wire is located on the stator. This is the field winding. A single but more robust winding exists on the rotor. This is the armature or high-power winding. The path of currents through this winding is constantly changing with time due to the connection of this winding to the outside world via a series of brushes sliding over a **commutator**. The commutator is basically a mechanical rectifier that rectifies the AC voltages generated in the **armature winding** to produce a DC terminal EMF.

In this chapter only DC machines excited with shunt or separate fields will be discussed. The equivalent circuit for DC machines of this type is shown in Fig. 74.7. This circuit can be used for either motor or generator operation, but it is vital that the proper polarity for the armature current be used. Since DC machines are used primarily as motors, that mode of operation will be emphasized.

Terms used in Fig. 74.7 are defined as follows:

- $V_f$  = Field voltage in V
- $R_f$  = Field resistance in ohms
- $L_f$  = Field inductance in H
- $I_f$  = Field current in A
- $V_t$  = Terminal voltage in V
- $E_g$  = Generated internal voltage in V
- $R_a$  = Armature resistance in ohms
- $L_a$  = Armature inductance in H
- $I_a$  = Armature current in A
- $k$  = A constant relating generated voltage to flux and rotor speed
- $\phi$  = Air gap flux per pole in webers
- $\omega_m$  = Rotor speed in radians/second
- $T$  = Torque produced in N·m

**Figure 74.7** Equivalent circuit of a DC motor.

Note that the field copper loss is  $I_f^2 R_f$  and the armature copper loss is  $I_a^2 R_a$ . The machine also has a number of other losses due to friction, windage, and core losses. These are generally taken as fixed losses.

The product of the internal generated voltage and the armature current is equal to the power converted in the machine, electrical to mechanical in a motor or mechanical to electrical in a generator. By energy conservation,

$$E_g I_a = T \omega_m \quad (74.19)$$

or

$$k\phi\omega_m I_a = T \omega_m \quad (74.20)$$

so

$$T = k\phi I_a \quad (74.21)$$

The steady state DC equations governing motor operation are as follows:

$$V_f = R_f I_f \quad (74.22)$$

$$V_t = E_g + R_a I_a \quad (74.23)$$

$$E_g = k\phi\omega_m \quad (74.24)$$

$$T = k\phi I_a \quad (74.25)$$

The flux per pole,  $\phi$ , is a function of the construction of the machine and the field current,  $I_f$ . A typical relationship is shown in Fig. 74.8. Note that, if  $\omega_m$  is constant,  $E_g$  is proportional to  $\phi$  and the vertical axis can be relabeled so that Fig. 74.8 becomes a plot of  $E_g$  versus  $I_f$  and is then called the machine's *open-circuit characteristic* at the given speed,  $\omega_m$ . In the linear region,

$$\phi = k_f I_f .$$

**Figure 74.8** Open-circuit characteristic of a shunt-wound DC motor.

Solving Eq. (74.23) for  $I_a$  and substituting into Eq. (74.25) yields

$$T = \frac{k_f I_f V_t}{R_a} - \frac{k_f^2 I_f^2}{R_a} \omega_m \quad (74.26)$$

This relationship is the torque speed characteristic of the motor and is plotted in [Fig. 74.9](#). It is clear that the motor runs at nearly a constant speed as load changes.

**Figure 74.9** Torque-speed curve for a shunt-wound DC motor.

### Defining Terms

**Armature winding:** The power or high current winding in an electric machine. This contrasts to the field winding, which generally has lower current and/or voltage level.

**Commutator:** A mechanical rectifier used to convert alternating voltages, generated internal to a DC machine, into DC voltages at the terminals of the DC machine.

**Infinite bus:** An idealization of a large AC power system in which the rms voltage is constant, as is the system frequency and voltage phase angle, regardless of the load level supplied by the power system.

**Squirrel cage winding:** A series of conducting bars embedded in axial slots on the surface of the rotor of an induction motor that are shorted together at each end. The name arises from the

physical appearance of the winding, which resembles a squirrel cage.

**Torque-speed curve:** The value of torque in N·m produced by a motor as a function of the rotor speed.

The oil crises in 1973 and 1979 created a powerful incentive for producing the greatest amount of light products from crude oil. The Shell Pernis complex oil refinery located in the Netherlands was able to treat the heavy oil residue remaining after atmospheric distillation by redistilling it under high vacuum. By redistilling the residue, valuable products such as gasoline, gasoil, and lubricating oil distillates could be manufactured. However, even after this conversion method, a black, viscous mass still remained and to create a usable product from this material was a costly endeavor.

Shell laboratories made a start with the development of a better economic process called hydroconversion. This process is based on the fact that the vacuum residue contains much less hydrogen than the lighter products. The aim, therefore, is to reduce the size of the molecules and to increase the ration of hydrogen atoms to carbon atoms. This ratio can be increased either by removing some carbon from the molecules or by attaching hydrogen to the atoms with the aid of a catalyst. Shell chose the latter approach and called its process HYCON. For additional information on HYCON see page 811. (Photo courtesy of Shell Group.)

**77 The Scaleup of Chemical Reaction Systems from Laboratory to Plant** *J. B. Cropley*

General Considerations in the Rational Design of Chemical Reactors • Protocol for the Rational Design of Chemical Reactors

CHEMICAL REACTORS ARE THE MOST IMPORTANT PART of a chemical plant. In most cases, multiple reactions take place, multiple reactors are required, and catalysts are used to obtain sufficient rates and desired selectivities. Improvements in reaction rates and selectivities to desired products can have significant influences on other parts of the chemical plant such as the separations processes. Thus, design of the chemical reactor can control the economics of a plant even though the reactor is not the most expensive part. The chemical reactor also determines the amounts of waste products that form and thus the plant's effect on the environment. Because highly exothermic reactions are often carried out in chemical reactors on a large scale, the reactor is also the biggest safety hazard in the plant.

The first chapter of Section X is concerned with chemical kinetics and the analysis of kinetic data. The most important aspect of chemical kinetics is the rate at which a chemical reaction takes place and the selectivity to reaction products. Also of interest is how the rate and selectivity depend on concentrations, temperature, and other reaction conditions. Reaction rates and the products that form for a given set of reactants and reaction conditions cannot be predicted; such kinetic information must be measured. These measurements are particularly sensitive to temperature because most chemical reactions exhibit an exponential dependence on temperature. They also must be made in the absence of transport effects such as diffusion and mass transfer. Moreover, many large-scale chemical processes use catalysts, and the composition and preparation of the catalyst can have a large influence on both the rate of reaction and the product distribution. The basic methods for analyzing laboratory kinetic data to determine rate expressions are presented in this section, and the mechanisms by which reactions occur on a molecular scale are also discussed.

The second chapter discusses the design and analysis of chemical reactors. Reaction engineering involves determining how the type of reactor, its size, and its operating conditions affect production rates and distribution of products. Industrial processes almost always involve multiple reactions taking place simultaneously, and the desired product is often not the more favored

thermodynamically. Batch, semibatch, continuous stirred tank (CSTR), and plug flow reactors are discussed. These ideal reactor types are often used in combination and are used to model real reactors, which may deviate significantly from ideal behavior. Once kinetic data have been obtained in the laboratory, the kinetic rate expression, thermodynamic equilibrium, and reaction stoichiometry can be used in material balances (conservation of mass) and energy balances (first law of thermodynamics) to obtain equations that predict how a large-scale reactor will behave. Large-scale reactors must take account of pressure drop, nonideal flow patterns, and transport limitations.

The last chapter describes scale-up of a reaction system from the laboratory to a large-scale plant using laboratory data and correlations, and presents a protocol for rational design. This could be called scale-down since it starts from a potential type of commercial reactor, and then a laboratory system is designed to generate the necessary kinetic data. A statistically valid kinetic model is then developed from the data, and this is used with the material and energy balances to develop a model that simulates the reactor. This model of a reactor can then be used to develop an optimal design, which is then validated in a pilot plant. This chapter also discusses industrial reactor types, reactor mass balances, and design of laboratory reactors. In addition to the basic ideal reactors, fluidized beds, shell-and-tube packed beds, multiphase packed beds, and slurry reactors are discussed.

## 75.2 Analysis of Kinetic Data

Data Acquisition • Evaluation of Reaction Mechanism • Development of Rate Equation • Determination of Rate Constant and Arrhenius Parameters

### K. H. Lin

*Oak Ridge National Laboratory*

This chapter presents a brief overview of reaction kinetics primarily for engineers who are not directly involved in the investigation of reaction kinetics or in the design of chemical reactors. For a comprehensive treatise on reaction kinetics, the reader should consult the references at the end of the chapter.

In contrast to the static and equilibrium concept of thermodynamics, reaction kinetics is concerned with dynamics of chemical changes. Thus, reaction kinetics is the science that investigates the rate of such chemical changes as influenced by various process parameters and attempts to understand the mechanism of the chemical changes. For any reaction system to change from an initial state to a final state, it must overcome an energy barrier. The presence of such an energy barrier is commonly manifested in the observed relationship between the reaction rate and temperature, which will be discussed in some detail in the section to follow.

## 75.1 Fundamentals

---

### Basic Terms and Equations

One of the key terms in reaction kinetics is the **rate of reaction**,  $r_A$ , the general definition of which is given by

$$r_A = \frac{1}{y} \frac{dN_A}{dt} \quad (75.1)$$

which expresses the rate  $r_A$  as the amount of a chemical component of interest being converted or produced per unit time per unit quantity of a reference variable  $y$  [e.g., volume of reacting mixture ( $V$ ) or of reactor ( $V_R$ ), mass ( $W$ ), surface area ( $S$ ), etc.]. It delineates the time

dependence of chemical changes involving component  $A$  as a derivative. In homogeneous fluid reactions,  $y$  is normally represented by  $V$  or  $V_R$ , whereas the mass ( $W$ ) or the surface area ( $S$ ) of the solid reactant may be taken as  $y$  in heterogeneous solid-fluid reactions. Here,  $N_A$  refers to the amount of component  $A$ , and  $t$  is time. By convention,  $r_A$  is negative when  $A$  is a reactant and positive when  $A$  is a product. Molal units are commonly used as the amount of  $N_A$ , but other units such as mass, radioactivity, pressure, and optical property are also used. When  $V$  remains constant (as in a liquid-phase batch reactor), Eq. (75.1) is simplified to

$$r_A = dC_A/dt \quad (75.2)$$

where  $C_A$  represents the concentration of component  $A$ .

## Rate Constant and Elementary Reactions

In general, the rate of reaction in terms of component  $i$  is a function of the concentration of all components participating in the reaction,  $C$ ; the temperature,  $T$ ; the pressure,  $P$ ; and other parameters,  $m$ :

$$r_i = \text{function } (C, T, P, m) \quad (75.3)$$

Thus, the rate expression for a simple irreversible reaction in terms of the reacting components may assume the following form:

$$-r_A = k(C_A)^{n_1}(C_B)^{n_2} \dots (C_i)^{n_i} \quad (75.4)$$

The proportionality constant,  $k$ , is the **rate constant** that is markedly influenced by the temperature and may be subject to the influence of pressure, pH, kinetic isotopes, and so on, and the presence of catalysts. The exponents  $n_1, n_2, \dots, n_i$  are *orders of reaction* with respect to individual reacting components  $A, B, \dots, i$ . The *overall order of reaction* refers to the sum of  $n_1, n_2, \dots, n_i$ , which does not have to be an integer and may be determined empirically.

The units and value of rate constant  $k$  vary with the units of  $C$ , the specific component that  $k$  refers to, and the reaction order. The effect of temperature on  $k$  was first described by Arrhenius through the following equation:

$$k = Ae^{-\frac{E}{RT}} \quad (75.5)$$

where  $A$ , termed the *frequency factor*, has the same units as  $k$ ,  $E$  is **activation energy**, and  $R$  is the gas law constant.  $E$  was considered by Arrhenius as the amount of energy that a reacting system must have in excess of the average initial energy level of reactants to enable the reaction to proceed.

A *simple* or *elementary* reaction is one in which the order of reaction is identical to the *molecularity* (the number of molecules actually participating in the reaction). Under these circumstances, the chemical stoichiometric equation represents the true reaction mechanism, and

the rate equation may therefore be derived directly from the stoichiometric equation. Thus, for an elementary reaction  $n_1A + n_2B = n_3D$ , the rate equation in terms of disappearance of A would be  $-r_A = k(C_A)^{n_1}(C_B)^{n_2}$ . The values of  $n_1$  and  $n_2$  in this equation are positive integers.

## Complex (or Multiple) Reactions

A reaction that proceeds by a mechanism involving more than a single reaction path or step is termed a *complex reaction*. Unlike elementary reactions, the mechanisms of complex reactions differ considerably from their stoichiometric equations. Most industrially important reactions are complex reactions, the mechanisms of which can often be determined by assuming that the overall reaction consists of several elementary reaction steps. The resulting overall rate expression is then compared with the experimental data, and the procedure is repeated until a desired degree of agreement is obtained. Each of the elementary reaction steps may proceed *reversibly*, *concurrently*, or *consecutively*.

A *reversible reaction* is one in which conversion of reactants to products is incomplete at equilibrium because of an increasing influence of the reverse reaction as the forward reaction approaches equilibrium. For a reversible reaction of the type

the net forward rate of reaction in terms of disappearance of A is

$$-r_A = k_f C_A C_B - k_r C_D C_E \quad (75.6)$$

which assumes both forward and reverse reactions to be elementary.

A simple example of *consecutive reaction* is illustrated by

Again, assuming an elementary reaction for each reaction step, the following rate equations result:

$$-r_A = k_1 C_A \quad (75.8)$$

$$r_D = k_2 C_B \quad (75.9)$$

$$r_B = k_1 C_A - k_2 C_B \quad (75.10)$$

*Parallel or simultaneous reactions* are those involving one or more reactants undergoing reactions of more than one scheme, as in

The rate equations may assume the following forms:

$$-r_A = k_1(C_A)^a + k_2(C_A)^b \quad (75.11)$$

$$r_B = k_1(C_A)^a \quad (75.12)$$

$$r_D = k_2(C_A)^b \quad (75.13)$$

Under a constant-volume condition,  $r_B = dC_B/dt$  and  $r_D = dC_D/dt$ . Therefore, the relative rate of formation of  $B$  and  $D$  is derived from Eqs. (75.12) and (75.13) as

$$dC_B/dC_D = (k_1/k_2)(C_A)^{a-b} \quad (75.14)$$

The ratio  $dC_B/dC_D$  is termed the *point selectivity*, which is the ratio of the *rate* of formation of product  $B$  to the *rate* for product  $D$ . The *overall* (or *integrated*) *selectivity* is obtained by integration of this ratio, and it represents the ratio of the overall *amount* of product  $B$  to that of product  $D$ . Equation (75.14) implies that the relative rate of formation of  $B$  is proportional to  $C_A$  when  $a > b$ , whereas it is inversely proportional to  $C_A$  when  $a < b$ .

In a chemical process involving complex reactions that consist of several reaction steps, one or more steps may represent major factors in governing the overall rate of reaction. Such reaction steps are termed the **rate-controlling steps**. The rate-controlling reaction steps are observed in homogeneous complex reactions and heterogeneous reactions.

## Uncatalyzed Heterogeneous Reactions

Heterogeneous reactions involve more than one phase (e.g., gas-liquid, gas-solid, liquid-solid, and gas-liquid-solid) and are generally more complicated than homogeneous reactions due to interaction between physical and chemical processes; that is, reactants in one phase have to be transported (physical process) to the other phase, containing other reactants where the reactions take place.

In a gas-solid reaction, for example, the reaction may proceed in several steps, as follows:

1. Reactants in the gas phase diffuse to the gas-solid interface.
2. When there is a layer of solid product and/or inert material at the interface (e.g., ash), the reactants from the gas phase would have to diffuse through this layer before they can reach the unreacted solid core containing other reactants.
3. The chemical reaction takes place between the reactants from the gas phase and those in the unreacted solid core.
4. The reaction products diffuse within the solid phase and/or diffuse out of the solid phase into the bulk of gas phase.

The step that controls the overall reaction rate will be determined by the nature of the phases and specific reactions involved and by process conditions. Thus, the overall reaction rate is subject to the influence of parameters that affect both the physical and chemical processes, including (a)

patterns of phase contact, (b) the reactor geometry, (c) fluid dynamic factors (e.g., velocity and degree of turbulence), (d) interfacial surface area, (e) mass transfer factors, (f) chemical kinetics of reactions involved, and (g) process parameters (e.g., temperature and pressure). Some of these parameters may interact with one another. For example, in a reaction involving two distinct fluid phases (e.g., gas-liquid or liquid-liquid), parameters (d) and (e) would be affected by parameter (c).

The overall reaction rate expression of a heterogeneous reaction is fairly complex, since it considers all of these parameters. Further, the form of rate equation varies with the type of heterogeneous reaction system and with the nature of the controlling step. Some examples of the industrially significant uncatalyzed heterogeneous reactions are given in [Table 75.1](#).

--	---

## Homogeneous and Heterogeneous Catalytic Reactions

A catalytic reaction is a chemical reaction the rate of which is modified in the presence of a catalyst. A **catalyst** is a substance that may or may not change chemically during the reaction and is regenerated at the end of the reaction. The catalytic reaction proceeds appreciably faster than does an uncatalyzed reaction, presumably because an intermediate compound, formed between the catalyst and some reactants, reacts with other reactants by a mechanism that requires a lower activation energy to form desired products. In *homogeneous catalysis* the catalyst forms a homogeneous phase with the reaction mixture. In *heterogeneous catalysis*, however, the catalyst is present in a phase different from that of the reaction mixture.

### Homogeneous Catalysis

Most homogeneous catalysis takes place in the liquid phase. Perhaps the most widely studied type of liquid-phase catalysis is the acid-base catalysis that exerts influence on the rates of many important organic reactions, including (a) esterification of alcohols, (b) hydrolysis of esters, and (c) inversion of sugars. One of the industrially important gas-phase catalytic reactions is the oxidation of  $\text{SO}_2$  to  $\text{SO}_3$  in the production of sulfuric acid, catalyzed by nitric oxide in the lead chamber.

### Solid-Catalyzed Reaction

This reaction, the most common type of heterogeneous catalysis, finds extensive applications in many important industrial processes that produce inorganic and organic chemicals. Well-known examples of such chemicals include  $\text{HNO}_3$ ,  $\text{HCl}$ , ammonia, aniline, butadiene, ethanol, formaldehyde, methanol, organic polymers, and petrochemicals. The generally accepted, simplified mechanism of solid-catalyzed fluid (gas or liquid) phase reactions is outlined as follows:

1. Reactants diffuse from the main body of the fluid phase to the exterior surface of catalyst pellets, and subsequently into catalyst pores.
2. Reactants are adsorbed onto both the catalyst exterior and pore surfaces.
3. Products are formed from interaction of the reactants on the surfaces (catalyst exterior and pore).
4. Products thus formed are desorbed (or released) from the surfaces; those formed on the pore surface are released to the fluid phase within the pores and then diffuse out of pores to the exterior surface of the catalyst pellet.
5. Products then diffuse from the exterior surfaces into the bulk of the fluid phase.

The relative importance of these steps in influencing the overall reaction rate depends upon a variety of factors, among which are thermal factors, fluid dynamic factors, properties of the catalyst, and diffusion characteristics of the reactants and products. Besides the process steps described earlier, there are various deactivation processes that cause loss of catalytic efficiency, such as fouling and poisoning.

## 75.2 Analysis of Kinetic Data

---

### Data Acquisition

Because chemical reactions involved in most industrial processes are complex, development of the database for the design of the chemical reactor facility can be quite time consuming. Accordingly, selection of experimental methods and equipment for acquisition of kinetic data is crucial in determining the development cost as well as the accuracy and reliability of the data obtained. In essence, the selection process is concerned with both the methods and the equipment to conduct the reactions and to monitor the progress of the reactions. The type of equipment to be used is generally determined by the experimental method for data acquisition. Acquisition of the kinetic

data for homogeneous reactions is frequently carried out using a batch reactor because of its relatively simple design and versatility. In heterogeneous reactions a flow reactor is often utilized for the data acquisition. For detailed discussion on various methods and equipment for obtaining the experimental kinetic data, the reader is referred to the references at the end of the chapter.

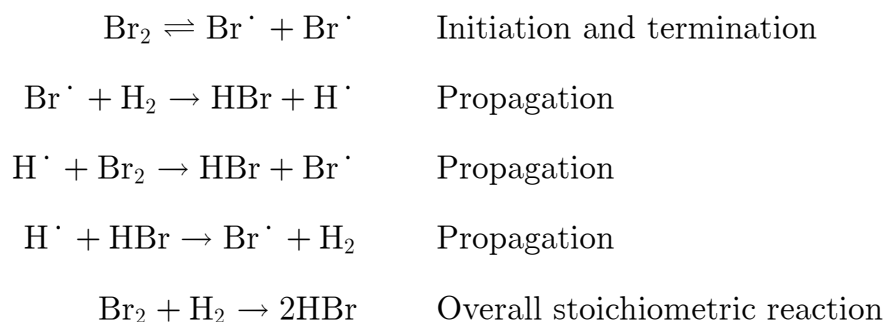

## Evaluation of Reaction Mechanism

Understanding of the reaction mechanism is important in the selection and design of an industrial reactor for a specific reaction. Full elucidation of the mechanism, however, is not always possible, in which case derivation of the rate equation may have to resort to the empirical method (see the following subsection). No simple standardized method is available for evaluation of the reaction mechanism. Nevertheless, a trial-and-error method is often used based on the experimental kinetic data acquired—including analysis of the reaction mixture to determine the distribution of the residual reactants, intermediates, and final products—following these steps:

1. Assume a simple elementary reaction mechanism and a corresponding stoichiometry and derive a rate equation from the assumed mechanism.
2. Evaluate the experimental data based on the proposed reaction mechanism and the corresponding rate equation using the integral method (described in the section to follow) first since it is relatively easy to use.
3. If the experimental data do not agree with the proposed mechanism, possibly suggesting a nonelementary reaction, propose a new mechanism that consists of several elementary reaction steps with formation of intermediate compounds.
4. Develop rate equations for individual elementary reaction steps and combine the individual rate equations to represent the overall rate expression.
5. If the experimental kinetic data do not fit into the rate equation developed above, assume an alternate mechanism, and repeat step 4. Continue this process until a desired degree of agreement is reached between the experimental data and the rate expression.
6. Evaluation of the reaction mechanism may also be accomplished using the differential method (see the next subsection), especially for complicated reactions. The method of approach is similar to that using the integral method, but it requires more accurate and extensive experimental data.

An example of a nonelementary complex reaction consisting of several elementary reaction steps is the formation of hydrogen bromide from hydrogen and bromine:

Based on the above reaction mechanism, the following rate equation has been derived:

$$r_{\text{HBr}} = \frac{k_1 C_{\text{H}_2} C_{\text{Br}_2}^{0.5}}{1 + k_2 (C_{\text{HBr}} / C_{\text{Br}_2})} \quad (75.15)$$

## Development of Rate Equation

For reactions with simple mechanism under isothermal conditions, either the integral method or the differential method (discussed in a later section) may be used in the derivation of rate equations. It is assumed that the data representing the extent of an isothermal reaction are available in terms of the time variation of a selected component A .

### Integral Method

An elementary reaction mechanism is first assumed; for example, a second-order isothermal homogeneous reaction under *constant-volume* conditions,  $A + B \rightarrow C + D$ , results in the rate equation of the form

$$-r_A = \frac{dC_A}{dt} = k C_A C_B \quad (75.16)$$

and the integrated rate equation becomes

$$kt = \frac{1}{C_{B_0} - C_{A_0}} \ln \frac{C_{A_0} (C_A + C_{B_0} - C_{A_0})}{C_A C_{B_0}} \quad (75.17)$$

where  $C_{A_0}$  and  $C_{B_0}$  represent the initial concentrations of reactants A and B , respectively. One way to confirm the proposed reaction mechanism is to compute values of  $k$  at various values of  $C_A$  and  $t$  . If the values of  $k$  remain nearly constant, the proposed mechanism is accepted. Otherwise, another mechanism is assumed and the process is repeated until a desired degree of agreement is reached.

When the volume of the reaction mixture varies with the extent of reaction, the rate equation becomes more complicated. In this case, if it is assumed that the volume varies linearly with the

extent of reaction, derivation of the rate equation could be simplified. Using the fractional conversion  $x_A$  to replace  $C_A$  as the variable, the volume  $V$  is expressed as

$$V = V_0(1 + f_A x_A) \quad (75.18)$$

Here,  $V_0$  represents the initial volume of the reaction mixture and  $f_A$  is the fractional change in  $V$  between no conversion and complete conversion with respect to reactant  $A$ , as defined by

$$f_A = (V_{x_A=1} - V_{x_A=0})/V_{x_A=0} \quad (75.19)$$

Thus, for a *variable-volume* reaction, the reaction rate defined by Eq. (75.1) assumes the following form,

$$-r_A = -\frac{1}{V} \frac{dN_A}{dt} = -\frac{1}{V_0(1 + f_A x_A)} \frac{d}{dt} N_{A_0}(1 - x_A) \quad (75.20)$$

which simplifies to

$$-r_A = \frac{C_{A_0}}{1 + f_A x_A} \frac{dx_A}{dt} \quad (75.21)$$

and the integrated rate equation is

$$t = C_{A_0} \int_0^{x_A} \frac{dx_A}{(1 + f_A x_A)(-r_A)} \quad (75.22)$$

where  $-r_A$  stands for the rate expression for the assumed reaction mechanism to be evaluated. For example, for a first-order homogeneous reaction,

$$-r_A = kC_A = kC_{A_0} \frac{1 - x_A}{1 + f_A x_A} \quad (75.23)$$

Introducing this expression for  $-r_A$  into Eq. (75.22),

$$kt = -\ln(1 - x_A) \quad (75.24)$$

The steps to be taken to evaluate the assumed reaction mechanism for the variable-volume case are identical to the constant-volume case.

### Differential Method

This approach is based on the direct application of the differential rate equation in the analysis of the experimental kinetic data to determine the reaction mechanism. The method requires more accurate and extensive experimental data than the integral method. The basic principle of the method is illustrated by an example of assumed  $n$  th-order reaction under the isothermal and

constant-volume condition:

With initially equimolal concentrations of  $A$  and  $B$  (i.e.,  $C_A = C_B$ ), the rate equation may take the following form,

$$-r_A = kC_A^a C_B^b = kC_A^{a+b} = kC_A^n \quad (75.25)$$

which is rearranged into

$$\log(-r_A) = \log(-dC_A/dt) = \log k + n \log C_A \quad (75.26)$$

The assumption of the  $n$  th-order reaction mechanism is confirmed if a log-log plot of  $(dC_A/dt)$  versus  $C_A$  results in a straight line.

The next step is to evaluate the values of the rate constant  $k$  and the overall order of reaction  $n$  from the plot. With the known values of  $k$  and  $n$ , the reaction orders with respect to  $A$  and  $B$  can be determined by the method that follows. Rearranging Eq. (75.25),

$$-r_A = kC_A^a C_B^{n-a} = kC_B^n (C_A/C_B)^a \quad (75.27)$$

On further rearrangement,

$$\log \left( -\frac{r_A}{kC_B^n} \right) = a \log(C_A/C_B) \quad (75.28)$$

A log-log plot of Eq. (75.28) yields the reaction order  $a$  with respect to  $A$ , whereas the reaction order  $b$  is obtained as the difference between  $n$  and  $a$ .

### Empirical Method

This method, which finds uses when the reaction mechanism appears to be complex, is often based on a mathematical approach using the curve-fitting procedure. The method involves a trial-and-error technique to fit the experimental data to a relatively simple form of the empirical equation, including (a) linear form,  $y = a + bx$ , (b) semilogarithmic form,  $y = ae^{bx}$ , (c) logarithmic form,  $y = c + ax^n$ , and so forth. The initial step usually consists of plotting the experimental data on graph papers of different coordinates that may produce a straight line. Upon selection of a proper form of the empirical equation, the constants in the empirical equation are determined either by the graphic means or by the analytical technique using the method of averages or the method of least squares. Computer software is available for performing the curve-fitting procedure.

## Determination of Rate Constant and Arrhenius Parameters

The rate constant  $k$  can be obtained by using either a differential form [e.g., Eq. (75.16)] or an integrated form [e.g., Eq. (75.17)] of the rate equation. It is an average of values calculated at various experimental kinetic data points (i.e., reactant concentrations at various reaction times).

*Arrhenius parameters* consist of the activation energy  $E$  and the frequency factor  $A$ . The value of  $E$  may be calculated from the rate constants at two distinct but adjacent temperatures,  $T_1$  and  $T_2$ , as follows:

$$k_1 = Ae^{-E/RT_1} ; \quad k_2 = Ae^{-E/RT_2}$$

Combining the above two equations,

$$E = R \frac{\ln(k_2/k_1)}{1/T_1 - 1/T_2} \quad (75.29)$$

The value of  $A$  is calculated from one of the Arrhenius equations shown above.

## Defining Terms

**Activation energy:** A parameter associated with the Arrhenius equation and considered by Arrhenius as the energy in excess of the average energy level of reactants required to enable the reaction to proceed.

**Catalyst:** A substance that accelerates the reaction, presumably by making available a reaction path that requires a lower activation energy. The catalyst may or may not change chemically during the reaction and is regenerated at the end of the reaction.

**Rate constant:** A proportionality constant in the rate equation. The rate constant is markedly influenced by temperature and, to lesser degree, by pressure and the presence of catalysts. The units and value of the rate constant depend on the specific chemical component to which it refers, the units for concentration (or other quantity) of the component, and the reaction order.

**Rate-controlling step:** The slow steps that tend to control the overall rate of reaction. In a complex reaction consisting of several chemical reaction steps (and physical process steps in heterogeneous reaction), the reaction rate (and physical process rate) of one or more steps may be much slower than other steps.

**Rate equation:** A functional expression describing the relationship between the rate of reaction and the amounts (e.g., concentrations) of selected chemical components participating in the reaction at any time under isothermal condition.

**Rate of reaction:** The amount of a chemical component of concern being converted or produced per unit time per unit quantity of a reference variable. Examples of the reference variable include the volume of reacting mixture, the reactor volume, the mass of solid (solid-fluid reaction), and the surface area of solid.

## 76.5 Summary

### H. Scott Fogler

University of Michigan

Chemical reaction engineering (CRE) sets chemical engineers apart from other engineers. Students and professionals can easily learn the elements of CRE because it has a very logical structure. The six basic pillars that hold up what you might call the "temple" of chemical reaction engineering are shown in Fig. 76.1 .

**Figure 76.1** Pillars of the temple of chemical reaction engineering. (Source: Fogler, H. S. 1992. *The Elements of Chemical Reaction Engineering*, 2nd ed. Prentice Hall, Englewood Cliffs, NJ.)

The pillar structure shown in Fig. 76.1 allows one to develop a few basic concepts and then to arrange the parameters (equations) associated with each concept in a variety of ways. Without such a structure, one is faced with the possibility of choosing or perhaps memorizing the correct equation from a multitude of equations that can arise for a variety of reactions, reactors, and sets of conditions. This chapter shall focus on five types of chemical reactors commonly used in industry: **batch**, **semibatch**, **CSTR**, **plug flow**, and **packed bed reactors**. Table 76.1 describes each of these reactors.

**Table 76.1** Comparison of Five Types of Chemical Reactors

Type of Reactor	Characteristics	Usage	Advantages	Disadvantages
Batch	<ul style="list-style-type: none"> <li>Reactor is charged (filled) via two holes in the top of the tank; while reaction is carried out, nothing else is put in or taken out until reaction is done; tank easily cooled or heated by jacket</li> </ul>	<ul style="list-style-type: none"> <li>Small-scale production</li> <li>Intermediate or one-shot productions</li> <li>Pharmaceuticals</li> <li>Fermentations</li> </ul>	<ul style="list-style-type: none"> <li>High conversion per unit volume for one pass</li> <li>Same reactor can be used to produce one product one time and a different product the next</li> </ul>	<ul style="list-style-type: none"> <li>High operating cost (labor)</li> <li>Product quality more variable than with continuous operation</li> </ul>
Semibatch	<ul style="list-style-type: none"> <li>Either one reactant is charged and the other is fed continuously (at small concentrations) or else one of the products can be removed continuously (to avoid side reactions)</li> </ul>	<ul style="list-style-type: none"> <li>Small-scale production</li> <li>Competing reactions</li> </ul>	<ul style="list-style-type: none"> <li>Good selectivity; feed can be controlled so as to minimize side runs.</li> </ul>	<ul style="list-style-type: none"> <li>High operating labor cost</li> <li>Product quality more variable than with continuous operation</li> </ul>
Continuously stirred tank reactor (CSTR)	<ul style="list-style-type: none"> <li>Run at steady state with continuous flow of reactants and products; the feed assumes a uniform composition throughout the reactor, exit stream has the same composition as in the tank</li> </ul>	<ul style="list-style-type: none"> <li>When agitation is required</li> <li>Series configuration for different concentration streams</li> </ul>	<ul style="list-style-type: none"> <li>Continuous operation</li> <li>Good temperature control</li> <li>Good control</li> <li>Simplicity of construction</li> <li>Low operating (labor) cost</li> </ul>	<ul style="list-style-type: none"> <li>Lowest conversion per unit volume</li> <li>Bypassing and channeling possible with poor agitation</li> </ul>
Plug flow reactor (PFR)	<ul style="list-style-type: none"> <li>Arranged as one long reactor or many short reactors in a tube bank; no radial variation in reaction rate (concentration); concentration changes with length down the reactor</li> </ul>	<ul style="list-style-type: none"> <li>Large-scale production</li> <li>Homogeneous reactions</li> <li>Heterogeneous reactions</li> <li>Continuous production</li> <li>High temperature</li> </ul>	<ul style="list-style-type: none"> <li>Highest conversion per unit volume</li> <li>Low operating labor cost</li> <li>Continuous operation</li> <li>Good heat transfer</li> </ul>	<ul style="list-style-type: none"> <li>Undesired thermal gradients may exist</li> <li>Poor temperature control</li> <li>Shutdown, cleaning may be expensive</li> </ul>
Tubular packed bed reactor (PBR)	<ul style="list-style-type: none"> <li>Tubular reactor that is packed with solid catalyst particles</li> </ul>	<ul style="list-style-type: none"> <li>Used primarily in heterogeneous gas phase reactions with a catalyst</li> </ul>	<ul style="list-style-type: none"> <li>Highest conversion per unit mass of catalyst</li> <li>Low operating cost</li> <li>Continuous operation</li> </ul>	<ul style="list-style-type: none"> <li>Undesired thermal gradients may exist</li> <li>Poor temperature control</li> <li>Channeling may occur</li> </ul>

By using an algorithm to formulate CRE problems, we can formulate and solve CRE problems in a very logical manner. Step 1 in the CRE algorithm is to begin by choosing the mole balance for one of the five types of reactors shown. In step 2 we choose the rate law and in step 3 we specify whether the reaction is gas or liquid phase. Finally, in step 4 we combine steps 1, 2, and 3 and obtain an analytical solution or solve the equations using an *ordinary differential equation (ODE) solver* [Sacham and Cutlip, 1988].

## 76.1 The Algorithm

We now address each of the individual steps in the algorithm to design isothermal reactors: (1) mole balances, (2) rate laws, (3) stoichiometry, and (4) combine.

### Mole Balances

The general mole balance equation (GBE) on species  $j$  in a system volume  $V$  is:

$$\begin{bmatrix} \text{Molar flow} \\ \text{rate} \\ \text{IN} \end{bmatrix} - \begin{bmatrix} \text{Molar flow} \\ \text{rate} \\ \text{OUT} \end{bmatrix} + \begin{bmatrix} \text{Molar rate} \\ \text{of} \\ \text{GENERATION} \end{bmatrix} = \begin{bmatrix} \text{Molar rate} \\ \text{of} \\ \text{ACCUMULATION} \end{bmatrix}$$

$$F_{j0} - F_j + \int_0^v r_j dV = \frac{dN_j}{dt} \quad (76.1)$$

We now make use of the definition of conversion,  $X$ , with respect to the limiting reactant, which we shall call species  $A$ ,

$$\begin{array}{cc} \text{Batch} & \text{Flow} \\ X = (N_{A0} - N_A)/N_{A0} & X = (F_{A0} - F_A)/F_{A0} \end{array}$$

and apply the GME to each of the following reactors: batch, continuous stirred tank reactors (CSTR), plug flow reactor (PFR), and packed bed reactor (PBR). The CSTR, PFR, and PBR are all operated at steady state (i.e.,  $dN_j/dt = 0$ ) and it is assumed that the PBR and PFR are in plug flow (no radial gradients or dispersion) and that the contents of the CSTR are well mixed. There is no in-flow or out-flow ( $F_{j0} = F_j = 0$ ) in the batch reactor. When these conditions and the definition of conversion are applied to the general mole balance, the design equations (76.2 to 76.8) in [Table 76.2](#) result.

**Table 76.2** Design Equations

Reactor	Differential	Algebraic	Integral
Batch	$N_{A0} \frac{dX}{dt} = -r_A V \quad (76.2)$		$t = N_{A0} \int_0^x \frac{dX}{-r_A V} \quad (76.3)$
CSTR		$V = \frac{F_{A0} X}{-r_A} \quad (76.4)$	
PFR	$F_{A0} \frac{dX}{dV} = -r_A \quad (76.5)$		$V = F_{A0} \int_0^x \frac{dX}{-r_A} \quad (76.6)$
PBR	$F_{A0} \frac{dX}{dW} = -r'_A \quad (76.7)$		$W = F_{A0} \int_0^x \frac{dX}{-r'_A} \quad (76.8)$

In order to evaluate the design equations given in [Table 76.2](#) we must determine the form of the rate of formation,  $r_A$ . We do this with the aid of a rate law.

## Rate Laws

The power law model is one of the most commonly used forms for the rate law. It expresses the rate of reaction as a function of the concentrations of the species involved in the reaction.

For the irreversible reaction in which  $A$  is the limiting reactant,

the rate law is

$$-r_A = kC_A^\alpha C_B^\beta \quad (76.10)$$

We say the reaction is  $\alpha$  order in  $A$ ,  $\beta$  order in  $B$ , and overall order  $= \alpha + \beta$ . For example, if the reaction  $A + B \rightarrow C + D$  is said to be second order in  $A$  and first order in  $B$  and overall third order, then the rate law is

$$-r_A = kC_A^2 C_B \quad (76.11)$$

The temperature dependence of specific reaction rate,  $k$ , is given by the Arrhenius equation,

$$k = Ae^{-E/RT} \quad (76.12)$$

where  $A$  is the frequency factor and  $E$  the activation energy. Taking the natural log of both sides of Eq. (76.12),

$$\ln k = \ln A - \frac{E}{R} \left( \frac{1}{T} \right) \quad (76.13)$$

we see the slope of a plot of  $\ln k$  versus  $(1/T)$  will be a straight line equal to  $(-E/R)$ .

The specific reaction rate at temperature  $T$  is commonly written in terms of the specific reaction rate,  $k_1$ , at a reference temperature  $T_1$  and the activation energy  $E$ . That is,

$$k = k_1(T_1) \exp \left[ \frac{E}{R} \left( \frac{1}{T_1} - \frac{1}{T} \right) \right] \quad (76.14)$$

**Example.** The following reaction is carried out in a constant volume batch reactor:

Determine the appropriate linearized concentration-time plots for zero-, first-, and second-order reactions.

**Solution.** Use the algorithm to determine the concentration of A as a function of time.

$$\text{Mole balance: } \frac{dN_A}{dt} = r_A V \quad (76.15)$$

$$\text{Rate law: } -r_A = kC_A^\alpha \quad (76.16)$$

$$\text{Stoichiometry: } V = V_0 \quad C_A = N_A/V_0 \quad (76.17)$$

$$\text{Combine: } -\frac{dC_A}{dt} = kC_A^\alpha \quad (76.18)$$

Solving Eq. (76.18) for a first-, second-, and third-order rate law, we can arrive at the following linearized concentration-time plots.

**Zero order,  $\alpha = 0$**

$$C_A = C_{A0} - kt$$

**First Order,  $\alpha = 1$**

$$\ln C_{A0}/C_A = kt$$

**Second Order,  $\alpha = 2$**

$$\frac{1}{C_A} - \frac{1}{C_{A0}} = kt$$

For reversible reactions at equilibrium the rate law must reduce to a thermodynamically consistent equation for the equilibrium constant.

## Stoichiometry

Now that we have the rate law as a function of concentration (i.e.,  $-r_A = kC_A^\alpha C_B^\beta$ ), we need to express the concentrations of the reacting species as functions of conversion in order to evaluate any one of the reactor design equations.

### Concentration

We start by defining concentration for a flow system and a batch system. For a flow system,

$$C_i = \frac{F_i}{v} \quad (76.19)$$

where  $v$  is the volumetric flow rate. For a batch system,

$$C_i = \frac{N_i}{V} \quad (76.20)$$

The next step is to express  $N_i$  and  $F_i$  as a function of conversion using a stoichiometric table.

### The Stoichiometry Table

Using our definition of conversion we can construct the following stoichiometric table.

Stoichiometry	$A + \frac{b}{a}B \rightarrow \frac{c}{a}C + \frac{d}{a}D$			
Batch systems Species	Symbol	Initial	Change	Remaining
$A$	$A$	$N_{A0}$	$-N_{A0}X$	$N_A = N_{A0}(1 - X)$
$B$	$B$	$N_{A0}\Theta_B$	$-\frac{b}{a}N_{A0}X$	$N_B = N_{A0}\left(\Theta_B - \frac{b}{a}X\right)$
$C$	$C$	$N_{A0}\Theta_C$	$+\frac{c}{a}N_{A0}X$	$N_C = N_{A0}\left(\Theta_C + \frac{c}{a}X\right)$
$D$	$D$	$N_{A0}\Theta_D$	$+\frac{d}{a}N_{A0}X$	$N_D = N_{A0}\left(\Theta_D + \frac{d}{a}X\right)$
Inert	$I$	$N_{A0}\Theta_I$	—	$N_I = N_{A0}\Theta_I$
		$N_{T0}$		$N_T = N_{T0} + \delta N_{A0}X$
where $\delta = \frac{d}{a} + \frac{c}{a} - \frac{b}{a} - 1$ , $\varepsilon = y_{A0}\delta$ , and $\Theta_i = \frac{N_{i0}}{N_{A0}} = \frac{y_{i0}}{y_{A0}} = \frac{C_{i0}}{C_{A0}}$				

For flow systems the number of moles of species  $i$ ,  $N_i$  in this table are simply replaced by the molar flow rates of species  $i$ ,  $F_i$ .

### Expressing Concentration as a Function of Conversion in Batch System

Constant volume batch:  $V = V_0$ .

$$C_B = \frac{N_B}{V} = \frac{N_B}{V_0} = \frac{N_{A0}}{V_0} \left( \Theta_B - \frac{b}{a}X \right)$$

$$C_B = C_{A0} \left( \Theta_B - \frac{b}{a}X \right) \quad (76.21)$$

### Expressing Concentration as a Function of Conversion in Flow System

For flow systems, the stoichiometric table is the same, except replace  $N_i$  by  $F_i$ . Because there is hardly ever a volume change with reaction, the concentration of  $A$  in a *liquid* flow system is as follows. For liquid systems,

$$C_A = \frac{F_A}{v_0} = \frac{F_{A0}}{v_0}(1 - X) = C_{A0}(1 - X) \quad (76.22)$$

For gas systems,

$$C_A = \frac{F_A}{v} \quad (76.23)$$

In ideal gas systems the gas volumetric flow rate,  $v$ , can change with conversion, temperature, and pressure according to the following equation:

$$v = v_0 \left( \frac{F_T}{F_{T0}} \right) \frac{P_0}{P} \frac{T}{T_0} \quad (76.24)$$

Taking the ratio of  $F_T/F_{T0}$  and then using the stoichiometric table, we arrive at the following equation for the volumetric flow rate at any point in the reactor.

$$v = v_0(1 + \varepsilon X) \frac{P_0}{P} \frac{T}{T_0} \quad (76.25)$$

Substituting this result and Eq. (76.22) into Eq. (76.23) gives

$$C_A = \frac{C_{A0}(1 - X)}{(1 + \varepsilon X)} \frac{P}{P_0} \frac{T_0}{T} \quad (76.26)$$

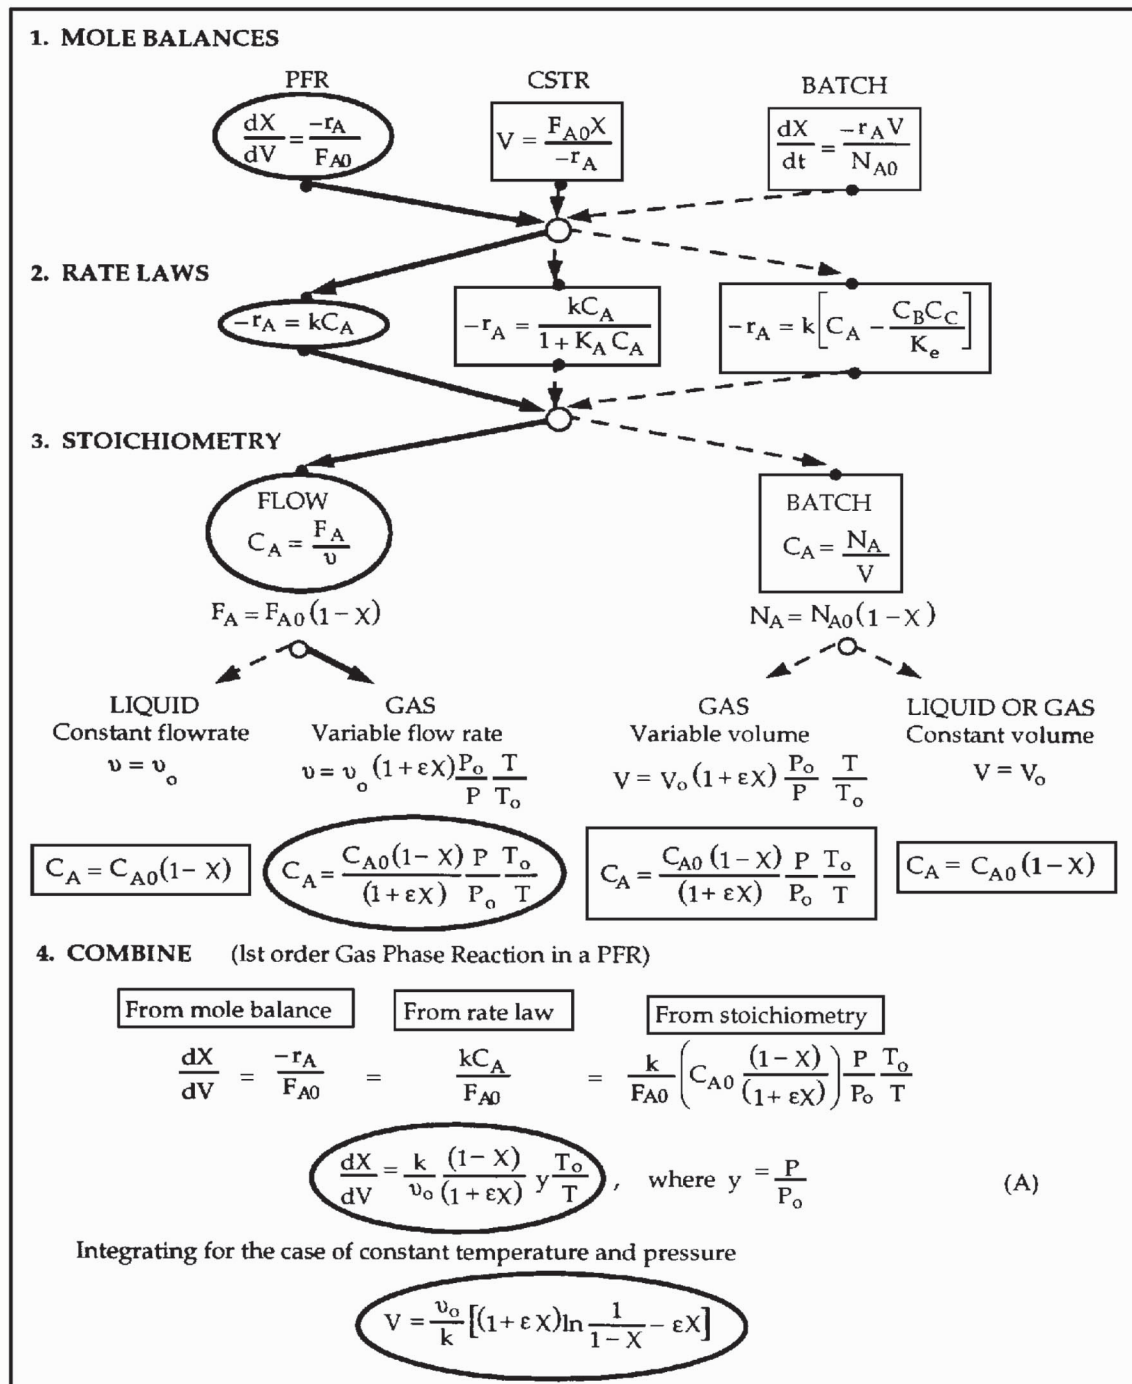

We now will apply the algorithm described earlier to a specific situation. Suppose we have, as shown in Fig. 76.2, mole balances for three reactors, three rate laws, and the equations for concentrations for both liquid and gas phases. In Fig. 76.3 the algorithm is used to formulate the equation to calculate the PFR reactor volume for a first-order gas-phase reaction. The pathway to arrive at this equation is shown by the ovals connected to the dark lines through the algorithm. The dashed lines and the boxes represent other pathways for other solutions. For the reactor and reaction specified, we follow these steps:

1. Choose the *mole balance* on species  $A$  for a PFR.
2. Choose the *rate law* for an irreversible first-order reaction.
3. Choose the equation for the concentration of  $A$  in the gas phase (*stoichiometry*).
4. Finally, *combine* to calculate the volume necessary to achieve a given conversion or calculate the conversion that can be achieved in a specified reaction volume.

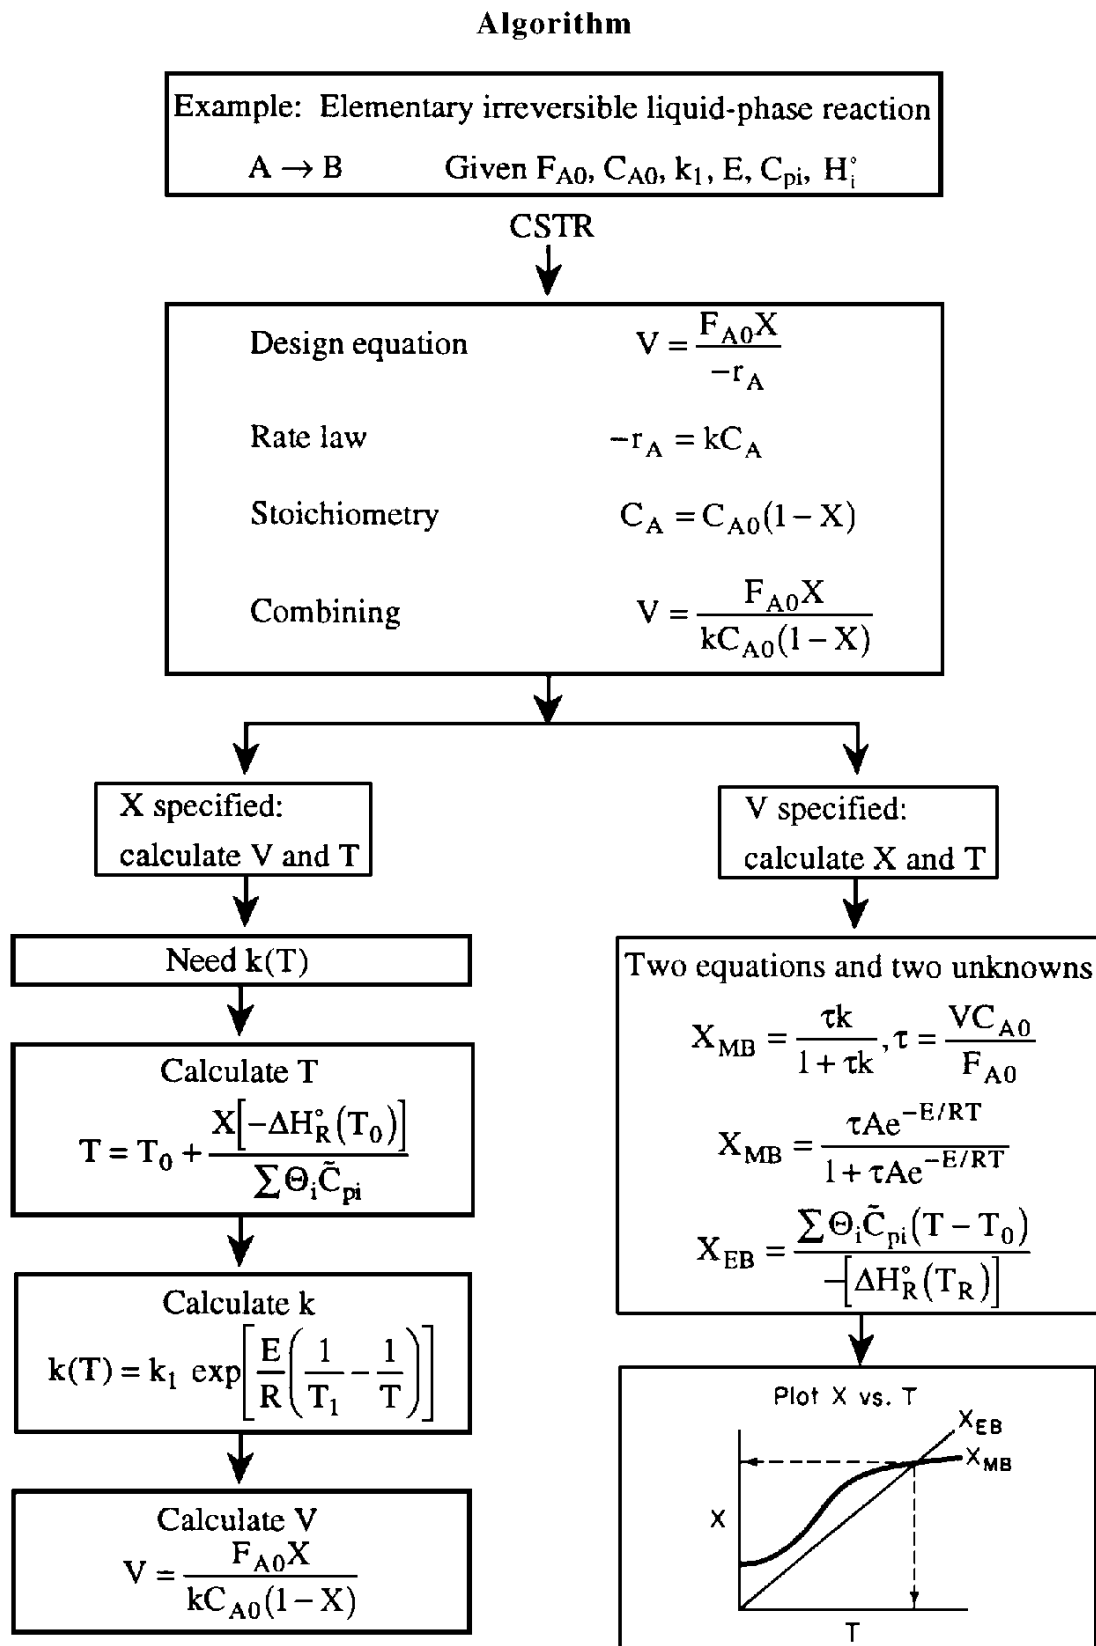

For the case of isothermal operation with no pressure drop, we were able to obtain an analytical

solution, given by equation (A) in Fig. 76.2, which gives reactor volume necessary to achieve a conversion  $X$  for a gas phase reaction carried out isothermally in a PFR. However, in the majority of situations, analytical solutions to the ordinary differential equations appearing in the combine step are not possible. By using this structure, one should be able to solve reactor engineering problems through reasoning rather than memorization of numerous equations together with the various restrictions and conditions under which each equation applies (i.e., whether there is a change in the total number of moles, etc.). In perhaps no other area of engineering is mere formula plugging more hazardous; the number of physical situations that can arise appears infinite, and the chances of a simple formula being sufficient for the adequate design of a real reactor are vanishingly small.

**Figure 76.3** Algorithm for nonisothermal CSTR design. (Source: Fogler, H. S. 1992. *The Elements of Chemical Reaction Engineering*, 2nd ed. Prentice Hall, Englewood Cliffs, NJ.)

**Example.** The elementary gas phase reaction

$$-r_A = k_A C_A^2 C_B$$

is carried out at constant  $T$  (500 K) and  $P$  (16.4 atm) with  $k_A = 10 \text{ dm}^6/\text{mol}^2 \cdot \text{s}$ . Determine the CSTR reactor volume necessary to achieve 90% conversion when the feed is 50% mole  $A$  and 50%  $B$ .

**Solution.** The feed is equal molar in  $A$  and  $B$ ; therefore,  $A$  is the limiting reactor and taken as our basis of calculation:

Mole balance is given as:

$$V = \frac{F_{A0} X}{-r_A} \quad (76.27)$$

Rate law is given as:

$$-r_A = k_A C_A^2 C_B \quad (76.28)$$

Stoichiometry is found as follows:

$$C_A = C_{A0} \cdot \frac{(1 - X)}{(1 + \varepsilon X)} \frac{P}{P_0} \frac{T_0}{T} = C_{A0} \frac{(1 - X)}{(1 + \varepsilon X)}$$

$$\varepsilon = y_{A0} \delta = 0.5 \left[ \frac{1}{2} - \frac{1}{2} - 1 \right] = -0.5 \quad (76.29)$$

$$C_A = C_{A0} (1 - X) / (1 - 0.5X)$$

$$C_{A0} = \frac{y_{A0} P_0}{RT_0} = \frac{(0.5)(16.4 \text{ atm})}{\frac{0.082 \text{ atm m}^3}{\text{kmol K}} \cdot 500 \text{ K}} = 0.2 \frac{\text{kmol}}{\text{m}^3} = 0.2 \frac{\text{mol}}{\text{dm}^3} \quad (76.30)$$

$$C_B = C_{A0} \frac{\Theta_B - \frac{1}{2}X}{(1 + \varepsilon X)} = C_{A0} \frac{(1 - 0.5X)}{(1 - 0.5X)} = C_{A0} \quad (76.31)$$

For the combine step,

$$\begin{aligned} -r_A &= k_A C_A^2 C_B = k_A C_{A0}^3 \frac{(1 - X)^2}{(1 - 0.5X)^2} \\ &= 0.08 \frac{\text{mol}}{\text{dm}^3 \cdot \text{s}} \frac{(1 - X)^2}{(1 - 0.5X)^2} \end{aligned} \quad (76.32)$$

For a CSTR,

$$\begin{aligned} V &= \frac{F_{A0} X}{-r_A} = \frac{(5 \text{ mol/s})(0.9)[1 - 0.5(0.9)]^2}{(0.08) \frac{\text{mol}}{\text{dm}^3 \cdot \text{s}} (1 - 0.9)^2} \\ &= 1701 \text{ dm}^3 \end{aligned} \quad (76.33)$$

## 76.2 Pressure Drop in Reactors

---

If pressure drop is not accounted for in gas phase reactions, significant underdesign of the reactor size can result. This variation is handled in the stoichiometry step, in which concentration is expressed as a function of conversion, temperature, and total pressure. The change in total pressure is given by the Ergun equation [Fogler, 1992]:

$$\frac{dP}{dL} = -\frac{G(1 - \phi)}{\rho g_C D_p \phi^3} \left[ \frac{150(1 - \phi)\mu}{D_p} + 1.75G \right] \quad (76.34)$$

For isothermal operation the density is (assuming ideal gas)

$$\rho = \frac{\rho_0}{(1 + \varepsilon X)} \frac{P}{P_0} \quad (76.35)$$

The catalyst weight,  $W$ , and length down the reactor,  $L$ , are related by the equation

$$W = LA_c(1 - \Phi)\rho_{\text{cat}}$$

Substituting back in the Ergun equation,

$$\frac{dP}{dW} = -\frac{\alpha_P}{2} \frac{(1 + \varepsilon X)}{\frac{1}{P_0} \left( \frac{P}{P_0} \right)} \quad (76.36)$$

where

$$\alpha_p = \frac{\frac{G(1 - \Phi)}{\rho_0 g_c D_p \Phi^3} \left[ \frac{150(1 - \Phi)\mu}{D_p} + 1.75G \right]}{A_c(1 - \Phi)\rho_{\text{cat}} P_0}$$

We now need to solve this differential equation to obtain the pressure as a function of the weight of catalyst the gas has passed over. We can obtain an analytical solution of  $\varepsilon = 0$ . Otherwise, we must solve the equation numerically and simultaneously with the mole balance. For an analytical solution,

$$\frac{d(P/P_0)^2}{dW} = -\alpha_p(1 + \varepsilon X) \quad (76.37)$$

For POLYMATH solution, letting  $y = P/P_0$ ,

$$\frac{dy}{dW} = -\frac{\alpha_p(1 + \varepsilon X)}{2y} \quad (76.38)$$

**Example.** To understand the effect pressure drop has on gas phase reaction in a packed bed, we analyze the reaction  $A \rightarrow B$  carried out in a packed bed reactor (PBR). Mole balance (PBR) is

$$F_{A0} \frac{dX}{dW} = -r'_A$$

Wherever pressure drop occurs in a PBR we must use the differential form of the mole balance to separate variables. Pressure drop only affects  $C_A$ ,  $C_B$ , and so on, as well as  $-r'_A$ .

Rate law is second order in A and irreversible, according to the formula  $-r'_A = kC_A^2$ .

Stoichiometry is given by

$$C_A = C_{A0} \frac{(1 - X)}{(1 + \varepsilon X)} \frac{P}{P_0} \frac{T_0}{T}$$

For  $\varepsilon = 0$  and isothermal operation,

$$\frac{P}{P_0} = (1 - \alpha_p W)^{1/2}$$

$$C_A = C_{A0}(1 - X) \frac{P}{P_0} = C_{A0}(1 - X) (1 - \alpha_p W)^{1/2}$$

Combining,

$$F_{A0} \frac{dX}{dW} = -r'_A = kC_{A0}^2 (1 - X)^2 (1 - \alpha_p W)$$

By integrating with limits  $W = 0, X = 0$  we obtain the desired relationship between conversion and catalyst weight.

$$\frac{X}{1 - X} = \frac{kC_{A0}^2}{F_{A0}} \left[ W - \frac{\alpha_p W^2}{2} \right]$$

## 76.3 Multiple Reactions

---

There are three basic types of multiple reactions: series, parallel, and independent. In *parallel reactions* (also called *competing reactions*) the reactant is consumed by two different reactions to form different products:

In *series reactions*, also called *consecutive reactions*, the reactant forms an intermediate product, which reacts further to form another product:

Multiple reactions involve a combination of both series and parallel reactions, such as

*Independent* reactions are of the type

and occur in feed stocks containing many reactants. The cracking of crude oil to form gasoline is an example of an independent reaction.

To describe selectivity and yield we consider the following competing reactions.

The rate laws are

$$r_D = k_D C_A^{\alpha_1} C_B^{\beta_1} \quad (76.39)$$

$$r_U = k_U C_A^{\alpha_1} C_B^{\beta_2} \quad (76.40)$$

We want the rate of  $D$ ,  $r_D$ , to be high with respect to the rate of formation  $U$ ,  $r_U$ . Taking the ratio of these rates, we obtain a rate *selectivity parameter*,  $S$ , which is to be maximized:

$$S_{DU} = \frac{r_D}{r_U} \quad (76.41)$$

Substituting Eqs. (76.39) and (76.40) into Eq. (76.41) and letting  $a = \alpha_1 - \alpha_2$  and  $b = \beta_2 - \beta_1$ , where  $a$  and  $b$  are both positive numbers, we have

$$S_{DU} = \frac{r_D}{r_U} = \frac{k_1 C_A^a}{k_2 C_B^b}$$

To make  $S_{DU}$  as large as possible we want to make the concentration of  $A$  high and the concentration of  $B$  low. To achieve this result, use the following:

A semibatch reactor in which  $B$  is fed slowly into a large amount of  $A$

A tubular reactor with side streams of  $B$  continually fed to the reactor

A series of small CSTRs with  $A$  fed only to the first reactor and  $B$  fed to each reactor

Another definition of selectivity used in the current literature is given in terms of the flow rates leaving the reactor:

$$\tilde{S}_{DU} = \text{Selectivity} = \frac{F_D}{F_U} = \frac{\text{Exit molar flow rate of desired product}}{\text{Exit molar flow rate of undesired product}} \quad (76.42)$$

For a batch reactor the selectivity is given in terms of the number of moles of  $D$  and  $U$  at the

end of the reaction time:

$$\tilde{S}_{DU} = \frac{N_D}{N_U} \quad (76.43)$$

One also finds that the reaction yield, like the selectivity, has two definitions: one based on the ratio of reaction rates and one based on the ratio of molar flow rates. In the first case the yield at a point can be defined as the ratio of the reaction rate of a given product to the reaction rate of the key reactant A [Carbery, 1967]:

$$Y_D = \frac{r_D}{-r_A} \quad (76.44)$$

In the case of reaction yield based on molar flow rates, the yield is defined as the ratio of moles of product formed at the end of the reaction to the number of moles of the key reactant, A, that have been consumed. For a batch system,

$$\tilde{Y}_D = \frac{N_D}{N_{A0} - N_A} \quad (76.45)$$

For a flow system,

$$\tilde{Y}_D = \frac{F_D}{F_{A0} - F_A} \quad (76.46)$$

Because of the various definitions for selectivity and yield, when reading literature dealing with multiple reactions, check carefully to ascertain the definition intended by the author.

## 76.4 Heat Effects

For nonisothermal reaction in CRE we must choose which form of the energy balance to use (e.g., PFR, CSTR) and which terms to eliminate (e.g.,  $Q = 0$  for adiabatic operation). The structure introduced to study these reactors builds on the isothermal algorithm by introducing the Arrhenius equation,  $k = Ae^{-E/RT}$  in the **rate law** step, which results in one equation with two unknowns,  $X$  and  $T$ , when we finish with the combine step. For example, using again the PFR mole balance and conditions in Fig. 76.2[Eq. (A)], we have, for constant pressure,

$$\frac{dX}{dV} = \frac{k(1-X)}{v_0(1+\varepsilon X)} \frac{T_0}{T} \quad (76.47)$$

$$\frac{dX}{dV} = \frac{Ae^{-E/RT} (1-X)}{v_0(1+\varepsilon X)} \left( \frac{T_0}{T} \right) \quad (76.48)$$

We can now see the necessity of performing an energy balance on the reactor to obtain a second equation relating  $X$  and  $T$ . We will use energy balance to relate  $X$  and  $T$ .

$$\begin{aligned}
 \left[ \begin{array}{c} \text{Rate of} \\ \text{accumulation} \\ \text{of energy} \\ \text{within the} \\ \text{system} \end{array} \right] &= \left[ \begin{array}{c} \text{Rate of flow} \\ \text{of heat to} \\ \text{the system} \\ \text{from the} \\ \text{surroundings} \end{array} \right] - \left[ \begin{array}{c} \text{Rate of work} \\ \text{done by} \\ \text{the system} \\ \text{on the} \\ \text{surroundings} \end{array} \right] \\
 &+ \left[ \begin{array}{c} \text{Rate of energy} \\ \text{added to the} \\ \text{system by mass} \\ \text{flow into the} \\ \text{system} \end{array} \right] - \left[ \begin{array}{c} \text{Rate of} \\ \text{energy leaving} \\ \text{system by mass} \\ \text{flow out of} \\ \text{the system} \end{array} \right]
 \end{aligned}$$

$$\frac{dE}{dt} = \dot{Q} - \dot{W} + \sum F_{in} E_{in} - \sum F_{out} E_{out}$$

Neglecting potential and kinetic energy, the energy  $E_i$  is just the internal energy of species  $i$ , substituting for  $W$  in terms of the flow work and the shaft work,  $W_S$ , and using the definition of enthalpy gives for steady state operation

$$\dot{Q} - \dot{W}_s + \sum F_{i0} H_{i0} - \sum F_i H_i = 0 \quad (76.49)$$

For adiabatic operation, no work done on the system and constant heat capacity and  $\Delta C_p = 0$ , the energy balance reduces to

$$T = T_0 + \frac{(-\Delta H_R) X}{\sum \theta_i C_{pi} + \Delta C_p X} \quad (76.50)$$

We now use this relationship to solve adiabatic reactor design problems.

The procedure for nonisothermal reactor design can be illustrated by considering the first-order irreversible liquid-phase reaction  $A \rightarrow B$ . The CSTR design equation is

$$V = \frac{F_{A0} X}{-r_A}$$

Rate law is found by

$$-r_A = kC_A \quad (76.51)$$

with the Arrhenius equation:

$$k = Ae^{-E/RT}$$

Stoichiometry for the liquid phase (i.e.,  $v = v_0$ ) is given by

$$C_A = C_{A0}(1 - X)$$

Combining yields

$$V = \frac{v_0}{Ae^{-E/RT}} \left( \frac{X}{1 - X} \right) \quad (76.52)$$

Continuing from this point requires two distinct cases. For the first case, the variables  $X$ ,  $v_0$ ,  $C_{A0}$ , and  $F_{i0}$  are specified and the reactor volume,  $V$ , must be determined. The procedure is as follows:

1. Evaluate Eq. (76.50) to find the temperature,  $T$ , for the conditions specified.
2. Calculate  $k$  from the Arrhenius equation.
3. Calculate the reactor volume,  $V$ , from Eq. (76.52).

For the second case, the variables  $v_0$ ,  $C_{A0}$ ,  $V$ , and  $F_{i0}$  are specified and the exit temperature,  $T$ , and conversion,  $X$ , are unknown quantities. The procedure is as follows:

1. Solve the energy balance for  $X$  as a function of  $T$ . If adiabatic, Eq. (76.50) becomes

$$X_{EB} = \frac{\sum \Theta_i \tilde{C}_{pi} (T - T_0)}{-[\Delta H_R^\circ(T_R)]} \quad (76.53)$$

2. Solve the mole balance [Eq.(76.52)]for  $X$  as a function of  $T$ .

$$X_{MB} = \frac{\tau Ae^{-E/RT}}{1 + \tau Ae^{-E/RT}}$$

where  $\tau = V/v_0$

3. Plot the previous two steps on the same graph to determine the intersection. At this point the values of  $X$  and  $T$  satisfy both the energy balance and mole balance. As an alternative, one may equate the equations for  $X$  from the previous two steps and solve numerically.

An energy balance on a PFR with heat exchange yields the second equation we need relating our independent variables  $X$  and  $T$ :

$$\frac{dT}{dV} = \frac{[U A_c (T_a - T) + (r_A)(\Delta H_R)]}{F_{A0} C_{P_A}} \quad (76.54)$$

The differential equation describing the change of temperature with volume (i.e., distance) down the reactor,

$$\frac{dT}{dV} = g(X, T) \quad (76.55)$$

must be coupled with the mole balance, Eq. (76.5),

$$\frac{dX}{dV} = \frac{-r_A}{F_{A0}} f(X, T) \quad (76.56)$$

and solved simultaneously. A variety of numerical integration schemes and ODE solvers can be used to solve these two equations simultaneously.

#### SHELL'S HYCON PROCESS

As long ago as 1967, the laboratory of the Royal Dutch/Shell Group in Amsterdam headed the development of the HYCON process, by which even the heaviest oil fraction could be converted into premium products, such as gasoline, kerosene, and gasoil.

This had not really been necessary before the first oil crisis in 1973. Oil then was still cheap and in plentiful supply and there was a ready market for all products.

After the oil crises in 1973 and 1979, however, prices had risen to such a level as to provide a powerful incentive for producing the greatest amount of light products from the crude oil, which had, moreover, been getting gradually heavier.

Initially, this was no problem for complex refineries such as Shell Pernis. In contrast with other refineries, Shell Pernis was able to treat the heavy residue remaining after atmospheric distillation by redistilling it under high vacuum. In this way, valuable products such as gasoline, gasoil, and lubricating oil distillates could be manufactured.

But even after this conversion method, a black, viscous mass still remained, which could only be used as a component of heavy fuel oil after adding gasoil. Adding gasoil, however, was a costly solution for a product that was earning less and less. In the Shell laboratories, meanwhile, people were hard at work on a process with better economic prospects: HYCON.

This process is based on the fact that the vacuum residue contains much less hydrogen than the

lighter products. The aim, therefore, is to reduce the size of the molecules and to increase the ratio of hydrogen atoms to carbon atoms.

This ratio can be increased either by removing some carbon from the molecules or by attaching hydrogen to the atoms with the aid of a catalyst. Shell chose the latter approach and called its process HYCON (hydroconversion).

This all sounds much simpler than it actually is. Reducing the size (cracking) of the large molecules is only possible at high temperatures, but the problem with heating is that it produces a heavy deposit of carbon on the catalyst. This problem, and also the addition of hydrogen to the molecules, was solved by carrying out the process under high pressure. Another difficulty is that the asphaltenes (substances with a complex molecular structure) in the residue react very slowly. The reaction mixture therefore has to remain in the reactors for a long time. All in all, this means: several reactors in series, large amounts of catalyst, and high pressures and temperatures in the reactors.

There was another problem that had to be solved in the laboratories. The residue contains heavy metals, such as vanadium and nickel, which poison the catalyst. The solution for this is first of all to pass the residue through a number of reactors containing a specially developed catalyst which removes most of the metals. A technique was also developed to regenerate this catalyst during the process.

The HYCON process required the largest capital investment ever made by Shell in the Netherlands. HYCON in Pernis was put into operation at the beginning of 1989. (Courtesy of the Shell Group.)

## 76.5 Summary

---

By arranging chemical reaction engineering in a structure analogous to a French menu, we can study a multitude of reaction systems with very little effort. This structure is extremely compatible with a number of user-friendly ordinary differential equation (ODE) solvers. Using **ODE solvers** such as POLYMATH, the student is able to focus on exploring reaction engineering problems rather than crunching numbers. Thus, the teacher is able to assign problems that are more open ended and give students practice at developing their creativity. Practicing creativity is extremely important, not only in CRE, but in every course in the curriculum if students are to compete in the world arena and succeed in solving the relevant problems that they will be faced with in the future.

### Nomenclature

$A$	frequency factor (appropriate units)
$A_C$	cross-sectional area, $\text{m}^2$
$C_i$	concentration of species $i$ ( $i = A, B, C, D$ ), $\text{mol/dm}^3$
$C_{Pi}$	heat capacity of species $i$ , $\text{J/g/K}$

$D_P$	particle diameter, m
$E$	activation energy, J/mol
$F_i$	entering molar flow rate of species $i$ , mol/s
$G$	superficial gas velocity g/m <sup>2</sup> /s
$g_c$	conversion factor
$k$	specific reaction rate (constant), appropriate units
$K_A$	adsorption equilibrium constant (dm <sup>3</sup> /mol)
$K_e$	equilibrium constant, appropriate units
$L$	length down the reactor, m
$N_t$	number of moles of species $i$ , mol
$P$	pressure, kPa
$r_t$	rate of formation of species $i$ per unit volume, mol/s/dm <sup>3</sup>
$r_t'$	rate of formation of species $i$ per unit mass of catalyst, mol/s/g
$R$	ideal gas constant, J/mol/K
$t$	time, s
$T$	temperature, K
$U$	overall heat transfer coefficient, J/(dm <sup>3</sup> s K)
$V$	volume, dm <sup>3</sup>
$W$	catalyst weight, g
$X$	conversion
$y$	pressure drop parameter ( $P/P_0$ )
$y_A$	mole fraction of $A$
$a$	ambient temperature
$A$	refers to species $A$
cat	catalyst density kg/m <sup>3</sup>
EB	energy balance
MB	mole balance
$T$	total number of moles
0	entering or initial condition
$\alpha$	reaction order
$\alpha_P$	pressure drop parameter, g <sup>-1</sup>
$\beta$	reaction order
$\Delta H_R$	heat of reaction, J/mole $A$
$\delta$	change in the total number of moles per mole of $A$ reacted
$\epsilon$	volume change parameter = $y_{A0} \delta$
$\phi$	porosity
$\mu$	viscosity, cp
$\rho$	density, g/dm <sup>3</sup>
$\nu$	volumetric flow rate, dm <sup>3</sup> /s

$$\Theta_i \quad N_i/N_{A0}$$

## Defining Terms

**Batch reactor:** A closed vessel (tank) in which there is no flow in or out of the vessel during the time the reaction is taking place.

**Continuous stirred tank reactor (CSTR):** A reactor in which the reactant and products flow continuous into and out of (respectively) the tank. A reactor where the contents are well mixed.

**ODE solver:** A user-friendly software package that solves ordinary differential equations, for example, Mathematica, POLYMATH, Matlab.

**Packed bed reactor:** Usually a tubular reactor packed with solid catalyst pellets.

**Plug flow reactor:** Usually a tubular reactor used for gas phase reactions in which it is assumed there are no radial gradients in temperature or concentration as well as no dispersion of reactants.

**Semibatch reactor:** A reactor (vessel) in which one of the reactants is placed in the reactor and a second reactant is slowly added to the reactor.

## 77.1 General Considerations in the Rational Design of Chemical Reactors

Reaction Kinetics Models and Reactor Models

## 77.2 Protocol for the Rational Design of Chemical Reactors

Step 1: Select the Type of Reactor for the Commercial Process • Step 2: Design the Laboratory to Generate Reaction Kinetics Data • Step 3: Use Statistically-Valid Experimental Programs and Models • Step 4: Develop Computer Programs for Reactor Simulation and Design • Step 5: Develop the Economically Optimum Reactor Design • Step 6: Validate the Design in a Pilot Plant Reactor

### J. B. Cropley

*Union Carbide Corporate Fellow(Retired)*

*Scaleup* is one of those overworked terms that has come to mean almost anything and everything, depending on who is using it. In this article we will use it very little, and then only to indicate the generic process of commercializing new chemical technology. The alternative to scaleup is rational design, which utilizes mathematical relationships and computer simulation to develop the best design for the reactor. The mathematical relationships describe both the reaction kinetics and the attributes of the reactor and its associated auxiliary equipment.

Geometric scaleup was practiced routinely in the chemical industry as a design protocol until a few decades ago, but, today, rational design—based on laboratory data and correlations—has largely replaced it for most types of industrial chemical reaction systems. To understand why this is so, it is necessary to note how the chemical industry has changed over the years.

Forty or 50 years ago, merely producing a chemical on an industrial scale was usually sufficient to ensure a profit for the manufacturer. Chemical processes were labor intensive, but capital and energy were cheap and the selling price of a pound of finished product was typically several times the raw material cost. Furthermore, the environment had not yet been discovered either by industry or by the public at large.

It was really unnecessary to design reactors rationally for most kinds of processes in that era, because any questions about productive capacity could be addressed simply by making the reactor larger, raw material selectivities usually were not economically critical, and the large quantities of energy that were expended in complex distillation trains to remove by-products and impurities were both practicable and inexpensive.

In contrast, the petrochemical industry today utilizes chemical reactions that produce the desired products much more directly and cleanly, with as little waste as possible. Raw material cost is

frequently the largest component of the final product cost, and the crude product must not contain unexpected by-products that the refining system cannot remove adequately and efficiently. The failure to meet tight product specifications can produce chemicals that either cannot be sold at all without expensive reprocessing or can be sold only for little more than their value as fuel.

In any case, both today's marketplace and concerns for the environment demand that chemical reaction systems produce no more than extremely small amounts of waste or off-specification product per pound of refined salable product. Reactors must be accurately designed and operated because today's chemistry frequently is strongly dependent upon carrying out just the desired amount of reaction in order to avoid the production of unwanted by-products by over-reaction. The energy efficiencies of refining systems strongly depend upon their receiving crude product of uniform and predictable composition, because product specifications are usually tight and must be met at minimum cost. Simply put, today's chemical reaction systems must operate as intended.

## 77.1 General Considerations in the Rational Design of Chemical Reactors

---

### Reaction Kinetics Models and Reactor Models

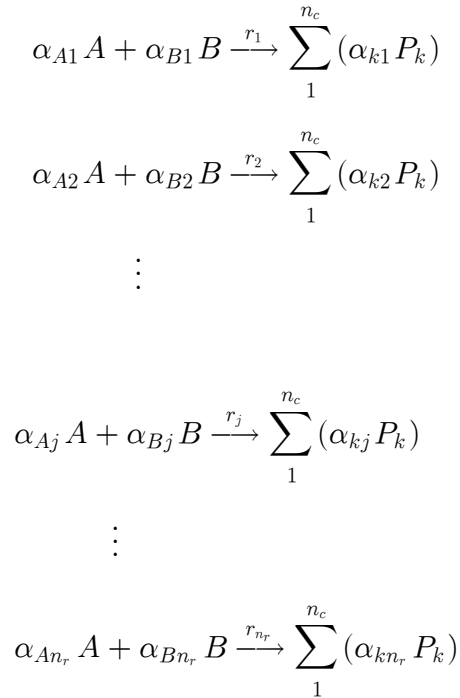

The rational design of any type of reactor involves the marriage of one or more reaction kinetics models and a reactor model. It is important to recognize exactly what these two kinds of models describe:

- *Reaction kinetics models* describe the response of reaction rates to the reaction environment—that is, to temperature and the concentrations of virtually everything in the system—reactants, products, by-products, catalysts, and contaminants. For design purposes, it is necessary and sufficient that the kinetic model reflect the reaction stoichiometry accurately and that it predict reaction rates accurately. It is not important that it reflect the actual reaction mechanism.
- *Reactor models* describe how the reaction environment is shaped by the geometry of the reactor, by physical processes like fluid dynamics and heat and mass transport, and by process variables and conditions such as mean reactor residence time and residence time distribution, flow rate, pressure, and temperature.

These distinctions are subtle, but important. It is sufficient to remember that kinetics models contain *only* temperature and concentration terms, whereas reactor models may contain these as well as everything else that influences the conduct of the reaction.

### Kinetics of a Simple Hypothetical System of Reactions

Real systems will have their own individual structures and characteristics and will reflect the particular stoichiometry of the reaction system at hand. In this chapter, we will use a general, somewhat simplified set of reactions and reactor equations for illustration. Consider the general group of  $n_r$  reactions presented below, in which chemical species  $A$  and  $B$  react to produce several products  $P_k$  according to the following scheme:

Kinetic models for the rational design of reaction systems will usually be of one of two basic mathematical forms, each given in moles/volume/time and describing the response of the reaction rates  $r_j$  to temperature and concentration. For exponential models,

$$r_j = K_{o_j} e^{-\frac{E_{a_j}}{RT}} C_A^{a_j} C_B^{b_j} C_{P_1}^{P_{1j}} \dots C_{P_n}^{p_{nj}} \quad (77.1)$$

For hyperbolic models,

$$r_j = \frac{K_{o_j} e^{-\frac{E_{a_j}}{RT}} C_A C_B}{1 + K_{A_j} C_A + K_{B_j} C_B + \sum_1^{n_c} (K_{P_{kj}} C_{P_k})} \quad (77.2)$$

Each of these two types of kinetic models has its own preferred uses. Their development will be discussed in a later section of this chapter. For now, assume that either of these types is to be used in a combined kinetics and reactor model to predict reaction rates, as described in the following section.

### Combined Kinetics and Reactor Models: The General Continuity Equation

Virtually all combined reaction kinetics and reactor models utilize some form of the general continuity equation for flow and reaction in an element of volume of some kind of reactor, such as that shown in [Fig. 77.1](#). In its simplest form, this equation states that the quantity of each component  $k$  that enters the volume element of the reactor must either leave, react, or accumulate:

$$F_{e_{in}} C_{k_{in}} = F_{e_{out}} C_{k_{out}} - V_e \sum_1^{n_r} (\alpha_{kj} r_j) + \frac{d(V_e C_{k_e})}{dt} \text{ mol/time} \quad (77.3)$$

**Figure 77.1** Flow and concentration in a volume element of a chemical reactor.

Different types of idealized reactors can be represented by this equation, simply by noting what terms are not appropriate and eliminating them. Thus, a simple *batch reactor* has no flow in or out, and therefore terms containing  $F$  drop out. So, for a simple batch reactor,

$$\frac{d(V_e C_{k_e})}{dt} = \sum_1^{n_r} (\alpha_{kj} r_j) V_e \quad (77.4)$$

which may be further simplified by canceling the  $V_e$  terms as well if the reaction volume is constant. Note that the volume element in this case is simply the entire filled volume of the reactor, because the concentration is assumed to be uniform throughout.

A steady state *continuous stirred tank reactor (CSTR)* may have the same flow rate in and out, and the entire contents of the reactor comprise the volume element, as in the batch reactor. The time-derivative term is absent because the reactor is at steady state. The concentrations of all species in the reactor are the same as in the outlet. Thus we have, for the CSTR,

$$F C_{k_{in}} = F C_{k_{out}} - V \sum_1^{n_r} (\alpha_{kj} r_j) \quad (77.5)$$

which can be rearranged to

$$\sum_1^{n_r} \alpha_{kj} r_j = \frac{F(C_{k_{out}} - C_{k_{in}})}{V} \text{ mol/volume/time} \quad (77.6)$$

Weight of catalyst,  $W_c$ , replaces reactor volume,  $V$ , for a catalytic reaction:

$$\sum_1^{n_r} \alpha_{kj} r_j = \frac{F(C_{k_{out}} - C_{k_{in}})}{W_c} \text{ mol/wt. catalyst/time} \quad (77.7)$$

This simple relationship makes the CSTR the preferred type of reactor for many kinds of kinetics studies, in which the net rates of formation or disappearance [that is,  $\sum_1^{n_r} (\alpha_{kj} r_j)$ ] for each individual component can be observed directly.

For design purposes it is more convenient to integrate the unsteady state form of the general continuity equation for the CSTR until the steady state concentrations are attained. (The model will behave very much as the real reactor would in this respect.) This procedure avoids the need to use constrained nonlinear estimation to predict the reactor outlet concentrations. Again, assuming that flows in and out of the reactor are the same and that volume is constant,

$$\frac{d(C_k)}{dt} = \frac{F(C_{k_{in}} - C_{k_{out}})}{V} + \sum_1^{n_r} (\alpha_{kj} r_j) \text{ mol/h} \quad (77.8)$$

The reactor model will comprise an equation like Eq. (77.8) for each component  $k$  in the CSTR. Another advantage of the unsteady state model is that stoichiometry is automatically preserved without the need for any constraints. It may be used readily to simulate a system comprising a large number of components and reactions in a multistage system of CSTRs, which is otherwise mathematically intractable. And, of course, it may be used to study the dynamic behavior of the system as well. Therefore, it is the preferred design approach for multistage CSTR systems.

In the *ideal steady state plug flow reactor*, all elements of fluid that enter the reactor together travel down its length and exit together, having thus stayed in the reactor for identical lengths of time. The volume element will be only a differential slice of the reactor cross section, denoted by  $dV$ . There will be no accumulation term, since the reactor is at steady state. The differential concentration difference across the differential volume element will be denoted by  $dC$ . Thus, Eq. (77.3) is once again applicable and simplifies to

$$F_e dC_k = \sum_1^{n_r} (\alpha_{kj} r_j) dV_e \quad (77.9)$$

If  $F$  changes as the reaction proceeds (as with many gas-phase reactions), then this can be accommodated down the length of the plug flow reactor by modifying the above equation to

$$d(F_e C_k) = \sum_1^{n_r} (\alpha_{kj} r_j) dV_e$$

whence

$$F_e \frac{dC_k}{dV_e} + C_k \frac{dF_e}{dV_e} = \sum_1^{n_r} (\alpha_{kj} r_j) dV_e$$

$$\frac{dC_k}{dV_e} = \frac{\sum_1^{n_r} (\alpha_{kj} r_j)}{F_e} - \frac{C_k}{F_e} \frac{dF_e}{dV_e} \quad (77.10)$$

Equation (77.10) describes the rate of change of concentration  $C$  of species  $k$  with volume down a plug flow reactor as a function of the reaction rates, concentration, and flow. It also reflects the change in molar flow as the reaction proceeds.

A complete *isothermal* plug flow reactor model can readily be constructed using as many Eqs. (77.10) as there are components  $k$ , and as many kinetic models as there are reactions  $j$ . For *nonisothermal* reactors, differential equations that describe the temperature changes down the length of the reactor can be constructed in an analogous fashion, using the molar heat generation for each reaction  $j$  and its corresponding reaction rate  $r_j$  and heat transfer terms appropriate to the reactor type and geometry. For a multitube plug flow reactor with coolant on the outside of the tubes, the equation for reaction temperature (in degrees/volume) is as follows:

$$\frac{dT_r}{dV_e} = \frac{\sum_1^{n_r} (r_j \Delta H_j) - \frac{4U}{D_t} (T_r - T_c)}{F_e \rho_p c_p} \quad (77.11)$$

For coolant temperature,

$$\frac{dT_c}{dV_e} = \frac{\frac{4U}{D_t} (T_r - T_c) (\text{Mode})}{F_c \rho_c c_c} \quad (77.12)$$

Combined model equations like these are simplified in the sense that they do not account for departures from ideality because of nonideal mixing patterns in the case of stirred reactors, radial and axial diffusion effects in the case of tubular catalytic reactors, or the very specialized phenomena in fluidized beds and fixed-bed multiphase reactors. Yet they are surprisingly applicable in many industrial applications—and will certainly be preferred to geometric scaleup in almost all cases.

## 77.2 Protocol for the Rational Design of Chemical Reactors

---

Given the distinctions between kinetics models and reactor models, as well as the characteristics of combined reaction and reactor models, we can now establish a general protocol for rational design that will apply to many types of chemical reactors in industrial situations. The protocol comprises several steps, each of which is discussed in the following sections.

### Step 1: Select the Type of Reactor for the Commercial Process

First, select one or more potentially useful types of reactors for the commercial process. In many instances, the preferred reactor type will be known from past experience with the same or similar reactions. Even so, the scaleup characteristics and requirements for two important types of reaction—batch reactions and solid-catalyzed reactions—merit special attention here. The reader is referred to the large open literature for additional information. Texts by Froment and Bischoff [1979], and Levenspiel [1972] are classic and are particularly recommended.

## Scaleup of Laboratory Batch Reactions

***Plant-Size Batch Reactors.*** Many reactions are conveniently studied in laboratory batch reactors, but batch reactors often are not preferred for full-scale operations, particularly if the reaction is rapid or if the planned plant will be quite large. Plant-size batch reactors are costly to operate, simply because they must be shut down, emptied, and recharged after a fairly short time—typically after only a few hours. This means that each reactor produces chemicals only on a part-time basis. As a consequence, batch reactors are usually preferred only for fairly high-priced specialty chemicals like pharmaceuticals that are produced at fairly low volumes—say, under 50 000 000 pounds per year—so that the required number and size of batch reactors are reasonable.

***Ideal Plug Flow Reactors (PFRs).*** PFRs have the same residence-time distribution as ideal batch reactors—that is, each element of feed is exposed to reaction conditions for exactly the same length of time. They are particularly useful for high-volume, low-priced commodity chemicals, for which the laboratory batch reactor is preferred. If the reaction time is short—say, under an hour—it may be practicable to use some type of large-scale plug flow reactor (PFR) for the plant. A baffled column is a common example. More often than not, however, batch times are at least several hours, and a plug flow continuous reactor would be too large and too costly for full-scale plant use. However, PFRs are routinely used in industry for solid-catalyzed reactions, as discussed later. The difference here is that the catalyst dramatically accelerates the reaction so that large-scale plug flow reactors are quite practicable.

***Single and Multistage CSTRs.*** The single-stage continuous stirred tank reactor (CSTR) is relatively inexpensive and provides good temperature control, but it has a broad residence-time distribution. This means that some of the feed may be under reaction for a very short time and some may be in the reactor for an extended time. Also, concentrations of reactants and products throughout a CSTR will be the same as their exit concentrations, so that the reactions are conducted at minimum reactant concentration and maximum product concentration. This will mean a relatively slow reaction rate with maximum exposure of products to further reaction, which may lead to relatively low production rates and relatively high by-product formation rates.

***Residence-Time Distribution and the Effects of Staging.*** To overcome some of the disadvantages of both the PFR and CSTR reactors for reactions that are ideally carried out by batch in the laboratory, several CSTRs are frequently connected in series. Their residence-time distributions will be intermediate between the very narrow distributions of the batch reactor or PFR and the very broad distributions of the CSTR. Such a multistage reactor may be a good compromise, but it will not operate identically to the laboratory batch reactor.

The effect of staging on a chemical reaction may be inferred from Fig. 77.2, in which a simple sequential reaction of  $A$  going to  $B$  (desired) and then to  $C$  (undesired) is assumed. The figure shows that the batch reactor has the highest conversion of  $A$  and the highest yield of  $B$ , and that the CSTR has the lowest. The three- and five-stage CSTRs are intermediate between the batch and CSTR reactors. In practice, multistage systems of two to five CSTRs are common. Froment and Bischoff [1979], Levenspiel [1972], and others have written extensively on residence-time distribution and its impact on product yields and selectivities. These concepts are important to the successful commercialization of batchwise laboratory reaction technology.

**Figure 77.2** Effects of residence-time distribution.

### Scaleup of Solid-Catalyzed Reactions

Solid catalysts are widely used in the chemical industry in several types of packed-bed reactors, slurry reactors, and fluidized bed reactors. Commercial processes frequently utilize solid-catalyzed gas-phase reactions, but it is not uncommon for them to use both gas and liquid streams, which greatly complicates the hydrodynamics. Reactors for solid-catalyzed reactions are all subject to scaleup problems because of differences in mass- and heat-transport in large-scale equipment and laboratory equipment.

*Packed-bed reactors* are probably used more than any other type for solid-catalyzed reactions. They tend to have residence-time distributions that closely approach plug flow, especially for plant-scale single-phase systems in which the bed length is at least 5 to 10 meters. Their narrow residence-time distribution makes them preferred from the standpoint of being able to control product distribution in systems of sequential reactions. Equations (77.10)–(77.12) are appropriate here.

*Shell-and-tube packed-bed reactors* have excellent heat removal characteristics, particularly if the tube diameters are fairly small—say, one to one-and-a-half inches. A schematic of a typical plant-scale shell-and-tube reactor is shown in Fig. 77.3. Although relatively expensive, such reactors can usually be designed rationally with confidence.

**Figure 77.3** Conceptual shell-and-tube fixed-bed reactor. (Source: Reproduced with permission of the American Institute of Chemical Engineers from Cropley, J. B. 1990. Development of optimal fixed bed catalytic reaction systems. *Chemical Engineering Progress* 86(2): 32–39. American Institute of Chemical Engineers, New York, February 1990. ©1990 AIChE. All rights reserved.)

*Adiabatic packed-bed reactors* are attractive because of their relatively low cost. (At their simplest, they can be little more than an empty tank filled with catalyst pellets.) However, they suffer from the effects of an uncontrolled reaction temperature and tend to drift towards the maximum possible attainable temperature, which usually means that the limiting reactant is completely consumed or that equilibrium has been reached. This is a desirable property for some reactions (e.g., hydrogenations), but usually the chemical selectivity suffers as a result. Unwanted

by-products may result, even in hydrogenation systems. The adiabatic reactor usually is not recommended where temperature control is important.

*Multiphase packed-bed reactors* (e.g., trickle beds) are widely used, but the transport of reactants and products between the flowing gas and liquid and the solid catalyst is a major uncertainty. A lot of work remains to be done before the rational design of these reactors can be undertaken with confidence. Instead, back-and-forth experimentation and mathematical analysis of the hydrodynamics is necessary. Suffice it to note here that the transport characteristics of multiphase reactors are different in each of the several hydrodynamic regimes that may be experienced (e.g., trickle flow, bubbling flow, pulsing flow, slug flow, mist flow). A priori calculations using relationships from the open literature can often predict whether reaction kinetics or mass transfer will limit the reactor's performance, and the preliminary design sometimes can be developed rationally thereafter. Pilot-scale experimental verification of the performance of the final design in the *same hydrodynamic region* as the plant reactor is nonetheless essential to avoid surprises. There is an abundant literature on this type of reactor, and the excellent text by Ramachandran and Chaudhari [1983] is a good place to obtain an introduction to this complex technology.

*Fluidized-bed reactors* are widely used in fluidized catalytic cracking, the manufacture of polyethylene and polypropylene, the manufacture of silicones from silicon, and some other commercial reactions. The fluid and solid dynamics of these systems are extremely complex, and available models are best described as learning models, rather than predictive models for reaction system design. Scaleup is typically done incrementally in a series of pilot-plant reactors. Despite the well-known advantages of these systems for some purposes (excellent temperature control, absence of diffusional and transport restrictions), the decision to use fluidized systems for new applications must not be taken lightly. Although the solid phase may usually be assumed to be well mixed, the residence-time distribution of the fluid phase is complex and largely unpredictable. It follows that the performance of a scaled-up reactor is also largely unpredictable if the fluid-phase residence-time distribution is important.

It is worth noting that, with few exceptions, all successful commercial fluidized bed reaction systems involve a solid phase that is always in some kind of rapid transition. Fluidized catalytic-cracking catalyst becomes coked and inactive in only 3 to 5 seconds and is continuously removed from the fluidized riser reactor and regenerated by burning in dilute oxygen. The solid phase is in fact the product polyolefin in fluidized systems like Union Carbide's Unipol™ polyolefins process. Dimethyldichloro silane (an intermediate in the manufacture of silicone oils and other products) is manufactured by reacting silicon metal and methyl chloride in a fluidized-bed reactor. Here, the silicon reactant is in the form of a fine metal powder that is continually consumed by the reaction and that comprises the solid phase in the reactor. An exception to the above observation is the Badger process for the manufacture of phthalic anhydride in a fluidized-bed reactor, in which the solid is a catalyst that is not undergoing any rapid change. It is carried out in a fluidized bed because the temperature control is important to the process.

The technology of fluidization has been studied in depth since before World War II and continues to be studied still because of its importance in those industries that depend upon it. AIChE has published several volumes on fluidization in its symposium series, and more appear

periodically. Some excellent texts exist on fluidization phenomena; that by Kunii and Levenspiel [1969] is considered a classic.

*Slurry reactors* are attractive for many gas-liquid systems that are catalyzed by solid catalysts, but their design is nearly as complicated as for fluidized-bed systems. There is an extensive open literature on this type of reactor. The Air Products Company has published a number of reports on work done under contract for the U.S. Department of Energy and has a large pilot plant at LaPorte, Texas, for the manufacture of methanol and higher alcohols from CO and hydrogen. These reports and the text on multiphase reactors by Ramachandran and Chaudhari [10] are recommended.

## Step 2: Design the Laboratory to Generate Reaction Kinetics Data

The second step in the protocol for rational design is to design the laboratory reaction system specifically to generate kinetics rate data. By now it should be clear that the kinetic model is the link between the laboratory operations and the large-scale plant design. The experimental reactor for kinetics studies will ordinarily not look at all like the final plant reactor. Rather, it will be designed to obtain the kinetic data necessary for kinetic model development. Three primary types of laboratory reactor are suitable for design-quality kinetics studies:

- The batch reactor
- The long-tube reactor with sample points along its length
- The continuous stirred tank reactor, or CSTR

The following paragraphs discuss each of these types, with the emphasis upon what kinds of reactions are suitable for each and any special considerations that may apply.

*Laboratory batch reactors* are found in virtually limitless variety in most industrial chemical laboratories. For kinetics studies it is imperative that chemical analyses be obtained at several times during the reaction period. This sometimes poses problems if the reaction starts before the desired reaction temperature has been reached or if the reaction proceeds so quickly that multiple samples are not practical. Likewise, the loss of reacting volume due to sampling may be important, particularly if a solid catalyst is involved. Both of these problems are best handled during mathematical analysis of the data by forcing the simulated time-temperature and time-reacting volume profiles to be the same as the observed ones.

Batch laboratory reactors are suitable for either uncatalyzed or catalyzed liquid-phase or gas-liquid reactions. In special situations they may be useful for gas-phase reactions as well. They are especially useful for slurry-catalyzed reactions, but they can also be used with pelleted catalysts, provided that provision is made to retain the pellets in a basket or container through which the fluid passes. Both the Berty reactor [see Fig. 77.4 and (Berty, 1974)] and the Carberry rotating basket reactor [Levenspiel, 1972] have been widely used for batchwise kinetic studies of catalytic reactions, although their best use is probably in continuous gas-phase kinetics studies.

**Figure 77.4** The Berty reactor for experimental catalyst testing and kinetics. (Source: Reproduced with permission of the American Institute of Chemical Engineers from Cropley, J. B. 1990. Development of optimal fixed bed catalytic reaction systems. *Chemical Engineering Progress* 86(2): 32–39. American

*Long-tube reactors* for kinetics studies will typically be of a length to promote both plug flow characteristics and good mass and heat transfer so that these physical processes do not mask the chemical reaction rates. Tube length per se is not critical, although it is highly desirable that the length-to-diameter ratio be at least 100:1 to avoid the effects of axial mixing and departure from plug flow behavior. Tube diameter is not particularly important, but should be small enough to ensure good heat transfer. If solid-catalyst pellets are to be used, the tube diameter should be no more than four or five pellet diameters to avoid radial temperature gradients. It is important that provision be made for samples to be taken at multiple points down the tube length. Reactors like these are particularly well suited for kinetics studies using plant-scale catalyst pellets and for the

study of the kinetics of sequential by-product formation, in which the desired product reacts to form unwanted by-products.

Perhaps the most difficult requirement from the standpoint of experimental reactor design is to provide for multiple sampling points down the length of the tube. It is relatively easy to make such a reactor using lengths of stainless steel tubing connected by tubing tees, which can then be used simultaneously as sample taps and for the insertion of thermocouples. Tubing diameter will typically be between 0.25 and 0.50 inches, and the length will be five to six feet. Sample taps at 12-inch intervals will provide good composition and temperature profiles. Excellent temperature control can be attained in such a reactor if it is immersed in a thermostated heat transfer fluid or fluidized sand-bath heater.

*Continuous stirred tank reactors (CSTRs)* are ideally suited for kinetics studies for many types of reactions, owing largely to the ease with which reaction rates can be measured directly. Kinetics models are readily developed from CSTR data, as discussed by Cropley [1978]. The Berty and Carberry reactors cited previously are especially useful for continuous studies of catalytic kinetics, using real catalyst pellets. There is an abundant literature on their use; Cropley [1990] describes an overall strategy for their use in catalytic reactor design.

### Step 3: Use Statistically-Valid Experimental Programs and Models

The third element of the protocol is to utilize statistically valid experimental programs and data analysis for kinetic model development. Usually, kinetic data should be generated from statistically designed experimental programs, such as the factorial or central composite design, for which an abundant literature is available. The writings of Hendrix [1979] are recommended. Cropley [1978] describes the heuristic development of both exponential and hyperbolic kinetic models from a statistically designed data set. Table I from that article is an example of a central composite statistical design for the study of the kinetics of a fictitious catalytic reaction (the oxidation of Dammitol to Valualdehyde). The experimental reactor was assumed to be a CSTR like the Berty reactor, which permitted kinetic rates to be observed directly, as in Eq. (77.7). The synthetic data in that table were developed from the following "true" model, with the incorporation of 20% normally distributed random error [reproduced with permission of the American Chemical Society from (Cropley, 1978)].

$$r_{\text{Val}} = \frac{4.67(10^{11})e^{-20000/RT} (P_{\text{O}_2})^{0.5} (P_{\text{Dam}})^{1.0}}{1 + 5.52(10^{-4})e^{5000/RT} (P_{\text{O}_2})^{0.5} + 7.64(10^{-4})e^{5000/RT} (P_{\text{Val}})^2} \text{ Gmols/Kgcat/H}$$

(77.13)

If a CSTR is used as the experimental reactor, the experimental design should include the independent control of any product species that might influence the reaction rates to avoid systematic bias in the kinetic parameters, as discussed by Cropley [1987].

In the heuristic study cited above, log-linear multiple regression was used for the development of exponential models, and the Nelder-Mead nonlinear search algorithm [Nelder and Mead,

1965] was used for estimation of the nonlinear parameters in the hyperbolic models. (Although Nelder-Mead tends to converge more slowly than some other algorithms, it is robust, stable, and reliable for nonlinear estimation and optimization studies.)

## **Step 4: Develop Computer Programs for Reactor Simulation and Design**

The fourth element of the protocol is to develop computer programs for reactor simulation and design. The typical reaction system design model will comprise several dozen differential equations and a number of nonlinear constraints as well. Consider very carefully just how complex the final models should be. The determination of the true economic optimum may require that the reactor be simulated iteratively many thousands of times, and the model at this point should be no more complex than necessary in order to minimize computer time. Therefore, simulation models for reactor design and optimization should in most cases be based primarily upon the kind of simple idealized reactors represented by Eqs. (77.3)–(77.12), as discussed earlier. Even so, simulation models can become unwieldy. For example, a five-stage CSTR model for a system of four chemical components and temperature will comprise 25 nonlinear differential equations similar to Eq. (77.8). Any of a number of numerical integration techniques may be used for the solution of the differential equations; the fourth-order Runge-Kutta algorithm is perhaps the most common.

## **Step 5: Develop the Economically Optimum Reactor Design**

The fifth protocol for rational design is to develop economically optimum reactor designs. The potentially useful reactor types should be compared to one another at their individual economic optimum design and operating conditions. Arrive at these for each type by varying the simulated reactor size and geometry (e.g., diameter, length and number of tubes, or agitator horsepower and vessel diameter and height) and operating conditions (like pressure, flow rate, reactant concentration, coolant temperature, and so on). A suitable optimization procedure, such as the Nelder-Mead algorithm cited previously [Nelder and Mead, 1965], should be used.

### **The Objective Function for Optimization**

The design process will include the computation of objective economic or reactor performance criteria for the comparison of optimized design alternatives. This objective function must be reasonably accurate, yet simple enough to be evaluated easily and quickly for each iteration. It is convenient and quite accurate to use simple linear relationships for optimization criteria like that in Fig. 77.5, which illustrates the dependence of incremental product cost on cycle gas flow rate and catalyst bed pressure drop for a hypothetical process. Several similar relationships can comprise an easily used objective function for optimization. Relationships like this can be developed easily from detailed economic analyses of a small number of base case designs. Their development was discussed by Cropley [1990].

**Figure 77.5** Elements of product cost. (Source: Reproduced with permission of the American Institute of Chemical Engineers from Cropley, J. B. 1990. Development of optimal fixed bed catalytic reaction systems. *Chemical Engineering Progress* 86(2): 32–39. American Institute of Chemical Engineers, New York, February 1990. ©1990 AIChE. All rights reserved.)

### Explicit and Implicit Constraints

The optimization package will normally utilize both explicit and implicit constraints to relate the reactor to the rest of the process. In a typical design, for example, reactor inlet pressure and reactor gas flow rate might be *explicitly* constrained to reasonable ranges. Likewise, the maximum reactor temperature might be *implicitly* constrained not to exceed a stipulated maximum. Constraints like these are at the very heart of the optimization process. At the same time, their formulation is both esoteric and beyond the scope of this article, and they are not extensively treated in the open literature. It is recommended that an optimization or numerical analysis specialist be consulted in their development.

## Step 6: Validate the Design in a Pilot Plant Reactor

The final step in the protocol for rational design is to validate the overall optimum design by operation of a pilot reactor system. This is the *only time* that scaleup, per se, will be considered in the design. Here again, this may not necessarily involve a pilot reactor that is geometrically similar to the final plant design, although it may be in some cases. It will be important to design the pilot reactor to be able to confirm the predicted reaction yields and selectivities under design conditions. It is vital that all important recycle streams be incorporated into the pilot plant system—which will then be, to the extent possible, a scaled-down version of the integrated commercial process. Typically, recycle streams include previously unreacted raw materials, by-products that can be reverted to useful product, or potential pollutants that can simply be destroyed by further reaction in the reactor. But trace components and minor species can build up in recycle systems to many times their single-pass concentrations, and they may have adverse effects on catalyst life, equilibrium conversion, crude product quality, and so on. It is important that the effects of recycled species be incorporated into the kinetics model for operational monitoring and control. Unanticipated effects of recycle streams probably account for a significant fraction of scaleup problems in commercial systems.

Finally, please note that this chapter has not discussed the *size* of the pilot plant reactor—size per se really is not an issue. What *is* important is that it function in such a way as to test the rational design before it is built. More discussion of process optimization and validation can be found in Cropley [1990].

## Nomenclature

### Uppercase Symbols

$A, B$	Reactants
$C_k$	Concentration of $k$ th chemical component, in mols/volume units
$D_t$	Tube diameter, in linear units
Dam	Fictitious component Dammitol
$F_e, F_c$	Flow rate of process fluid ( $e$ ) or of coolant ( $c$ ) through the volume element, in volume/time units
$\Delta H_j$	Heat of reaction of $j$ th reaction in heat/mol units
$K_{oj}, E_{aj}$	Arrhenius kinetic parameters for reaction $j$
$K_{Aj},$ $K_{Bj},$ $K_{Pkj}$	Kinetic parameters associated with reactants $A$ and $B$ and products $P_k$ for reaction $j$
Mode	(-1) if coolant flows countercurrent to process stream flow (+1) if flows are cocurrent (0) if coolant is isothermal (infinite flow, boiling, etc.)

$P_k$	Reaction products
$R$	Gas constant, typically 1.987 cal/Gmol/K for kinetics models
$T_r, T_c$	Reaction and coolant temperature, respectively
$U$	Overall heat transfer coefficient, in heat/area/time/temperature units
Val	Fictitious component Valualdehyde
$V_e$	An element of volume of any reactor
$W_c$	Weight of catalyst in the reactor, in weight units

## Lowercase and Greek Symbols

$\alpha_{kj}$	Stoichiometric coefficient for species $k$ in reaction $j$
$c_c$	Heat Capacity of coolant stream, in heat/mass/temperature units
$c_p$	Heat capacity of flowing process stream, in heat/mass/temperature units
$n_c$	Total number of products $k$ in the kinetic model
$n_r$	Number of reactions $j$ in the kinetic model
$n_t$	Number of tubes in a tubular reactor
$\rho_p, \rho_c$	Density of process stream ( $p$ ) or coolant ( $c$ ), in mass/volume units
$r$	Kinetic reaction rate, mols/volume/time (or mols/wt. catalyst/time for catalytic reactions)
$t$	Time, in units consistent with $F, r, U$

## Defining Terms

**Chemical reaction:** The chemical transformation of one or more reactant species into one or more chemical products, usually with the evolution or absorption of heat.

**Chemical reactor:** The vessel in which a chemical reaction is conducted.

**Continuous stirred tank reactor:** A well-mixed continuous reactor, characterized by a broad residence time distribution.

**Conversion:** The fraction of a feed component that undergoes chemical transformation in the reactor.

**Plug flow reactor:** A type of reactor in which all entering elements of fluid have the same residence time. The residence time distribution is thus extremely narrow.

**Residence time:** The amount of time that a reactive mixture spends in a chemical reactor.

**Residence-time distribution (RTD):** The spread of residence times that different elements entering a reactor spend in it. RTD is one of the distinguishing characteristics of different reactor types.

**Selectivity:** The fraction of all of a feed component that is converted to form a specified product.

**Yield:** The fraction of all of a feed component entering a reactor that is converted to a specified product. Yield = (Selectivity)(Conversion).

Harr, M. E. "Geotechnical"  
*The Engineering Handbook*.  
Ed. Richard C. Dorf  
Boca Raton: CRC Press LLC, 2000

This tunnel-boring machine (TBM) was one of the largest built to bore the 24 miles (38 km) under the English Channel for the Eurotunnel project. Today the Eurotunnel is a massive transportation system which links Britain and France.

This TBM is 28.17 ft (8.78 m) in diameter and weighs 1575 tonnes. The teeth of the TBM's revolving cutting heads are made of a very hard material called tungsten carbide. This allowed the TBM to cut its way through the chalk marl at a rate of up to 0.62 miles (1 km) per month. At full speed the TBM was pumping out 2400 tonnes of spoil per hour on the British side of the tunnel. A total of 8 million cubic meters of spoil was removed and disposed of. It required incredible geotechnical ingenuity to build the Eurotunnel, which now transports thousands of vehicles and tens of thousands of people each day. (Courtesy of ©Eurotunnel 1994. Weight–Volume Relationship Hydraulic Conductivity Effective Stress Consolidation Shear Strength

A SOIL BODY, IN ITS GENERAL FORM, is a complex conglomeration of discrete particles, in a compact array of varying shapes and orientations. These may range in magnitude from the microscopic elements of clay to the macroscopic boulders of a rock fill. Soil mechanics deals with the action and reaction of soil bodies when acted upon by energy sources.

Today the world is in the midst of a scientific revolution that requires new types of structures for which past experience is either inadequate or absent. Earth structures of unprecedented height and size are becoming commonplace engineering problems. Confronted with these problems, engineers are finding it necessary to rely on rational, scientific methods of analysis with correspondingly less emphasis on empirical rules.

In an engineering handbook it is difficult to present the subtle details in such a specialized area as soil mechanics. However, Dr. Das has covered some of the fundamentals quite well.

78.4 Consolidation

Time Rate of Consolidation

78.5 Shear Strength

**Braja M. Das**

*California State University, Sacramento*

Soil mechanics is the branch of science that deals with the study of the physical properties of soil and the behavior of soil masses while being subjected to various types of forces. Soils engineering is the application of the principles of soil mechanics to practical problems.

## 78.1 Weight- Volume Relationship

---

The three phases of a soil sample are solid, water, and air, as shown in [Fig. 78.1](#). Thus, a given soil sample of weight  $W$  can be expressed as

$$W = W_s + W_w + W_a \quad (78.1)$$

where  $W_s$  is the weight of the soil solids,  $W_w$  is the weight of the water, and  $W_a$  is the weight of air. Assuming that  $W_a \approx 0$ ,

$$W = W_s + W_w \quad (78.2)$$

As shown in [Fig. 78.1](#), the total volume of the soil sample is  $V$ . The volumes occupied by solid, water, and air are, respectively,  $V_s$ ,  $V_w$ , and  $V_a$ . Thus, the volume of void,  $V_v$ , is

$$V_v = V_w + V_a \quad (78.3)$$

Common weight and volume relationships are given in [Table 78.1](#).

**Figure 78.1** Weight-volume relationship.

**Table 78.1** Weight-Volume Relationships

Volume Relationships	
Void ratio, $e = \frac{V_v}{V_s} = \frac{n}{1 - n}$	
Porosity, $n = \frac{V_v}{V} = \frac{e}{1 + e}$	
Degree of saturation, $S = \frac{V_w}{V_v} = \frac{wG_s}{e}$	
Weight Relationships	
Moisture content, $w = \frac{W_w}{W_s}$	
Moist unit weight, $\gamma = \frac{W}{V}$	
$\gamma = \frac{(1_w)G_s\gamma_w}{1 + e}$	
$\gamma = \frac{(G_s + Se)\gamma_w}{1 + e}$	
$\gamma = G_s\gamma_w(1 - n)(1 + w)$	
Dry unit weight, $\gamma_d = \frac{\gamma}{1 + w}$	
$\gamma_d = \frac{G_s\gamma_w}{1 + e}$	
$\gamma_d = G_s\gamma_w(1 - n)$	
$\gamma_d = \frac{G_s\gamma_w}{1 + wG_s/S}$	

$$\begin{aligned}\text{Saturated unit weight, } \gamma_{\text{sat}} &= \frac{(G_s + e)\gamma_w}{1 + e} \\ \gamma_{\text{sat}} &= [(1 - n)G_s + n]\gamma_w \\ \gamma_{\text{sat}} &= \gamma_d + n\gamma_w\end{aligned}$$

$G_s$  = Specific gravity of soil solids

$\gamma_w$  = Unit weight of water (62.4 lb/ft<sup>3</sup>; 9.81 kN/m<sup>3</sup>)

## 78.2 Hydraulic Conductivity

In 1856, Darcy published a relationship for the discharge velocity of water through saturated soil (usually referred to as Darcy's law), according to which

$$v = ki \quad (78.4)$$

where  $v$  is the discharge velocity,  $i$  is the **hydraulic gradient**, and  $k$  is the *coefficient of permeability* or *hydraulic conductivity*. The unit of hydraulic conductivity is  $LT^{-1}$ . See [Table 78.2](#).

**Table 78.2** Typical Range of Hydraulic Conductivity

Soil Type	$k$ (cm/s)	Relative Hydraulic Conductivity
Clean gravel	$10^2 - 10^0$	High
Coarse sand	$10^0 - 10^{-2}$	High to medium
Fine sand	$10^{-2} - 10^{-3}$	Medium
Silt	$10^{-3} - 10^{-5}$	Low
Clay	Less than $10^{-6}$	Very low

One of the most well-known relationships for hydraulic conductivity is the Kozeny-Carman equation, which is of the form

$$k = \frac{1}{\eta} \frac{1}{s_p t^2 s_s^2} \frac{n^3}{(1 - n)^2} \quad (78.5)$$

where  $\eta$  is viscosity,  $s_p$  is pore shape factor,  $t$  is tortuosity,  $s_s$  is specific surface per unit volume, and  $n$  is porosity. [Table 78.2](#) gives the general magnitude of the hydraulic conductivity.

## 78.3 Effective Stress

In saturated soil the **total stress** in a given soil mass can be divided into two parts—a part that is carried by water present in continuous void spaces, which is called *pore water pressure*, and the remainder that is carried by the soil solids at their points of contact, which is called the *effective*

stress. Or

$$\sigma = \sigma' + u \quad (78.6)$$

where  $\sigma$  is total stress,  $\sigma'$  is effective stress, and  $u$  is pore water pressure.

In partially saturated soil, water in the void space is not continuous, and the soil is a three-phase system—that is, solid, pore water, and pore air. In that case,

$$\sigma = \sigma' + u_a - \chi(u_a - u_w) \quad (78.7)$$

where  $u_a$  is pore air pressure and  $u_w$  is pore water pressure.

## 78.4 Consolidation

---

Consolidation is the *time-dependent* volume change of saturated clayey soil due to the expulsion of water occupying the void spaces. When a load is applied to a saturated compressible soil mass, the increase in stress is initially carried by the water in the void spaces (that is, increase in pore water pressure) due to its relative incompressibility. With time, the water is squeezed out and the stress increase is gradually transferred to effective stress. The effective stress increase results in consolidation settlement of the clayey soil layer(s).

A clay is said to be *normally consolidated* when the present *effective* overburden pressure ( $p_o$ ) is the maximum pressure to which the soil has been subjected in the past. When the present effective overburden pressure of a clay is less than that which it experienced in the past, it is referred to as an *overconsolidated* clay. The maximum past effective overburden pressure is called the *preconsolidation pressure* ( $p_c$ ).

The *primary consolidation* settlement ( $S$ ) of a saturated clay layer of thickness  $H$  (Fig. 78.2) due to a load application can be calculated by the following relationships. In Fig. 78.2, for the clay layer,  $p_o$  is the effective overburden pressure before the load application,  $\Delta p$  is the increase in stress at the middle of the clay layer due to the load application, and  $e_o$  is the initial void ratio. For normally consolidated clay ( $p_o = p_c$ ),

$$S = \frac{C_c H}{1 + e_o} \log \left( \frac{p_o + \Delta p}{p_o} \right) \quad (78.8)$$

For overconsolidated clay with  $p_o + \Delta p \leq p_c$ ,

$$S = \frac{C_s H}{1 + e_o} \log \left( \frac{p_o + \Delta p}{p_o} \right) \quad (78.9)$$

For overconsolidated clay with  $p_o < p_c < p_o + \Delta p$ ,

$$S = \frac{C_s H}{1 + e_o} \log \left( \frac{p_c}{p_o} \right) + \frac{C_c H}{1 + e_o} \log \left( \frac{p_o + \Delta p}{p_c} \right) \quad (78.10)$$

where  $C_c$  is the compression index and  $C_s$  is the swelling index. The magnitudes of  $C_c$  and  $C_s$  can be obtained from laboratory consolidation tests. In the absence of the laboratory results the following empirical approximations can be used. From Skempton [1944],

$$C_c = 0.009(LL - 10) \quad (78.11)$$

where LL is liquid limit, in percent. From Nishida [1956],

$$C_c = 1.15(e_o - 0.27) \quad (78.12)$$

And, finally, from Rendon-Herrero [1980],

$$C_c = 0.156e_o + 0.0107 \quad (78.13)$$

$$C_s \approx 0.1-0.2 C_c \quad (78.14)$$

**Figure 78.2** Consolidation settlement of a clay layer.

## Time Rate of Consolidation

The average degree of consolidation ( $U$ ) of a clay layer due to an applied load can be defined as

$$U = \frac{S_t}{S} \quad (78.15)$$

where  $S_t$  is primary consolidation settlement after time  $t$  of load application, and  $S$  is the ultimate consolidation settlement. The degree of consolidation is a function of time factor  $T_v$ , which is a nondimensional quantity. Or

$$U = f(T_v) \quad (78.16)$$

$$T_v = \frac{C_v t}{H_{dr}^2} \quad (78.17)$$

where  $C_v$  is the **coefficient of consolidation**,  $t$  is the time after load application, and  $H_{dr}$  is the length of the smallest drainage path. [Figure 78.3](#) shows the definitions of  $H_{dr}$  and the initial excess pore water pressure ( $u_o$ ) distribution for seven possible cases. The variations of  $U$  with  $T_v$  for these cases are shown in [Table 78.3](#).

**Figure 78.3** Definition of  $H_{dr}$ .

**Table 78.3** Variation of Average Degree of Consolidation With Time Factor

Average Degree of Consolidation, $U$ (%)	Time factor, $T_v$		
	Case I, II, III	Case IV, V	Case VI, VII
0	0	0	0
10	0.008	0.003	0.004 7
20	0.031	0.009	0.100
30	0.071	0.025	0.158
40	0.126	0.048	0.221
50	0.197	0.092	0.294
60	0.287	0.160	0.383
70	0.403	0.271	0.500
80	0.567	0.440	0.665
90	0.848	0.720	0.940
100	$\infty$	$\infty$	$\infty$

## 78.5 Shear Strength

Shear strength of a soil mass is the internal resistance per unit area that the soil mass can offer to resist failure and sliding along any plane inside it. For most soil mechanics problems, it is sufficient to approximate the shear strength by the *Mohr-Coulomb failure criteria*, or

$$s = c + \sigma' \tan \phi \quad (78.18)$$

where  $c$  is the cohesion,  $\sigma'$  is the effective normal stress, and  $\phi$  is the drained friction angle. For normally consolidated clays and sands,  $c \approx 0$ .

Figure 78.4 shows an approximate correlation for  $\phi$  with porosity and **relative density** for coarse-grained soils. Table 78.4 gives typical values of  $\phi$  for sand and silt.

**Figure 78.4** Approximate correlation for  $\phi$  of coarse-grained soil with porosity and relative density. Note: GW—well-graded gravel, GP—poorly graded gravel, SW—well-graded sand, SP—poorly graded sand, SM—silty sand, ML—silt with low plasticity. (After Department of the Navy, 1971.)

**Table 78.4** Typical Values of  $\phi$  for Sand and Silt

Soil	$\phi$ (deg)
Sand	
Loose	28–35
Medium	30–40
Dense	35–45
Silt	25–35

## Defining Terms

**Coefficient of consolidation:** The coefficient of consolidation is defined by the relationship

$$C_v = \frac{k}{\gamma_w \left( \frac{\Delta e}{\Delta p} \frac{1}{1 + e_o} \right)}$$

where  $\Delta e$  is the change in void ratio due to a pressure increase in  $\Delta p$ .

**Hydraulic gradient:** The ratio of the loss of head to the length of flow over which the loss occurred.

**Relative density:** Relative density is defined as  $(e_{\max} - e)/(e_{\max} - e_{\min})$ , where  $e_{\max}$  and  $e_{\min}$  are, respectively, the maximum and minimum possible void ratios for a soil, and  $e$  is the in situ void ratio.

**Total stress:** The total stress at a given elevation is the force per unit gross cross-sectional area due to soil solids, water, and surcharge.

This aerial view of the Eurotunnel is located near Folkestone in England. The Eurotunnel, also called the

Channel Tunnel, stretches from the UK under the English Channel to Calais, France. The overall tunnel length is 31.35 miles (50.45 km); 24 miles (38 km) are under the sea. The tunnel lies an average of 148 ft (45 m) below the seabed, with a maximum depth of 246 ft (75 m) below the seabed.

The tunnel carries four types of traffic. At full capacity a shuttle carries 800 passengers, 120 cars, and 12 coaches (which could be replaced by an additional 60 cars). Up to 28 heavy-goods vehicles (HGVs) with a gross weight of 44 tonnes can be carried in a freight shuttle.

At peak times, trains thunder along the tunnel every three minutes at up to 100 mph (160 km/h). Thousands of vehicles and tens of thousands of people pass through the tunnel every day. The tunnel is in operation 24 hours a day, seven days a week, 52 weeks a year in virtually all types of weather. See pages 852 and 853 for additional information on the Eurotunnel. Mathematical Models • Summary

AS TRANSPORTATION IS CONCERNED with the movement of people and goods, it has a far-ranging impact on society. It plays a vital role in a country's economy. In the U.S. transportation makes up about 20% of GDP. Transportation engineering cuts through a broad array of disciplines to deal with planning design, construction, maintenance, and operation of various transportation modes. While it has drawn strong contributions from civil, mechanical, and electrical engineering, social, political, and management sciences are also becoming important areas in influencing the transportation engineering field. With the immense growth of the transportation sector in the 20th century, the environmental aspects are fast becoming the limiting constraint for transportation systems.

This section presents an overview of transportation engineering with emphasis on planning, facility design, operations and environmental impacts, characteristics of various transport modes, and safety. Transportation planning is concerned with meeting system demand in the most cost-effective manner. Through transportation planning, the formulation of optimal transportation policies can be achieved. The design of transportation facilities implements transportation policies, particularly in the supply side of transportation infrastructure development. Facility design must consider the traditional engineering aspects of design, such as geotechnical, structural, and geometric design as well as legal, environmental, and land use concerns. Once completed, operational aspects of transportation facilities must be continually monitored to provide for the safest and most efficient means of travel without causing environmental degradation. The

fundamental principles of highway traffic flow are presented, the understanding of which is essential to guide, advise, and regulate vehicle operators. The aspect of highway safety is emphasized from an impact-crashworthiness point of view in a separate chapter. Because transportation of people and goods uses various modes, another chapter presents a discussion of different subsystems. Modern-day challenges to the transportation system exist in the form of increasing system efficiency to minimize adverse environmental effects and to maintain economic viability. To meet such challenges, the synthesis of traditional modes of transportation with emerging technologies is required. Alternative forms of energy (e.g., electric vehicles) and support mechanisms (e.g., magnetic levitation) can provide meaningful solutions.

This section presents the key elements involved in the planning, design, and operation of a safe and efficient transportation system. The text applies basic laws of engineering to illustrate transportation-related concepts in a manner understandable to a wide range of readers.

# Transportation Planning

---

## 79.1 Basic Framework of Transportation Planning

Inventory of Facilities • Collect and Maintain Socioeconomic and Land Use Data • Define Goals and Objectives • Identify System Deficiencies or Opportunities • Develop and Analyze Alternatives • Evaluate Alternatives • Implement Plan • Monitor System Performance

## 79.2 Transportation Modeling

**Michael D. Meyer**

*Georgia Institute of Technology*

Transportation planning is the process of producing the information necessary to determine the most cost-effective strategy for improving the performance of the transportation system.

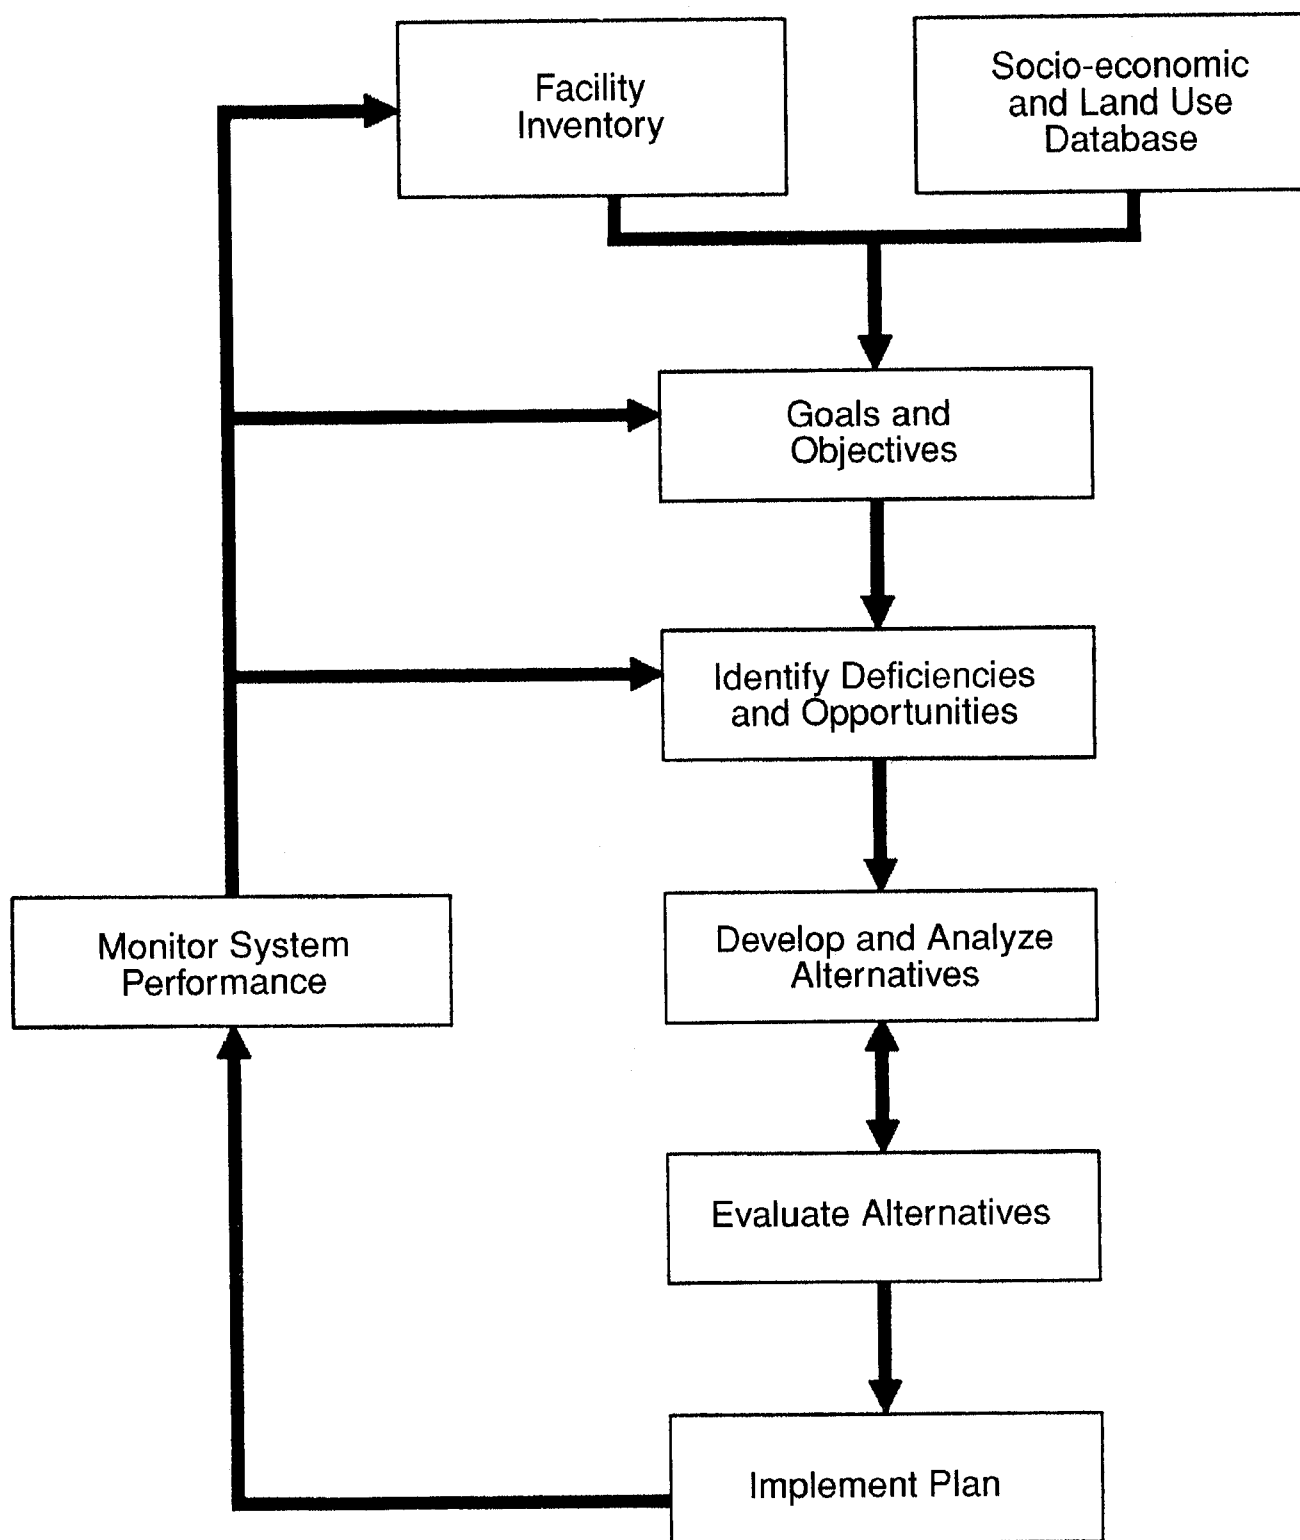

Transportation planning can occur on different scales of analysis—at the national, multistate, state, metropolitan, subarea or corridor, and local levels. At each level the planning methodologies used, databases developed, and information produced are often heavily influenced by government regulations. No matter what modeling approaches are used in transportation planning, a fundamental concept that influences the way transportation demand is estimated is called **derived demand**. Derived demand means that a trip is taken to accomplish some activity at the destination, and that the trip itself is simply a means of reaching this activity. Transportation planning must therefore relate trip making to the types of activities that occur in a study area and also to the characteristics of the trip maker that will influence the way these trips are made. This end is reached by combining similar uses of land into a land use category that can then be used in transportation planning to estimate how many trips are attracted to each type of land use (e.g., the number of trips to schools, shopping centers, residential units, office complexes, etc.).

## 79.1 Basic Framework of Transportation Planning

---

The basic framework for transportation planning at any scale of application is shown in [Fig. 79.1](#). The steps shown in this framework are discussed in the sections that follow.

**Figure 79.1** Basic elements of transportation planning.

## Inventory of Facilities

Knowing what a **transportation network** consists of and the condition and performance of these facilities is an important starting point for transportation planning. Transportation investment is usually aimed at upgrading the physical *condition* of a facility (e.g., repaving a road or building a new bridge) or at improving its *performance* (e.g., providing new person-carrying capacity by providing preferential treatment for high-occupancy vehicles or building a new road to serve existing demand).

## Collect and Maintain Socioeconomic and Land Use Data

Given the concept of derived demand, a basic starting point for planning is characterizing the variables that will influence this demand. Current land use is readily attained through land use inventories. The methods of estimating future land use range from trends analysis to large-scale land use models that predict household and employment sites decades into the future.

Socioeconomic characteristics often include the level of income, number of members in the household, number of autos in the household, number of children, age of the head of household, and highest level of education achieved.

## Define Goals and Objectives

*Goals* are generalized statements that indicate the desired ultimate achievement of a transportation plan. *Objectives* are more specific statements that indicate the means by which these goals will be achieved. The identification of goals and objectives is critical in that they define the evaluation criteria that will be used later in the planning process to assess the relative impacts of alternative projects and strategies. These criteria are often called *measures of effectiveness*.

## Identify System Deficiencies or Opportunities

The methods used to identify transportation deficiencies and opportunities can vary widely. In some cases large-scale transportation network models are used to estimate the future traffic volumes and then to compare them to the capacity of the road network to handle such volumes. This volume-to-capacity (V/C) ratio has served as the major means of identifying the location of system deficiencies. However, other *performance measures* can also be used in the transportation planning process that are much broader than the traditional V/C ratios, such as level of accessibility to economic activities, average travel times, and so on.

## Develop and Analyze Alternatives

Various types of strategies can surface from the planning process: (1) those focused on improvements to highways—for example, adding new lanes, improving traffic control through signals or signing, or improving traffic flow through channelization; and (2) other strategies, such as reducing the demand for transportation through flexible working hours, increasing average vehicle occupancy through such measures as carpools or transit use, or raising the "price" of travel

through the use of tolls. More recently, the application of advanced transportation technologies to the operation of a road system, known as *intelligent transportation systems*, has become an important type of strategy in many cities.

## Evaluate Alternatives

Evaluation brings together all of the information gathered on individual alternatives and provides a framework to compare the relative worth of the alternatives. This evaluation process most often relies on the various measures of effectiveness that relate to the goals and objectives defined at the beginning of the planning process.

## Implement Plan

The major products of the transportation planning process are the *transportation plan* and, at the state and metropolitan levels, the *transportation improvement program (TIP)*, which lists all of the transportation projects that will be implemented over the next few years in the region.

## Monitor System Performance

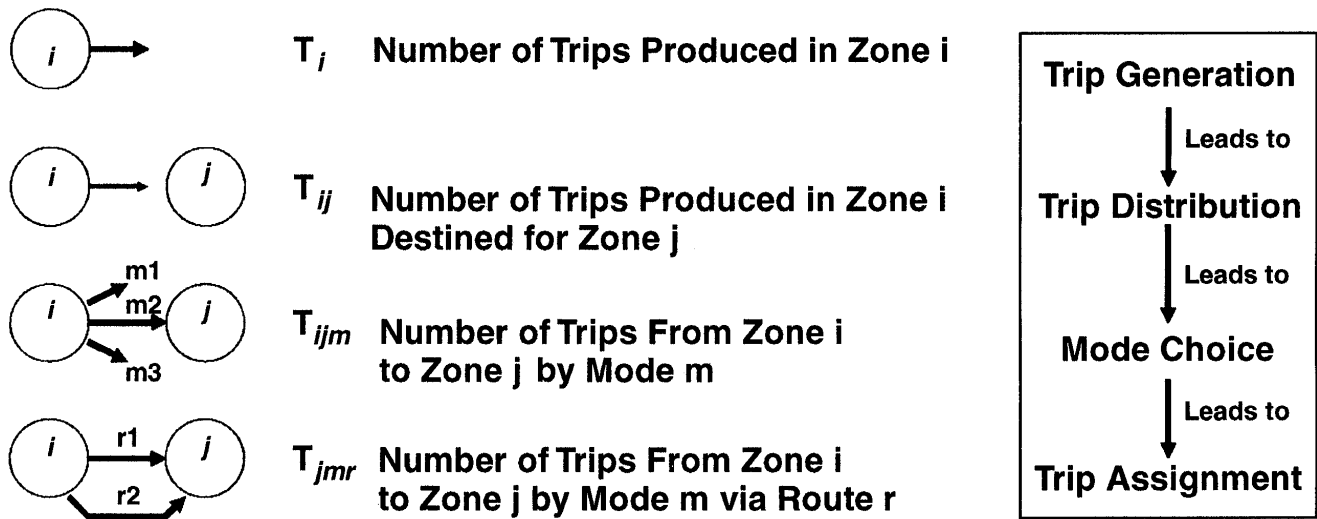

Transportation planning continually examines the performance and condition of the transportation system to identify where improvements can be made. Some means of monitoring system performance is necessary to systematically identify areas where these improvements might occur. This system monitoring has traditionally been based on traffic volumes obtained from traffic counters placed at strategic locations in the network (e.g., increasing traffic volumes indicate congestion).

## 79.2 Transportation Modeling

---

The level of transportation analysis can vary according to the level of complexity and scale of application. In most cases, however, the modeling process consists of four major steps—trip generation, trip distribution, mode split, and trip assignment. Each study area (whether a nation, state, metropolitan area, or neighborhood) is divided into zones of homogeneous characteristics (e.g., similar household incomes) that can then be used as the basic foundation for estimating trips from, or attracted to, that zone. In most cases, transportation planners try to create a **zonal system** by defining zones that are related to other data collection activities (e.g., the U.S. Census tracts). The transportation system is represented in models as a network of *links* and *nodes*. Links represent line-haul facilities, such as roads or transit lines, and nodes represent points of connection, such as intersections. Given the complex nature of transportation systems, the typical transportation network consists of links representing only highly used facilities. The transportation modeling process can thus be represented as shown in [Fig. 79.2](#).

**Figure 79.2** Transportation modeling framework.

*Trip generation* is the process of analytically deriving the number of trips that will be generated from a location or zone based on socioeconomic information of the travelers or, in the case of freight movement, zonal economic characteristics. The trip generation stage also includes predicting the number of trips that will be attracted to each zone in the study area:

Number of trips produced in a zone =  $f$  (Socioeconomic characteristics, land use, transportation mode availability)

Number of trips attracted to a zone =  $f$  (Attractiveness of zone)

There are two approaches for estimating trips generated. The first approach uses *trip rate models*. Based on existing data, trip rates can be calculated that relate trip-making to variables known to influence travel behavior. For an example, see [Table 79.1](#).

**Table 79.1** Cross-Classification Analysis

	Number of People in Households		
	1	2	3+
Low Income	2.4	3.3	4.5
Medium Income	3.5	3.8	4.8
High Income	3.9	4.2	5.4

The other approach is to use *regression models*. Based on existing data, multiple regression equations are estimated relating trip generation to variables found to be significant in travel behavior. For example,

$$\text{Zone estimate: } T_{iz} = 184.2 + 120.6(X1_i) + 34.5(X2_i)$$

$$\text{Household estimate: } T_{ih} = 0.64 + 2.3(X1_{ih}) + 1.5(X2_{ih})$$

$$\text{Zonal attractions: } T_j = 54.2 + 0.23(X3) + 0.43(X4)$$

where

- $T_{iz}$  = Total trips generated in zone  $i$
- $T_{ih}$  = Total trips generated per household in zone  $i$
- $T_j$  = Total trips attracted to zone  $j$
- $X1_i$  = Total number of workers in zone  $i$
- $X2_i$  = Total number of automobiles in zone  $i$
- $X1_{ih}$  = Number of employees per household in zone  $i$
- $X2_{ih}$  = Number of automobiles per household in zone  $i$
- $X3$  = Total number of office employees in zone  $j$
- $X4$  = Total number of retail employees in zone  $j$

*Trip distribution* is the process of estimating the number of trips that originate in each zone in the study area and their corresponding destinations. The result of the trip distribution process is a matrix called a *trip table*, which shows the number of trips originating in each study zone and their corresponding destinations for the time period being examined. The most commonly used method for distributing trips in a zonal system is the gravity model, which is of the following form:

$$T_{ij} = P_i \frac{A_j \times F_{ij} \times K_{ij}}{\sum_j (A_j \times F_{ij} \times K_{ij})}$$

where

- $T_{ij}$  = Number of trips originating in zone  $i$  and destined to zone  $j$
- $P_i$  = Number of trips produced in zone  $i$
- $A_j$  = Level of attractiveness of zone  $j$  (e.g., number of employees)
- $F_{ij}$  = Friction or impedance factor between zones  $i$  and  $j$  (a value usually a function of travel time)
- $K_{ij}$  = Socioeconomic adjustment factors for trips between zones  $i$  and  $j$  (a value that represents variables that influence trip making not accounted for by other variables)

*Mode choice* is the process of estimating the percentage of individuals who will use one mode of transportation versus the others available for a given trip. The basic concept in making this estimation is that each mode of transportation has associated with it some empirically known characteristics that, when combined in a mathematical equation, can define that mode's *utility*. Variables such as travel time, travel cost, modal reliability, and so on are often incorporated into a mode's **utility function**, along with socioeconomic characteristics of the traveler. Freight models use a similar concept in estimating commodity flows by mode. One of the most familiar forms of mode choice models is the logit model, which predicts mode shares based on the following equation:

$$P_{ik} = \frac{e^{U_k}}{\sum_{m=1}^n e^{U_m}}$$

where

- $P_{ik}$  = Probability of individual  $i$  choosing mode  $k$
- $U_k$  = Utility of mode  $k$
- $U_m$  = Utility of mode  $m$
- $n$  = Number of modes available for trip

The utility of each mode is often represented as a linear function of those variables found to influence an individual's choice of mode. For example, a utility function for the automobile mode might be of the form

$$U_a = 6.3 - 0.21(X_1) - 0.43(X_2) - 0.005(X_3)$$

where

- $U_a$  = Utility of automobile
- $X_1$  = Access and egress time when automobile is chosen
- $X_2$  = Line-haul time
- $X_3$  = Travel cost

The utility functions of other modes available for a specific trip would be similarly specified. The probabilities would then be multiplied by the total number of trips to obtain the number of trips made by mode.

*Trip assignment* is the process of estimating the travel flows through a transportation network based on a trip table (which is produced in trip distribution). The basic concept found in all trip assignment models is that travelers choose routes that will minimize travel time—that is, they will choose the shortest path through the network. Link performance functions that relate travel time to number of vehicles on the link (see [Fig. 79.3](#)) are used to iteratively update estimated link travel times so that minimum-path travel times reflect the effect of congestion. Recent research in trip assignment methods has introduced the concept of stochastic assignment, which means that some subset of trip routes will in fact have associated with them some characteristics that attract certain types of travelers, even if the travel time is longer.

**Figure 79.3** Link performance function.

## Defining Terms

**Derived demand:** An assumption that travelers make a trip to accomplish some objective at the destination and that the trip itself is simply a means of reaching this activity.

**Transportation network:** A transportation system is represented in models as a network of *links* and *nodes*. Links represent line-haul facilities, such as roads or transit lines, and nodes represent points of connection, such as intersections. Given the complex nature of transportation systems, the typical transportation network consists of links representing only higher functionally classified facilities, or those links that represent known highly traveled paths.

**Utility function:** A mathematical formulation that assigns a numerical value to the attractiveness of individual modes of transportation based primarily on that mode's characteristics.

**Zonal system:** Each study area (whether a nation, state, metropolitan area, or neighborhood) is divided into zones of homogeneous characteristics (e.g., similar household incomes) that can then be used as the basic foundation for estimating trips from, or attracted to, that zone. In most cases transportation planners try to define zones that are related to other data collection activities (e.g., the U.S. Census tracts).

### Michael D. Meyer

*Georgia Institute of Technology*

The efficient movement of people and goods requires transportation systems and facilities that are designed to provide sufficient capacity for the demands they face in as safe a manner as possible. In addition, in most modern societies, the design of transportation facilities must explicitly minimize harm to the natural and human-made environment while providing for mitigation measures that relate to those impacts that are unavoidable. In many ways the critical challenge to today's designers of transportation projects is successfully designing a facility that minimally harms the environment.

The design of a transportation facility almost always takes place within the context of a much broader **project development process**. This process can vary in complexity with the type of project under design and with the scale of implementation. The importance of the project development process to the designer is that it

- Establishes the key characteristics of the project that must be considered in the design
- Indicates the time frame that will be followed for project design
- Establishes which agencies and groups will be involved in the process and when this involvement will likely occur
- Links the specific elements of the project design with other tasks that must be accomplished

for the project to be constructed

- Satisfies legal requirements for a design process that is open for review and comment
- Indicates the specific products that must be produced by the designers to complete the project design process

In most cases the project development process consists of a well-defined set of tasks that must be accomplished before the next task can occur. These tasks include both technical activities and public involvement activities that are necessary for successful project development.

## **80.1 Components of the Project Development Process**

---

### **Identify Project Need**

A project need can be identified through a formal planning process or from a variety of other sources, including elected officials, agency managers, transportation system users, and citizens. Important in this early portion of project development is an indication of what type of improvement is likely to be initiated. For example, a project could relate to one or more of the following types of improvement strategies:

- *New construction.* A transportation facility constructed at a new location.
- *Major reconstruction.* Addition of new capacity or significant changes to the existing design of a facility, but usually occurring within the area where the current facility is located.
- *Rehabilitation/restoration.* Improvements to a facility usually as it is currently designed and focusing on improving the physical condition of the facility or making minor improvements to enhance safety.
- *Resurfacing.* Providing new pavement surface to a transportation facility that prolongs its useful life.
- *Spot improvements.* Correction of a problem or hazard at an isolated or specific location.

### **Establish Project Limits and Context**

One of the very first steps in the design process is to define the boundaries or limits of the project. This implies establishing how far the project will extend beyond the area being targeted for improvement and the necessary steps to ensure smooth connections to the existing transportation system.

### **Establish Environmental Impact Requirements**

The design of a project will very much be affected by environmental laws or regulations that require design compliance with environmental mandates. These environmental mandates could relate to such things as wetlands, historic properties, use of public park lands, water quality, navigable waterways, fish and wildlife, air quality, noise, and archaeological resources. One of the first steps in project development is to determine whether the likely project impacts are significant

enough to require environmental study.

## **Develop Strategy for Interagency Coordination and Public Involvement**

Depending on the complexity and potential impact of a project, the project designer could spend a great deal of time interacting with agencies having some role in or jurisdictional control over areas directly related to the project. These agencies could have jurisdiction by law (e.g., wetlands) or have special expertise that is important to project design (e.g., historic preservation). In addition to interagency coordination, transportation project development is often subject to requirements for public outreach and/or public hearings.

## **Initiate Project Design and Preliminary Engineering**

Topographic data of the study area and forecasted vehicular volumes expected to use the facility in the design year are used as input into the preliminary design of the horizontal and vertical alignment of the facility, that is, the physical space the facility will occupy once finished. This preliminary engineering step also includes the preparation of initial right-of-way (ROW) plans, which indicate the amount of land that must be available to construct the facility.

## **Project Engineering**

Once preliminary engineering has provided the basic engineering information for the project, the more detailed project design begins. This entails specific layouts of horizontal and vertical geometry, soils/subsurface examination and design, design of utility location, drainage design, more detailed ROW plans, and initial construction drawings. Concurrent with this design process, the environmental process continues with updated information on project changes that might cause additional environmental harm, the initiation of any permitting process that might be needed to construct the project (e.g., environmental agency permission to affect wetlands), and public hearings/meetings to keep the public involved with project development.

## **Final Engineering**

The final engineering step is the culmination of the design process, which basically completes the previous design plans to the greatest level of detail. This step includes finalizing ROW plans, cost estimates, construction plans, utility relocation plans, and any agreements with other agencies or jurisdictions that might be necessary to complete the project. Environmental permits are received and final project review for environmental impacts is completed.

A cross-section view of the three parallel tunnels of the Eurotunnel system. A double-deck passenger shuttle is shown in the rail tunnel on the left. The service tunnel is in the middle, and a freight shuttle is traveling in the rail tunnel on the right.

## EUROTUNNEL DESIGN

---

The Channel Tunnel or Eurotunnel system is not one tunnel, but actually three parallel tunnels. Two of these are one-way rail tunnels. Trains traveling from Britain to France use the northern tunnel, and those traveling from France to Britain use the southern tunnel. The third tunnel is a smaller service tunnel. It allows engineers to travel along the system without stopping shuttle traffic and is used primarily for routine maintenance and for evacuation in case of an emergency.

The three tunnels are connected by cross-passages every 1230 ft (375 m). These cross-passages give engineers access from the service tunnel into the rail tunnels for necessary maintenance work. In addition to the cross-passages, the two rail tunnels are also joined by piston relief ducts. Open valves in these ducts allow the air pushed down the rail tunnel in front of the speeding trains to discharge harmlessly into the other rail tunnel. The valves are closed only during maintenance work. Air pressure within the service tunnel is kept higher than in the rail tunnels. This allows the atmosphere in the service tunnel to remain clear in the unlikely event of smoke being present in the rail tunnels.

There are two huge "crossover caverns" located at about one-third and two-thirds of the total undersea distance within the tunnel. These crossover caverns allow trains to change from one rail tunnel to the other. When one of the tunnels is closed for maintenance or repairs, the other is used as a single-track railway. As these crossovers divide each rail tunnel into three sections, only one-sixth of the entire system needs to be out of service at any time. This prevents the considerable delays that would occur if one entire tunnel had to be closed. Huge sliding doors separate the two tunnels when the crossovers are not in use. (Copyright Eurotunnel 1994/QA Photos. Used with permission.)

This illustrates one of the two crossover caverns within the Eurotunnel system.

---

## 80.2 Basic Concepts of Project Design

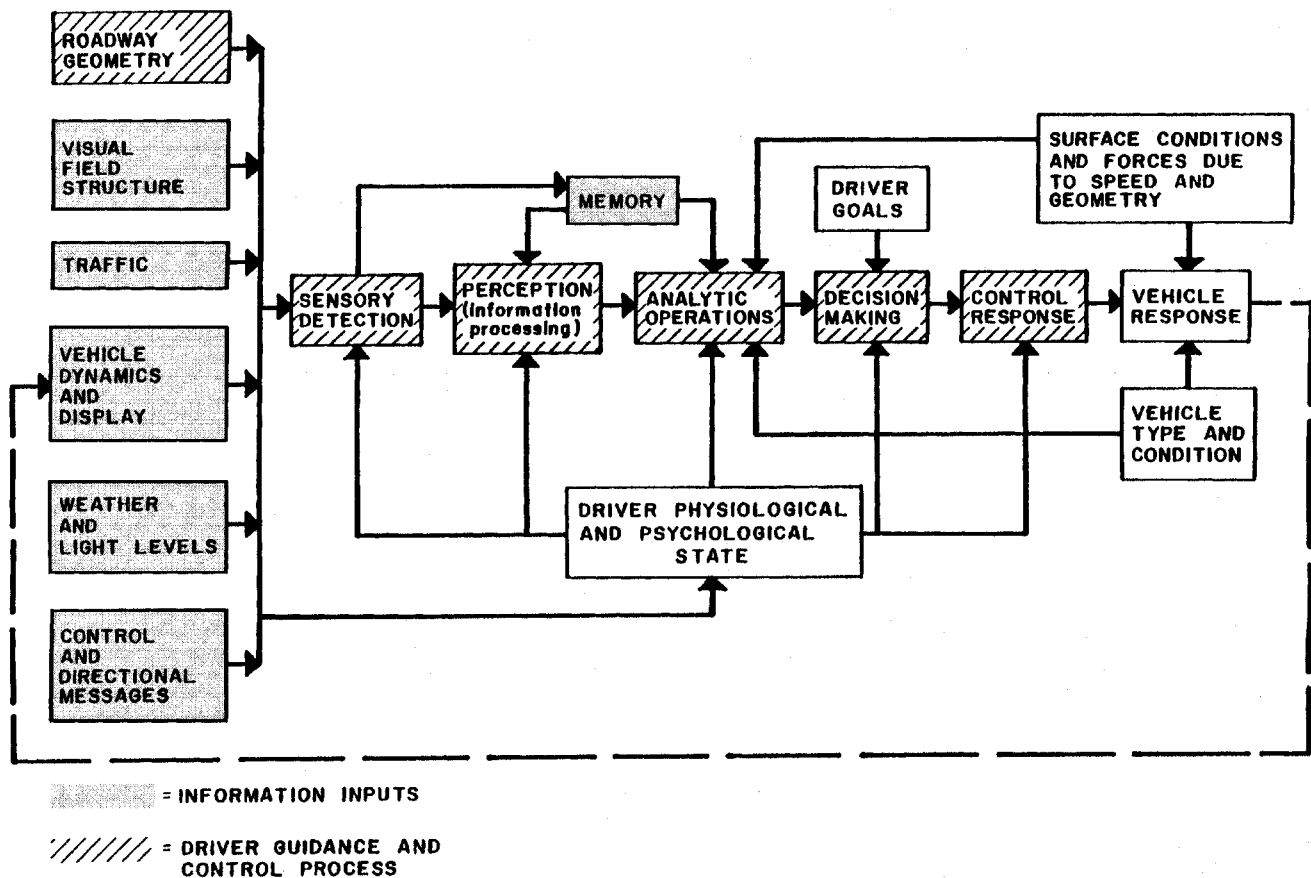

---

### Human Factors

Human factors have a great deal of influence on the design of transportation facilities in such things as width of facility, length and location of access/egress points, braking distance, location of information/guidance aids such as signs, and geometric characteristics of the facility's alignment.

The driver-vehicle-roadway interface is shown in Fig. 80.1.

**Figure 80.1** Driver-vehicle-roadway interface.

## Vehicle or User Performance Factors

The dynamics of vehicle motion play an important role in determining what is effective and safe design. The key vehicle characteristics that become important in design criteria include:

- *Vehicle size.* Influences vertical and horizontal clearances, turning radii, alignment width, and width of vehicle storage berths.
- *Vehicle weight.* Influences strength of material needed to support vehicle operations.
- *Vehicle or user performance.* Influences specifications for horizontal and vertical geometry, braking distances, and needed capacity to allow passing and successful maneuvering (e.g., assumed walking speed of pedestrians crossing a road).

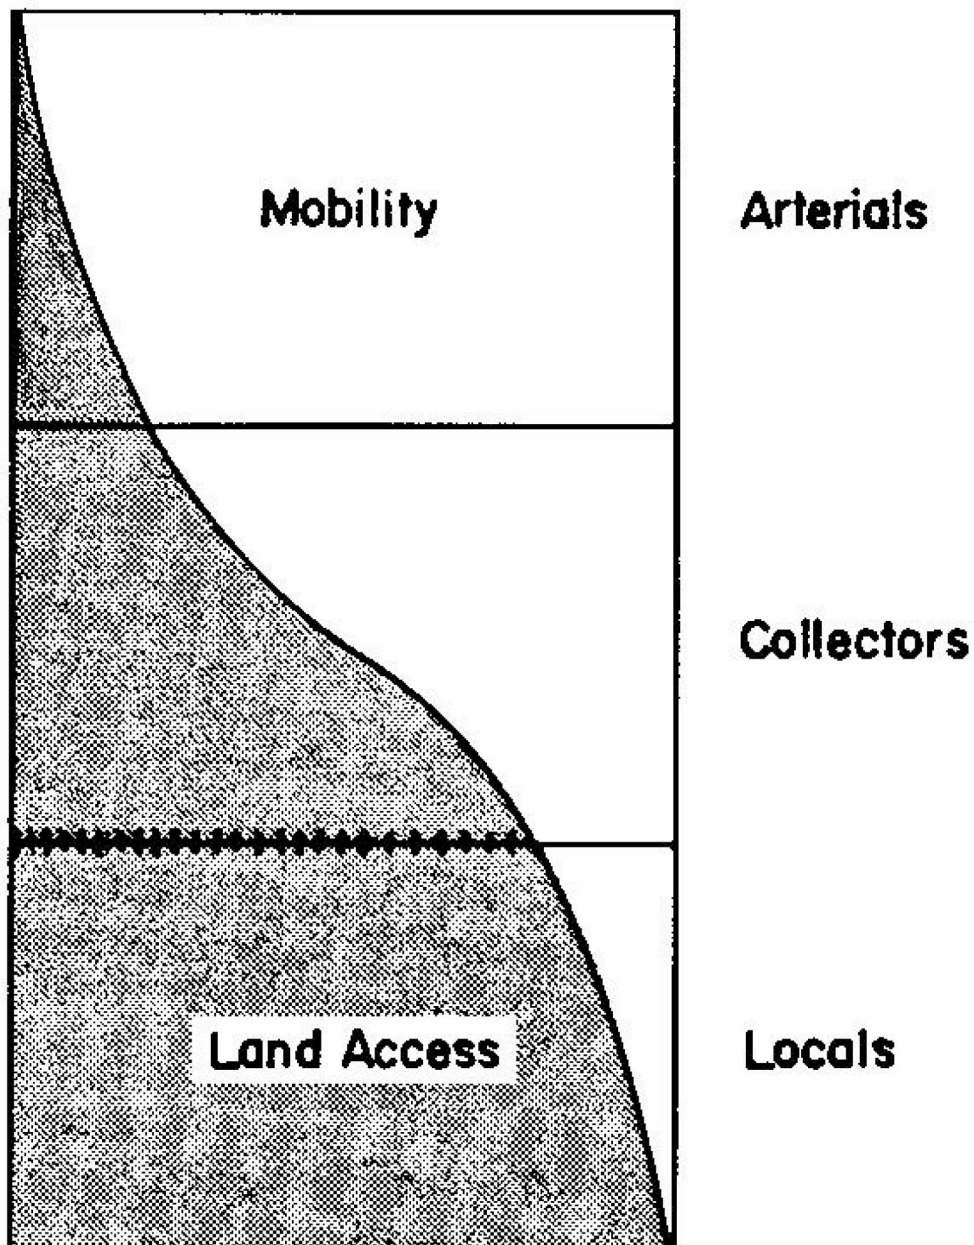

## Classification Schemes

The transportation system serves many functions, ranging from providing access to specific

locations to providing high-speed, high-capacity movement over longer distances. Classification schemes are used to represent these various roles and influence the design criteria that are associated with the facilities in each classification category. A common **functional classification** scheme for highways is shown in [Fig. 80.2](#).

**Figure 80.2** Relationship of functionally classified systems in service traffic mobility and land access. (Source: AASHTO, 1990, Figure I-5.)

## PROPORTION OF SERVICE

## Capacity and Level of Service

Every design usually begins with some estimation of the demand for the transportation facility that will likely occur if the facility is built. The key design question then becomes, what facility capacity (e.g., number of road lanes, runways, transit lines, or vehicle departures) is necessary if a certain level of service is desired? The definition of **level of service (LOS)** thus becomes a critical element in establishing this important design factor (see Fig. 80.3).

**Figure 80.3** Example level of service characteristics (*Source: Transportation Research Board. 1994. Highway Capacity Manual. Washington, DC.*)

FREEWAYS				
Level of Service	Maximum Density (pc/mi/ln)	Minimum Speed (mph)	Max Service Flow Rate (pcphpl)	Maximum v/c Ratio
Free-Flow Speed = 70 mph				
A	10.0	70.0	700	0.318/0.304
B	16.0	70.0	1120	0.509/0.487
C	24.0	68.5	1644	0.747/0.715
D	32.0	63.0	2015	0.916/0.876

Note: In table entries with split values, the first value is for four-lane freeways, and the second is for six- and eight-lane freeways.

PEDESTRIAN WALKWAYS				
Level of Service	Space (sq ft/ped)	Expected Flows and Speeds		
		Ave. Speed, S (ft/min)	Flow Rate, v (ped/min/ft)	Vol/Cap Ratio, v/c
A	≥ 130	≥ 260	≤ 2	≤ 0.08
B	≥ 40	≥ 250	≤ 7	≤ 0.28
C	≥ 24	≥ 240	≤ 10	≤ 0.40
D	≥ 15	≥ 225	≤ 15	≤ 0.60
E	≥ 6	≥ 150	≤ 25	≤ 1.000
F	< 6	< 150	—Variable—	

\*Average conditions for 15 min.

### SIGNALIZED INTERSECTIONS

Level of Service	Stopped Delay per Vehicle (sec)
A	≤ 5.0
B	5.1 to 15.0
C	15.1 to 25.0
D	25.1 to 40.0
E	40.1 to 60.0
F	> 60.0

### ARTERIAL ROADS

Arterial Class	I	II	III
Range of Free Flow Speeds (mph)	45 to 35	35 to 30	35 to 25
Typical Free Flow Speed (mph)	40 mph	33 mph	27 mph
Level of Service	Average Travel Speed (mph)		
A	≥ 35	≥ 30	≥ 25
B	≥ 28	≥ 24	≥ 19
C	≥ 22	≥ 18	≥ 13
D	≥ 17	≥ 14	≥ 9
E	≥ 13	≥ 10	≥ 7
F	< 13	< 10	< 7

## Design Standards

**Design standards** dictate minimum or maximum values of project characteristics that are associated with a particular facility type. Design standards usually result from extensive study of the relationship between various design characteristics and vehicle performance and the safe handling of the vehicles by human operators. Design standards often vary by the "design speed" of the facility (and thus the importance of the facility classification) and by the "design vehicle." Design standards are often the basis for developing typical cross sections (see Figs. 80.4 and 80.5).

**Figure 80.4** Example design criteria. (Source: Massachusetts Department of Public Works. 1988. *Highway Design Manual*. Boston, MA.)

**RECOMMENDED ROADWAY SECTION WIDTHS**

Functional Class	U/R	Number of Lanes	Travel Lane	Shoulder	
				Right	Left <sup>1</sup>
Freeway	Urban	4–8	12	10	4 <sup>2</sup>
	Rural	4–8	12	10	4 <sup>2</sup>
Arterial	Urban	Multilane with median	12	10	4
	Urban	Multilane without median	11–12	8–10 <sup>3</sup>	N/A
	Rural	2 lane	12	See Table 5.2	N/A
	Rural	Multilane with median	12	8–10	4

**WIDTH OF USABLE SHOULDER—EACH SIDE OF TRAVEL WAY  
RURAL TWO-LANE ARTERIAL**

Design Traffic Volume					
	Current ADT Under 400	Current ADT Over 400	DHV 100–200	DHV 200–400	DHV Over 400
All design speeds	4 ft	6 ft	6 ft	8 ft	10 ft

**RECOMMENDED WIDTH OF TRAVEL WAY AND GRADED SHOULDER  
RURAL COLLECTOR**

Design Traffic Volume					
Design Speed (mph)	Current ADT Under 400	Current ADT Over 400	DHV 100–200	DHV 200–400	DHV Over 400
30	20 ft	20 ft	20 ft	22 ft	24 ft
40	20 ft	22 ft	22 ft	22 ft	24 ft
50	20 ft	22 ft	22 ft	24 ft	24 ft
60	22 ft	22 ft	22 ft	24 ft	24 ft
Graded Shoulder (Each Side)*					
All speeds	2 ft	4 ft	6 ft	8 ft	8 ft

\*If right-of-way permits

**Figure 80.5** Example cross sections.

## 80.3 Intermodal Transportation Terminals or Transfer Facilities

Terminals or transfer facilities are locations where users of the transportation system change from one mode of travel to another. The effective design of such facilities is a critical element of successful transportation system performance, given the potential bottlenecks they represent if not designed appropriately. The design of terminals and transfer facilities must pay special attention to the needs of the users of the facility, in that they serve to establish the effective capacity of the facility, for example:

1. Internal pedestrian movement facilities and areas (stairs, ramps, escalators, elevators, corridors, etc.)
2. Line-haul transit access area (entry control, fare collection, loading, and unloading)
3. Components that facilitate movements between access modes and the station (ramps or electric doors)
4. Communications (public address systems and signage)
5. Special provisions for disabled patrons (elevators and ramps)

The criteria that could relate to the design of such a facility include threshold values for pedestrian level of service, delay at access points, connectivity from one area of the facility to another, and low-cost maintenance. For the vehicle side of such terminals, special consideration must be given to the performance of the design vehicle (e.g., turning radii of buses or semitrailer

trucks) and the vehicle storage requirements (e.g., the number, size, and orientation of loading/unloading berths).

## **80.4 Advanced Technology Projects**

---

One of the characteristics of transportation system development in recent years has been the increased application of advanced (usually electronic) technologies to improve system performance. The following steps apply to designing advanced technology projects.

### **Define Problems and Needs**

Typical problems or needs might relate to congestion, excessively high accident rates, or improving current system capabilities and levels of service.

### **Define System**

A system definition should include a mission statement, listing of physical components (e.g., roads, travelers, buses, rolling stock, existing rail lines, control centers, and communication links), and the physical relationship between those components.

### **Define Users**

*System users* is a rather broad description of all individuals, organizations, and other systems that might interact or have a stake in the fully implemented transportation system under study.

### **Establish Institutional Framework and Partnerships**

Various organizations possess differing missions, priorities, and policies—sometimes in conflict. Strong emphasis on coalition building during the early stages of project planning and engineering can help diffuse potential project-stopping disagreements later in the process.

### **Develop User Service Plan**

The development of a user service plan consists of the following steps: (1) establish user services, (2) identify technology areas, and (3) map user services to technology areas. User services might include:

- Traveler information services
- Freight and fleet management services
- Emergency vehicle management services
- Traffic management services
- Public transport services

Available technologies fall within one of the following functional areas: (1) surveillance, (2)

communications, (3) traveler interface, (4) control strategies, (5) navigation/guidance, (6) data processing, and (7) in-vehicle sensors.

## Define System Architecture

A logical architecture consists of a *block diagram* identifying the major systems and subsystems, the participating agencies, and users. Through the use of arrows, the flow of information between these elements is identified. A logical architecture also shows the allocation of responsibilities throughout the transportation system.

## Evaluate Alternative Technologies

Some of the factors to be considered in this evaluation include (1) cost, (2) performance, (3) reliability, (4) compatibility, (5) environmental impacts, and (6) compliance to standards.

## Defining Terms

**Design standard:** Physical characteristics of a proposed facility that are professionally accepted and often based on safety considerations.

**Functional classification:** Classifying a transportation facility based on the function it serves in the transportation system. Such classification becomes important in that design standards are often directly related to the functional classification of a facility.

**Level of service:** An assessment of the performance of a transportation facility based on measurable physical characteristics (e.g., vehicular speed, average delay, density, flow rate). Level of service is usually subjectively defined as ranging from level of service A (good performance) to level of service F (bad or heavily congested performance).

**Project development process:** The steps that are followed to take a project from initial concept to final engineering. This process includes not only the detailed engineering associated with a project design but also the interaction with the general public and with agencies having jurisdiction over some aspect of project design.

- 82.2 Evaluation Measures
- 82.3 Air Transportation
- 82.4 Railroad Transportation
- 82.5 Highway Transportation
- 82.6 Water Transportation
- 82.7 Public Transportation

## Paul Schonfeld

*University of Maryland*

The various forms of transportation that have been developed over time are called **modes**. The classification of modes may be very broad (e.g., highway transportation or air transportation) or more restrictive (e.g., chartered helicopter service). The major distinctions among transportation modes that help to classify them include:

1. Medium (e.g., air, space, surface, underground, water, underwater)
2. Users (e.g., passengers vs. cargo, general-purpose vs. special trips or commodities, common vs. private carrier)
3. Service type (scheduled vs. **demand responsive**, fixed vs. variable route, nonstop vs. express or local, mass vs. personal)
4. Right-of-way type (exclusive, semi-exclusive, shared)
5. Technology:
  - a. Propulsion (e.g., electric motors, diesel engines, gas turbines, linear induction motors, powered cables)
  - b. Energy sources (e.g., petroleum fuels, natural gas, electric batteries, electric power from conducting cables)
  - c. Support (e.g., aerodynamic lift, flotation on water, steel wheels on two steel rails, monorails, air cushions, magnetic levitation, suspension from cables)
  - d. Local control (e.g., lateral control by steering wheels, wheel flanges on railroad vehicles, rudders, longitudinal control by humans or automatic devices)
  - e. Network guidance and control systems (with various degrees of automation and optimization)

A mode may be defined by its combination of such features. The number of conceivable combinations greatly exceeds the number of modes that have been actually tried, which, in turn,

exceeds the number of successful modes. Success may be limited to relatively narrow markets and applications (e.g., for helicopters or aerial cablecars) or may be quite general. Thus, automobiles are successful in a very broad range of applications and have become the basis for distinct transportation modes such as taxis, carpools, or ambulances.

The relative success of various transportation modes depends on available technology and socio-economic conditions at any particular time, as well as on geographic factors. As technology or socio-economic conditions change, new transportation modes appear, develop, and may later decline as more effective competitors appear. For many centuries water transportation was considerably cheaper than overland transportation. Access to waterways was quite influential in the location of economic activities and cities. Access to good transportation is still very important to industries and communities. Technological developments have so drastically improved the relative effectiveness of air transportation that within a short period (approximately 1950 to 1965) aircraft almost totally replaced ships for transporting passengers across oceans. It is also notable that as economic prosperity grows, personal transportation tends to shift from the walking mode to bicycles, motorcycles, and then automobiles. Geography can significantly affect the relative attractiveness of transportation modes. Thus, natural waterways are highly valuable where they exist. Hilly terrain decreases the economic competitiveness of artificial waterways or conventional railroads while favoring highway modes. In very mountainous terrain even highways may become uncompetitive compared to alternatives such as helicopters, pipelines, and aerial cablecars.

The relative shares of U.S. intercity passenger and freight traffic are shown in [Table 82.1](#). The table shows the relative growth since 1929 of airlines, private automobiles, and trucks and the relative decline of railroad traffic.

**Table 82.1** Volume of U.S. Intercity Freight and Passenger Traffic

## 82.1 Transportation System Components

The major components of transportation systems are:

1. Links
2. Terminals
3. Vehicles
4. Control systems

Certain "continuous-flow" transportation systems such as pipelines, conveyor belts, and escalators have no discrete vehicles and, in effect, combine the vehicles with the link.

Transportation systems may be developed into extensive networks. The networks may have a hierarchical structure. Thus, highway networks may include freeways, arterials, collector streets, local streets, and driveways. Links and networks may be shared by several transportation modes (e.g., cars, buses, trucks, taxis, bicycles, and pedestrians on local streets). Exclusive lanes may be provided for particular modes (e.g., pedestrian or bicycles) or groups of modes (e.g., buses and carpools).

Transportation terminals provide interfaces among modes or among vehicles of the same mode. They may range from marked bus stops or truck loading zones on local streets to huge airports or ports.

## 82.2 Evaluation Measures

---

Transportation systems are evaluated in terms of their effects on their suppliers, users, and environment. Both their costs and benefits may be classified into supplier, user, and external components. Private transportation companies normally seek to maximize their profits (i.e., total revenues minus total supplier costs). Publicly owned transportation agencies should normally maximize net benefits to their jurisdictions, possibly subject to financial constraints.

From the supplier's perspective, the major indicators of performance include measures of **capacity** (maximum throughput), speed, **utilization rate** (i.e., fraction of time in use), **load factor** (i.e., fraction of maximum payload actually used), energy efficiency (e.g., Btu per ton-mile or per passenger mile), and labor productivity (e.g., worker hours per passenger mile or per ton-mile). Measures of environmental impact (e.g., noise decibels or parts of pollutant per million) are also increasingly relevant. To users, price and service quality measures, including travel time, wait time, access time, reliability, safety, comfort (ride quality, roominess), simplicity of use, and privacy are relevant in selecting modes, routes, travel times, and suppliers.

## 82.3 Air Transportation

---

Air transportation is relatively recent, having become practical for transporting mail and passengers in the early 1920s. Until the 1970s its growth was paced primarily by technological developments in propulsion, aerodynamics, materials, structures, and control systems. These developments have improved its speed, load capacity, energy efficiency, labor productivity, reliability, and safety, to the point where it now dominates long-distance mass transportation of passengers overland and practically monopolizes it over oceans. Airliners have put ocean passenger liners out of business because they are much faster and also, remarkably, more fuel efficient and labor efficient. However, despite this fast growth, the cargo share of air transportation is still small.

For cargoes that are perishable, high in value, or urgently needed, air transportation is preferred over long distances. For other cargo types, ships, trucks, and railroads provide more economic alternatives. In the 1990s, the nearest competitors to air cargo are containerships over oceans and trucks over land. For passengers, air transportation competes with private cars, trains, and intercity buses over land, with practically no competitors over oceans. The growth of air transportation has been restricted to some extent by the availability of adequate airports, by environmental concerns (especially noise), and by the fear of flying of some passengers.

There are approximately 10 000 commercial jet airliners in the world, of which the largest (as of 1995) are Boeing B-747 types, of approximately 800 000 lb gross takeoff weight, with a capacity of 550 passengers. The economic cruising speed of these and smaller "conventional" (i.e., **subsonic**) airliners has stayed at around 560 mph since the late 1950s. A few supersonic transports (SSTs) capable of cruising at approximately 1300 mph were built in the 1970s (the Anglo-French Concorde and the Soviet Tu-144) but, due to high capital and fuel costs, were not economically

successful. About eight Concorde SSTs are still operating, with government subsidies.

The distance that an aircraft can fly depends on its payload, according to the following equation:

$$R = \frac{V}{c'} \left( \frac{L}{D} \right) \ln(W_{TO}/W_L) \quad (82.1)$$

where

- $R$  = range (mi)
- $c'$  = specific fuel consumption (lb fuel/lb thrust  $\times$  h)
- $(L/D)$  = lift-to-drag ratio (dimensionless)
- $W_{TO}$  = aircraft takeoff weight (lb) =  $W_L + W_F$
- $W_L$  = aircraft landing weight (lb) =  $W_E + W_R + P$
- $W_E$  = aircraft empty weight (lb)
- $W_R$  = reserve fuel weight (lb)
- $W_F$  = consumed fuel weight (lb)
- $P$  = payload (lb)

This equation assumes that the difference between the takeoff weight and landing weight is the fuel consumed. For example, suppose that for a Boeing B-747 the maximum payload carried (based on internal fuselage volume and structural limits) is 260 000 lb, maximum  $W_{TO}$  is 800 000 lb,  $W_R = 15$  000 lb,  $W_E = 370$  000,  $L/D = 17$ ,  $V = 580$  mph, and  $c' = 0.65$  lb/lb thrust  $\times$  h. The resulting weight ratio [ $W_{TO}/W_L = 800/(370 + 15 + 260)$ ] is 1.24 and the range  $R$  is 3267 mi. Payloads below is 260 000 allow higher ranges.

Most airline companies fly scheduled routes, although charter services are common. U.S. airlines are largely free to fly whatever routes (i.e., origin-destination pairs) they prefer in the U.S. In most of the rest of the world, authority to serve particular routes is regulated or negotiated by international agreements. The major components of airline costs are direct operating costs (e.g., aircraft depreciation or rentals, aircrews, fuel, and aircraft maintenance) and indirect operating costs (e.g., reservations, advertising and other marketing costs, in-flight service, ground processing of passengers and bags, and administration).

The efficiency and competitiveness of airline service is heavily dependent on efficient operational planning. Airline scheduling is a complex problem in which demand at various times and places, route authority, aircraft availability and maintenance schedules, crew availability and flying restrictions, availability of airport gates and other facilities, and various other factors must all be considered. Airline management problems are discussed in [Wells, 1984].

Airports range from small unmarked grass strips to major facilities requiring many thousands of acres and billions of dollars. Strictly speaking, an airport consists of an airfield (or "airside") and terminal (or "landside"). Airports are designed to accommodate specified traffic loads carried by aircraft up to a "design aircraft," which is the most demanding aircraft to be accommodated. The design aircraft might determine such features as runway lengths, pavement strengths, or terminal gate dimensions at an airport. Detailed guidelines for most aspects of airport design (e.g., runway lengths and other airfield dimensions, pavement characteristics, drainage requirements, allowable noise and other environmental impacts, allowable obstruction heights, lighting, markings, and

signing) are specified by the U.S. Federal Aviation Administration (FAA) in a series of circulars.

Airport master plans are prepared to guide airport growth, usually in stages, toward ultimate development. These master plans:

1. Specify the airport's requirements.
2. Indicate a site if a new airport is considered.
3. Provide detailed plans for airport layout, land use around the airport, terminal areas, and access facilities.
4. Provide financial plans, including economic and financial feasibility analysis.

Major new airports tend to be very expensive and very difficult to locate. Desirable airport sites must be reasonably close to the urban areas they serve yet far enough away to ensure affordable land and acceptable noise impacts. Many other factors—including airspace interference with other airports, obstructions (e.g., hills, buildings), topography, soil, winds, visibility, and utilities—must be reconciled. Hence, few major new airports are being built, and most airport engineering and planning work in the U.S. is devoted to improving existing airports. Governments sometimes develop multi-airport system plans for entire regions or countries.

National agencies (such as the FAA in the U.S.) are responsible for traffic control and airspace management. Experienced traffic controllers, computers, and specialized sensors and communication systems are required for this function. Increasingly sophisticated equipment has been developed to maintain safe operations even for crowded airspace and poor visibility conditions. For the future we can expect increasing automation in air traffic control, relying on precise aircraft location with global positioning satellite (GPS) systems and fully automated landings. Improvements in the precision and reliability of control systems are increasing (slowly) the capacity of individual runways as well as the required separation among parallel runways, allowing capacity increases in restricted airport sites.

## **82.4 Railroad Transportation**

---

The main advantages of railroad technology are low frictional resistance and automatic lateral guidance. The low friction reduces energy and power requirements but limits braking and hill-climbing abilities. The lateral guidance provided by wheel flanges allows railroad vehicles to be grouped into very long trains, yielding economies of scale and, with adequate control systems, high capacities per track. The potential energy efficiency and labor productivity of railroads is considerably higher than for highway modes, but is not necessarily realized, due to regulations, managerial decisions, demand characteristics, or terrain.

The main competitors of railroads include automobiles, aircraft, and buses for passenger transportation, and trucks, ships, and pipelines for freight transportation. To take advantage of their scale economies, railroad operators usually seek to combine many shipments into large trains. Service frequency is thus necessarily reduced. Moreover, to concentrate many shipments, rail cars are frequently re-sorted into different trains, rather than moving directly from origin to destination, which results in long periods spent waiting in classification yards, long delivery times, and poor vehicle utilization. An alternative operational concept relying on direct nonstop "unit trains" is

feasible only when demand is sufficiently large between an origin-destination pair.

Substantial traffic is required to cover the relatively high fixed costs of railroad track. Moreover, U.S. railroads, which are privately owned, must pay property taxes on their tracks, unlike their highway competitors. By 1920 highway developments had rendered low-traffic railroad branch lines noncompetitive in the U.S. Abandonment of such lines has greatly reduced the U.S. railroad network, even though the process was retarded by political regulation.

The alignment of railroad track is based on a compromise between initial costs and operating costs. The latter are reduced by a more straight and level alignment, which requires more expensive earthwork, bridges, or tunnels. Hay [1982] provides design guidelines for railroads.

In general, trains are especially sensitive to gradients. Thus, compared to highways, railroad tracks are more likely to go around rather than over terrain obstacles, which increases the **circuity factors** for railroad transportation.

The resistance for railroad vehicles may be computed using the Davis equation [Hay, 1982]:

$$r = 1.3 + 29/w + bV + CAV^2/wn + 20G + 0.8D \quad (82.2)$$

where

$G$  = gradient (%)

$D$  = degree of curvature

$r$  = unit resistance (lb of force per ton of vehicle weight)

$w$  = weight (tons per axle of car or locomotive)

$n$  = number of axles

$b$  = coefficient of flange friction, swaying, and concussion (0.045 for freight cars and motor cars in trains, 0.03 for locomotives and passenger cars, and 0.09 for single-rail cars)

$C$  = drag coefficient of air [0.0025 for locomotives (0.0017 for streamlined locomotives) and single- or head-end-rail cars, 0.0005 for freight cars, and 0.00034 for trailing passenger cars, including rapid transit]

$A$  = cross-sectional area of locomotives and cars (usually 105 to 120 ft<sup>2</sup> for locomotives, 85 to 90 ft<sup>2</sup> for freight cars, 110–120 ft<sup>2</sup> for multiple-unit and passenger cars, and 70 to 110 ft<sup>2</sup> for single- or head-end-rail cars)

$V$  = speed (mph)

The coefficients shown for this equation reflect relatively old railroad technology and can be significantly reduced for modern equipment [Hay, 1982]. The equation provides the unit resistance in pounds of force per ton of vehicle weight. The total resistance of a railroad vehicle (in lb) is

$$R_v = rwn \quad (82.3)$$

The total resistance of a train  $R$  is the sum of resistances for individual cars and locomotives. The rated horsepower (hp) required for a train is:

$$\text{hp} = \frac{RV}{375\eta} \quad (82.4)$$

where  $\eta$  = transmission efficiency (typically about 0.83 for a diesel electric locomotive).

The hourly fuel consumption for a train may be computed by multiplying hp by a specific fuel consumption rate (approximately 0.32 lb/hp  $\times$  h for a diesel electric locomotive).

Diesel electric locomotives with powers up to 5000 hp haul most trains in the U.S. Electric locomotion is widespread in other countries, especially those with low petroleum reserves. It is especially competitive on high-traffic routes (needed to amortize electrification costs) and for high-speed passenger trains. Steam engines have almost disappeared.

The main types of freight rail cars are box cars, flat cars (often used to carry truck trailers or intermodal containers), open-top gondola cars, and tank cars. Passenger trains may include restaurant cars and sleeping cars. Rail cars have tended toward increasing specialization for different commodities carried, a trend that reduces opportunities for back hauls. Recently, many "double-stack" container cars have been built to carry two tiers of containers. Such cars require a vertical clearance of nearly 20 ft, as well as reduced superelevation (banking) on horizontal curves. In the U.S. standard freight rail cars with gross weights up to 315 000 lb are used.

High-speed passenger trains have been developed intensively in Japan, France, Great Britain, Italy, Germany, and Sweden. The most advanced (in 1995) appear to be the latest French TGV versions, with cruising speeds of 186 mph and double-deck cars. At such high speeds, trains can climb long, steep grades (e.g., 3.5%) without slowing down much. Construction costs in hilly terrain can thus be significantly reduced. Even higher speeds are being tested in experimental railroad and magnetic levitation (MAGLEV) trains.

## 82.5 Highway Transportation

---

Highways provide very flexible and ubiquitous transportation for people and freight. A great variety of transportation modes, including automobiles, buses, trucks, motorcycles, bicycles, pedestrians, animal-drawn vehicles, taxis, and carpools, can share the same roads. From unpaved roads to multilane freeways, roads can vary enormously in their cost and performance. Some highway vehicles may even travel off the roads in some circumstances. The vehicles also range widely in cost and performance, and at their lower range (e.g., bicycles) are affordable for private use even in poor societies.

Flexibility, ubiquity, and affordability account for the great success of highway modes. Personal vehicles from bicycles to private automobiles offer their users great freedom and access to many economic and social opportunities. Trucks increase the freedom and opportunities available to farmers and small businesses. Motor vehicles are so desirable and affordable that in the U.S. the number of registered cars and trucks approximates the number of people of driving age. Other developed countries are approaching the same state despite strenuous efforts to discourage motor vehicle use.

The use of motor vehicles brings significant problems and costs. These include:

1. Road capacity and congestion. Motor vehicles require considerable road space, which is

scarce in urban areas and costly elsewhere. Shortage of road capacity results in severe congestion and delays.

2. Parking availability and cost.
3. Fuel consumption. Motor vehicles consume vast amounts of petroleum fuels. Most countries have to import such fuels and are vulnerable to price increases and supply interruptions.
4. Safety. The numbers of people killed and injured and the property damages in motor vehicle accidents are very significant.
5. Air quality. Motor vehicles are major contributors to air pollution.
6. Regional development patterns. Many planners consider the low-density "sprawl" resulting from motor vehicle dominance to be inefficient and inferior to the more concentrated development produced by mass transportation and railroads.

In the U.S. trucks have steadily increased their share of the freight transportation market, mostly at the expense of railroads, as shown in [Table 82.1](#). They can usually provide more flexible, direct, and responsive service than railroads, but at higher unit cost. They are intermediate between rail and air transportation in both cost and service quality. With one driver required per truck, the labor productivity is much lower than for railroads, and there are strong economic incentives to maximize the load capacity for each driver. Hence, the tendency has been to increase the number, dimensions, and weights allowed for trailers in truck-trailer combinations, which requires increased vertical clearances (e.g., bridge overpasses), geometric standards for roads, and pavement costs.

Various aspects of highway flow characteristics, design standards, and safety problems were presented in **Chapters 79–81**. The main reference for highway design is the AASHTO manual [[AASHTO, 1990](#)]. For capacity, the main reference is the Transportation Research Board *Highway Capacity Manual* [[TRB, 1985](#)]. Extensive software packages have been developed for planning, capacity analysis, geometric design, and traffic control.

Currently (1995), major research and development efforts are being devoted to exploiting advances in information technology to improve highway operations. The Intelligent Transportation Systems (ITS) program of the U.S. Department of Transportation includes, among other activities, an Advanced Traffic Management System (ATMS) program to greatly improve the control of vehicles through congested road networks, an Advanced Travelers Information System (ATIS) program to guide users through networks, and, most ambitiously, an Automated Highway System (AHS) program to replace human driving with hardware. Such automation, when it becomes feasible and safe, has the potential to drastically improve lane capacity at high speeds, by greatly reducing spacing between vehicles. Other potential benefits include reduced labor costs for trucks, buses, and taxis; higher and steadier speeds; improved routings through networks; remote self-parking vehicles; and use of vehicles by nondrivers such as children and handicapped persons. However, substantial technological, economical, and political problems will have to be surmounted.

## 82.6 Water Transportation

---

Water transportation may be classified into (1) marine transportation across seas and (2) inland waterway transportation; their characteristics differ very significantly. Inland waterways consist mostly of rivers, which may be substantially altered to aid transportation. Lakes and artificial canals may also be part of inland waterways. Rivers in their natural states are often too shallow, too fast, or too variable in their flows. All these problems may be alleviated by impounding water behind dams at various intervals. (This also helps generate electric power.) Boats can climb or descend across dams by using **locks** or other elevating systems [Hochstein, 1981]. In the U.S. inland waterway network there are well over 100 major lock structures, with chambers up to 1200 ft long and 110 ft wide. Such chambers allow up to 18 large barges ( $35 \times 195$  ft) to be raised or lowered simultaneously.

In typical inland waterway operations, large diesel-powered "towboats" (which actually push barges) handle a rigidly tied group of barges (a "tow"). Tows with up to 48 barges ( $35 \times 195$  ft, or about 1300 tons/barge) are operated on the lower Mississippi, where there are no locks or dams. On other rivers, where locks are encountered at frequent intervals, tow sizes are adjusted to fit through locks. The locks constitute significant bottlenecks in the network, restricting capacity and causing significant delays.

Table 82.1 indicates that the waterway share of U.S. freight transportation has increased substantially in recent years. This is largely attributable to extensive improvements to the inland waterway system undertaken by the responsible agency, the U.S. Army Corps of Engineers.

The main advantage of both inland waterway and marine transportation is low cost. The main disadvantage is relatively low speed. Provided that sufficiently deep water is available, ships and barges can be built in much larger sizes than ground vehicles. Ship costs increase less than proportionally with ship size, for ship construction, crew, and fuel. Energy efficiency is very good at low speeds [e.g., 10–20 knots (nautical mi/h)]. However, at higher speeds the wave resistance of a conventional ship increases with the fourth power of speed ( $V^4$ ). Hence, the fuel consumption increases with  $V^4$  and the power required increases with  $V^5$ . Therefore, conventional-displacement ships almost never exceed 30 knots in commercial operation. Higher practical speed may be obtained by lifting ships out of the water on hydrofoils or air cushions. However, such unconventional marine vehicles have relatively high costs and limited markets at this time. Over time, ships have increased in size and specialization. Crude oil tankers of up to 550 000 tons (of payload) have been built. Tankers carrying fluids are less restricted in size than other ships because they can pump their cargo from deep water offshore without entering harbors. Bulk carriers (e.g., for coal, minerals, or grains) have also been built in sizes exceeding 300 000 tons. They may also be loaded through conveyor belts built over long pier structures to reach deep water. General cargo ships and containerhips are practically always handled at shoreline berths and require much storage space nearby.

The use of intermodal containers has revolutionized the transportation of many cargoes. Such containers greatly reduce the time and cost required to load and unload ships. Up to 4500 standard 20-ft containers ( $20 \times 8 \times 8$  ft) can be carried at a speed of about 24 knots on recently built containerhips.

Port facilities for ships should provide shelter from waves and sufficiently deep water, including approach channels to the ports. In addition, ports should provide adequate terminal facilities, including loading and unloading equipment, storage capacity, and suitable connections to other

transportation networks. Ports often compete strenuously with other ports and strive to have facilities that are at least equal to those of competitors. Since ports generate substantial employment and economic activities, they often receive financial and other support from governments.

Geography limits the availability of inland waterways and the directness of ship paths across oceans. Major expensive canals (e.g., Suez, Panama, Kiel) have been built to provide shortcuts in shipping routes. These canals may be so valuable that ship dimensions are sometimes compromised (i.e., reduced) to fit through these canals. In some parts of the world (e.g., Baltic, North Sea, most U.S. coasts) the waters are too shallow for the largest ships in existence. Less efficient, smaller ships must be used there. The dredging of deeper access channels and ports can increase the allowable ship size, if the costs and environmental impacts are considered acceptable.

## 82.7 Public Transportation

---

Public transportation is the term for ground passenger transportation modes available to the general public. It connotes public availability rather than ownership. "Conventional" public transportation modes have fixed routes *and* fixed schedules and include most bus and rail transit services. "Unconventional" modes (also labeled "paratransit") include taxis, carpools and van pools, rented cars, dial-a-ride services, and subscription services.

The main purposes of public transportation services, especially conventional mass transportation services in developed countries, are to provide mobility for persons without automobiles (e.g., children, poor, nondrivers); to improve the efficiency of transportation in urban areas; to reduce congestion effects, pollution, accidents, and other negative impacts of automobiles; and to foster preferred urban development patterns (e.g., strong downtowns and concentrated rather than sprawled development).

Conventional services (i.e., bus and rail transit networks) are quite sensitive to demand density. Higher densities support higher service frequencies and higher network densities, which decrease user wait times and access times, respectively. Compared to automobile users, bus or rail transit users must spend extra time in access to and from stations and in waiting at stations (including transfer stations). Direct routes are much less likely to be available, and one or more transfers (with possible reliability problems) may be required. Thus, mass transit services tend to be slower than automobiles unless exclusive rights-of-way (e.g., bus lanes, rail tunnels) can favor them. Such exclusive rights-of-way can be quite expensive if placed on elevated structures or in tunnels. Even when unhindered by traffic, average speeds may be limited by frequent stops and allowable acceleration limits for standing passengers. Prices usually favor mass transit, especially if parking for automobiles is scarce and expensive.

The capacity of a transit route can be expressed as:

$$C = FLP \quad (82.5)$$

where

$C$  = one-way capacity (passengers/hour) past a certain point

$F$  = service frequency (e.g., trains/hour)

$L$  = train length (cars/train)

$P$  = passenger capacity of cars (spaces/car)

For rail transit lines where high capacity is needed in peak periods,  $C$  can reach 100000 passengers/hour (i.e., 40 trains/hour  $\times$  10 cars/train  $\times$  250 passenger spaces/car). There are few places in the world where such capacities are required. For a bus line the train length  $L$  would usually be 1.0. If no on-line stops are allowed, an exclusive bus lane also has a large capacity (e.g., 1000 buses/hour  $\times$  90 passenger spaces/bus), but such demand levels for bus lanes have not been observed.

The average wait time of passengers on a rail or bus line depends on the headway, which is the interval between successive buses or trains. This can be approximated by:

$$\overline{W} = \overline{H}/2 + \text{var}(H)/2\overline{H} \quad (82.6)$$

where

$\overline{W}$  = average wait time (e.g., minutes)

$\overline{H}$  = average headway (e.g., minutes)

$\text{var}(H)$  = variance of headway (e.g., minutes<sup>2</sup>)

It should be noted that the headway is the inverse of the service frequency.

The number of vehicles  $N$  required to serve a route is:

$$N = RFL \quad (82.7)$$

where  $R$  = vehicle round trip time on route (e.g., hours).

The effectiveness of a public transportation system depends on many factors, including demand distribution and density, network configuration, routing and scheduling of vehicles, fleet management, personnel management, pricing policies, and service reliability. Demand and economic viability of services also depend on how good and uncongested the road system is for automobile users.

Engineers can choose from a great variety of options for propulsion, support, guidance and control, vehicle configurations, facility designs, construction methods, and operating concepts. New information and control technology can significantly improve public transportation systems. It will probably foster increased automation and a trend toward more personalized (i.e., taxilike) service rather than mass transportation.

## THE GOTTHARD PASS

*B. van Gelder, Purdue University*

St. Gotthard is a pass in the Central Alps connecting Switzerland and Italy, 2108 m above sea level. Road and railroad bridges and eventually the Gotthard tunnel greatly facilitate traffic between the Swiss canton Uri to the north and the canton of Ticino to the south. On a larger scale, these roads form the Central Traffic Route between Northern Europe and Italy.

The roads and railroads to the north cut through the valley of the Reuss River, where the city of Wassen is situated. Over the St. Gotthard pass or through the St. Gotthard tunnel the roads and railroads finally reach, to the south, the Leventina valley with the Ticino River and the city of Faido. Near the latter city the depicted modern traffic bridge and the older railroad bridge are situated. (Photo courtesy of the Swiss National Tourist Office.)

## Defining Terms

**Capacity:** The maximum flow rate that can be expected on a transportation facility. "Practical" capacity is sometimes limited by "acceptable" delay levels, utilization rates, and load factors.

**Circuitry factor:** Ratio of actual distance on network to shortest airline distance.

**Delay:** Increase in service time due to congestion or service interruptions.

**Demand-responsive:** A mode whose schedule or route is adjusted in the short term as demand varies, such as taxis, charter airlines, and "TRAMP" ships.

**Load factor:** Fraction of available space or weight-carrying capability that is used.

**Lock:** A structure with gates at both ends which is used to lift or lower ships or other vessels.

**Mode:** A distinct form of transportation.

**Subsonic:** Flying below the speed of sound (Mach 1), which is approximately 700 mph at cruising altitudes of approximately 33 000 ft.

**Utilization rate:** Fraction of time that a vehicle, facility, or equipment unit is in productive use.

### 83.1 Mathematical Models

Lumped Parameter Models • Hybrid Models • Finite Element Models

### 83.2 Summary

#### **Tawfik B. Khalil**

*General Motors Corp.*

Safety of transportation systems, including land, water, and space vehicles, can be defined as the ability of the vehicle structure to provide sufficient protection to mitigate occupants' harm and to reduce cargo damage in the event of a crash. This goal is typically achieved by a combination of structural **crashworthiness** to manage the crash energy and by a system of restraints within the passenger compartment to minimize the impact forces on the human body during the second collision. Crash energy management is viewed here as absorption of the crash kinetic energy of the vehicle while maintaining sufficient resistance to sustain the passenger compartment integrity.

Safety studies for land motor vehicles, the subject discussed in this chapter, are accomplished by a combination of experimental and analytical techniques. Experimental techniques involve sled tests, in which mechanical surrogates of humans (**anthropomorphic** test devices, or "dummies") are subjected to dynamic loads similar to a vehicle deceleration–time pulse to study occupant response, in either frontal or lateral impact modes. The measured dummy kinematics and associated loads (moments) provide a measure of the impact severity and the effectiveness of the restraint system in reducing loads transferred to the occupant. Another type of test typically run to ensure total vehicle structural integrity (crashworthiness) and compliance with government-mandated regulations is the full-scale frontal vehicle to barrier impact. In this test a fully instrumented vehicle with a dummy in the driver seat is launched to impact a rigid barrier from an initial velocity of 30 mph. Other tests include side impacts, rear impacts, and rollover simulations.

Such experimental studies are not only time consuming but also expensive, particularly at the early stages of design, where only prototype vehicles are available. The need to simulate the crash event by an analytical procedure is obvious. This chapter addresses the use of analytical techniques in design of transportation systems, with particular emphasis on motor vehicles.

## 83.1 Mathematical Models

---

Developing mathematical models for structural crashworthiness and occupant response to impact is conceptually easy; it involves solving a set of partial differential equations that govern the response of structures to dynamic loads, subject to initial and boundary conditions. In practice, however, the problem is complicated due to the following factors:

- The crash process is a dynamic event persisting for a short duration of approximately 100–200 milliseconds.
- Vehicle structures are typically complex in geometry, manufactured from metallic and composite shell components, and assembled by various fastening techniques.
- Biomechanical simulation of human or mechanical surrogates to impact requires extensive knowledge of human anthropometry, biological tissue properties, and human tolerance to impact.
- The governing equations are highly nonlinear due to large deformations, large rotations, buckling, elastic-plastic rate-dependent material response, and contact and folding in the shell structures.

Given the aforementioned factors, it is not surprising that analytical simulations of vehicle collisions and occupant response to impact have been evolving over the last 25 years. Three types of models are used in safety simulations: **lumped parameter models** (LP), **hybrid models** (HM), and *finite element* (FE) models.

### Lumped Parameter Models

The first vehicle structure LP model was developed [Kamal, 1970] by using lumped spring-mass components. It simulated the vehicle response to frontal impact into a rigid wall by a unidimensional model consisting of three masses, which represented the inertia of the vehicle body, engine, transmission, and drive shafts. The masses are interconnected by nonlinear springs to simulate the compliance of the vehicle structure. The force-deformation characteristics of the springs are determined by quasi-static crush of vehicle components, which incidentally require significant experience on the behavior of thin sheet metal structural components subject to large deformations and various end conditions (e.g., fixed, hinged, or free). This type of model is still widely used by crash engineers because of its simplicity and surprisingly relative accuracy in comparison with test data. In fact, this modeling approach has been extended to simulate side impact collisions between two vehicles. It is important to note, however, that developing such models relies on experimental data and extensive experience on structural behavior in crash environments. Further, translating model parameters into design data is not immediately obvious.

Two-dimensional and three-dimensional LP models [Prasad and Chou, 1989] are also developed to simulate occupant response to deceleration pulses generated by vehicle structures. These models consist of a group of masses that simulate the inertia and CG locations of anthropomorphic dummies used in crash testing. The dummy segments are connected by joints with appropriate moment-rotation and force-deformation characteristics to represent biomechanical human articulation. Interactions between the dummy model and the passenger interior compartment are achieved by specifying force-deformation curves between the dummy segment and the potential

contact target. Figure 83.1 shows an example of a three-dimensional average size dummy model used in crash simulations. Similar to LP models of vehicle structure, the occupant models are relatively simple to develop and not computationally demanding. In fact, all LP models can be run in minutes on an engineering workstation or a personal computer.

**Figure 83.1** Three-dimensional LP model of a seated dummy, represented by ellipsoidal rigid bodies interconnected by appropriate joints.

## Hybrid Models

Hybrid models were developed to remedy the limitations inherent in the LP spring-mass models. The modeling technique, simply, recommended calculation of the force-deformation component response from structural mechanics equations, instead of testing, which would subsequently be used as the spring property in the LP model. The recommended components initially were generic S-shaped hollow beams built from thin sheet metal [Ni, 1981]. Two beams typically represent the lower or mid-rails (also referred to as *torque boxes*) of the vehicle and represent the main longitudinal load-path carriers from the bumper to the vehicle body. The analysis was accomplished by a finite difference solution, which treated the shell structure by a series of beams with appropriate geometry and material models. Plastic behavior at the hinges was accomplished

by a moment-rotation curve, derived experimentally. Although the component response can be calculated in three dimensions, due to the inability of the LP technology to superimpose path-dependent plastic deformations, the analysis allowed only uniaxial deformations. Further, the boundary conditions at the spring ends cannot be accurately represented. These limitations rendered the technique approximate. Yet, it is commonly used in vehicle design due to its simplicity and to its low requirements of computer resources.

## Finite Element Models

There are two types of FE models, discussed in the following sections, that are used in structural crashworthiness:

### Heuristic Beam Models

Heuristic models (semianalytical models) are formulated by complementing the equations of mechanics with experimental data and empirical information. These models are developed to provide design guidelines for vehicle structure at the early stages in vehicle conception. Four types of models are constructed and analyzed in parallel to investigate the synergy between the major collision modes, namely, front, rear, side, and rollover impacts. At the early stage in vehicle design, crashworthiness is considered in parallel with other design requirements, such as packaging, vehicle dynamics, noise and vibrations, and so on. Accordingly, a computationally efficient scheme along with a fast process to build models is necessary. This led to the development of FE beam models [[Mahmood and Paluzeny, 1986](#)], which define all major components of the vehicle skeleton by means of beam elements. With skill and experience, the influence of connecting panels can be included in the analysis.

The basic building blocks of these models are structural members that are referred to as *columns* when subjected to uniaxial compression and as *beams* when subjected to bending deformations. In either case these components are manufactured from stamped thin sheet metal. Column members are typically exposed to axial or slightly off-angle loads, which can produce progressive (accordion) crush, as shown in [Fig. 83.2](#). This type of progressively stable collapse, highly desired in energy absorption, requires a compressive load smaller than the Euler buckling load and larger than the plastic yield of the column plates. Unstable column collapse, which can include some folding, is less efficient in absorbing energy.

**Figure 83.2** Schematic of axial compression of a straight column, showing progressive formation of accordion folds.

Beam bending is the dominant mode of collapse in many vehicle structures, due to its need for the least amount of energy. Collapse by pure bending is rare. In most vehicle crashes, structural deformations involve a combination of axial compression, bending, and torsion. Component collapse will initiate where the compressive stress exceeds the material yield/local-buckling strength by forming a plastic hinge. The structure cannot continue to support an increasing load at the hinge and stress redistribution occurs, followed by the formation of more plastic hinges. This continues until eventually the structure evolves into a kinematically movable framework, as shown in [Fig. 83.3](#). Therefore, it is important that the model captures the plastic hinge formations and subsequent linkage kinematics effects.

**Figure 83.3** Schematic of S-rail bending deformations, showing plastic hinge formations and subsequent linkage-like kinematics.

Approximate formulas, based on a force method or a displacement method, are derived [Mahmood and Paluszny, 1986] to determine the peak and average crush loads on the basis of local buckling and plastic yielding of thin-walled columns and beams. The component geometry is subdivided into plate elements, which are joined by nodes. A computer program is developed to determine the maximum load-carrying capacity of vehicle structures and subsequent energy absorption following large deformation collapse of the structure. The computation can account for compression and biaxial bending deformations.

### Analytically Based FE Models

All previously cited models require some prior knowledge of the potential failure mechanism of the structure, in addition to experimental data as input to the model. It has always been the desire of safety engineers to develop analytically based models for vehicle crash and occupant dynamics simulations. These models should be based on the physical process involved in the crash event—geometry of the structure, basic stress-strain response of the material, initial conditions of impact and boundary/constraint conditions. This type of analysis—known in mechanics as *initial-boundary value problem*—requires the solution of a nonlinear, coupled system of partial differential equations that can only be applied to extremely simple geometries. Accordingly, classical closed form solutions are nearly inapplicable to real-world structural mechanics problems.

FE technology was introduced in the early 1960s for linear structural analysis, in which the geometry of the structure can be discretized into a set of idealized substructures, called *elements*. Several Fortran computer codes were developed, for both research and commercial applications. Application of the FE technology to crashworthiness analysis did not gain serious momentum until the mid-1980s, due to accelerated advances in explicit time-integration nonlinear FE technology

[Liu *et al.*, 1986] and due to the development of FE codes with reduced integrated elements for spatial discretization and versatile contact algorithms [Goudreau and Hallquist, 1982]. In addition, the introduction of supercomputers provided the necessary impetus for applying the technology to practical problems.

FE crash codes are based on updated Lagrangian mechanics. The equations of motion are obtained from stating the balance of linear momentum in an integral form and introducing spatial discretization by linear isoparametric elements. The semidiscretized second-order set of equations of motion can be written as

$$\mathbf{M}\mathbf{a} = \mathbf{P}(x, t) - \mathbf{Q}(x, t)$$

where  $\mathbf{M}$  is the diagonal mass matrix,  $\mathbf{a}$  is the acceleration vector,  $\mathbf{P}$  is the external force vector,  $\mathbf{Q}$  is the nodal internal force vector,  $x$  is a spatial coordinate, and  $t$  is time. The solution of the previous set of equations in time is accomplished by the explicit central difference technique. The integration scheme, though conditionally stable, has the advantage of avoiding implicit integration and iterative solution of the stiffness matrix.

Initially, this technology was applied to analyze generic components (columns and S-rails) with emphasis on analytically capturing the plastic hinge formation, peak load, sustained collapse load, and associated energy absorption. Following this, a number of simulations modeled structural components manufactured from thin sheet metal and assembled by spot welding [Khalil and Vander Lugt, 1989]. Figure 83.4 shows the initial and deformed configurations of the front-end structure of an experimental vehicle launched to impact a rigid wall from an initial velocity of 50 km/h. The model simulated the structure by predominantly quadrilateral shell elements, which allows for both bending and membrane deformations. Elastic-plastic material properties with appropriate strain hardening and rate effects were assigned to the shell elements. Constraint conditions were used to tie the shell nodes where spot welds were used. A single-surface contact definition was specified for the frontal part of the structure to allow for sheet metal stacking without penetration. The predicted peak force from this impact was 250 kN, which agreed quite well with test data.

**Figure 83.4** FE model of a vehicle structure front end, launched to impact a rigid barrier from an initial velocity = 50 km/h.

After advances in the ability of FE technology to simulate subsystem impact response, the methodology was extended to simulate full-scale vehicle collisions. Current simulations include frontal vehicle collision with a rigid barrier, commonly conducted for compliance with federal safety standards. [Figure 83.5](#) shows an FE model of a vehicle structure before and after impact with a rigid barrier from an initial velocity of 50 km/h [[Johnson and Skynar, 1989](#)]. Other models of vehicle structures simulate a movable deformable barrier impacting the side of a stationary vehicle. Also, simulations of vehicle-to-vehicle frontal impact as well as rear impact have been successfully attempted.

**Figure 83.5** FE model of frontal vehicle collision with a rigid barrier, initial velocity = 50 km/h.

**Undeformed geometry**

**Deformed geometry at time = 70 ms**

Recently, the technology has been extended to simulate air bag inflation and deployment of driver-side and passenger-side air bags. [Figure 83.6](#) shows an isolated, folded driver-side air bag in its initial configuration and its shape subsequent to inflation. Of particular interest here, from the FE simulation point of view, is the technology's ability to simulate the bag fabric material, which can sustain tension and no compression; the gas dynamics and their interaction with the bag to allow for pressurization and controlled leakage; and, finally, the contact and interactions among the bag layers, which should allow for deployment without penetration.

**Figure 83.6** FE simulation of driver-side air bag inflation.

The limitation of using LP models in simulating occupants has been recognized for some time. With the success demonstrated in simulating vehicle structures, analysts were encouraged to extend FE analysis to simulate occupant interactions with interior passenger compartments [[Khalil and Lin, 1991](#)]. [Figure 83.7](#) shows an FE model of a dummy used to simulate an occupant in crash testing.

**Figure 83.7** FE representation of a seated dummy with three-point belt harness.

## 83.2 Summary

---

Several analytical techniques are used in safety analysis to simulate vehicle structural response and occupant behavior in a crash environment. Early models include lumped-parameter, hybrid, and FE heuristic beam models. These models are characterized by gross geometric approximations, and, consequently, they are quick to develop and require minimum computer resources that can be provided by a PC. In the past seven years, detailed representations of vehicle structures by FE models have evolved in size and complexity from geometries represented by 2800 shell elements with one or two material models to current models simulated by over 50 000 shell, solid, and beam elements. These models also include several material representations for metallic and nonmetallic components. Currently, vehicle models exist in the open literature for frontal, side, and rear-impact simulations. Also, modeling of occupant interactions with inflatable restraint systems has recently been published and discussed. It is anticipated that in the near future (within five years) system models representing vehicle structures, occupants, and restraint systems will be in the neighborhood of 100 000 elements and will become a routine design tool in the transportation

industry. However, this increase in model size—coupled with demands for lighter vehicles manufactured from materials such as aluminum and composites—will require new developments in FE technology and hardware architecture to allow for reducing model development effort and computation time.

## Defining Terms

**Anthropomorphic:** Describes a mechanical manikin that possesses geometric, inertial, and material characteristics similar to a human's.

**Crashworthiness:** The ability of a vehicle structure to absorb mechanically energy resulting from collision with another object while maintaining integrity of the passenger compartment.

**Heuristic model:** A model formulated from discrete deformable elements with built-in empirical knowledge.

**Hybrid model:** A lumped parameter model in which the discrete springs are replaced by deformable components.

**Lumped parameter model:** A mechanical system model that represents a continuum structure by discrete masses, springs, and dampers.

Bullwinkle, the world's tallest fixed offshore platform, is located approximately 150 miles southwest of New Orleans. With the platform and drilling rigs in place, the Bullwinkle structure stands at close to 1615 feet, which is 161 feet taller than the world's tallest building, the Sears Tower. Even more impressive than the sheer size of the structure is the fact that it was built to withstand a hurricane current of 4 ft/s, wave heights of 72 ft, and a wind velocity of 140 mph.

Twenty-eight piles were used to secure the jacket to the ocean floor. Each pile is 84 inches in diameter and up to 541 feet long. The piles were driven to penetrations of up to 437 feet with underwater hammers.

Since 1993 Bullwinkle has been producing more than 54 000 barrels of oil and 95 million cubic feet of natural gas per day. (Photo courtesy of Shell Oil Company.)

### 84 Shallow Water and Deep Water Engineering *J. B. Herbich*

Wave Phenomena • Sediment Processes • Beach Profile • Longshore Sediment Transport • Coastal Structures • Navigational Channels • Marine Foundations • Oil Spills • Offshore Structures

IN THE VIEW OF TRADITIONAL ENGINEERING, ocean engineering may be seen as a relatively new field. In contrast, it may be argued that ocean engineering originated when the first human launched a craft in pursuit of what lay beyond the ocean's horizon. Regardless of view, the field of ocean engineering involves the application of literally all of the disciplines of science and engineering to the oceans. The physics of ocean waves on structures, the chemistry of desalination, and the biology and electrical engineering of marine bioacoustics are but a few of the rapidly emerging areas of ocean engineering. What is particularly exciting is that the fundamentals have been around for a long time, yet their application to the ocean continues to evolve new areas of engineering interest.

The concept of ocean engineering encompasses all of the geographic extent of the ocean, but usage has led to the connotation of deep open ocean engineering. "Coastal" is used to refer to shallow water engineering, but this usage suffers from ambiguity because shallow water is defined relative to properties of ocean waves.

Recognizing that ocean wave behavior in deep and shallow water is fundamental to understanding the principal constructs of ocean and coastal engineering, the chapter in this section presents the basic concepts of ocean surface wave behavior. Important wave-related engineering problems such as sediment transport, beach profile adjustment, and forces on seawalls are presented to illustrate useful coastal engineering applications. Forces on offshore structures are used to exemplify wave and current effects in deep water. This chapter provides a useful base of information from which to expand into the multitude of ocean and coastal engineering disciplines.

### John B. Herbich

*Texas A&M University Consulting & Research Services, Inc.*

Ocean engineering is a relatively new branch of engineering. The need for this new specialty was recognized in the 1960s. Several universities, including Texas A&M, MIT, Florida Atlantic, the U.S. Coast Guard Academy, and the U.S. Naval Academy, established undergraduate degree programs in ocean engineering. Several universities have also developed programs at the graduate level specializing in ocean engineering.

Ocean and coastal engineering covers many topics, generally divided between shallow water (coastal engineering) and deep water (ocean engineering), shown in [Figs. 84.1](#) and [84.2](#).

**Figure 84.1** Coastal engineering (shallow water).

**Figure 84.2** Ocean engineering (deep water).

## 84.1 Wave Phenomena

Wave phenomena are of great importance in coastal and ocean engineering. Waves determine the composition and geometry of beaches. Since waves interact with human-made shore structures or offshore structures, safe design of these structures depends to a large extent on the selected wave characteristics. The structural stability criteria are often stated in terms of extreme environmental conditions (wave heights, periods, water levels, astronomical tides, storm surges, tsunamis, and winds). Waves in the ocean constantly change and are irregular in shape, particularly when under the influence of wind; such waves are called *seas*. When waves are no longer under the influence of wind and are out of the generating area, they are referred to as *swells*. Many wave theories have been developed, including the Airy, cnoidal, solitary, stream function, Stokian, and so forth. [Figure 84.3](#) describes the regions of validity for various wave theories. Cnoidal and stream function theories apply principally to shallow and transitional water, whereas Airy and Stokian theories apply to transitional and deep water (Airy applies to low amplitude waves).

**Figure 84.3** Regions of validity for various wave theories. (Source: Le Méhauté, 1969.)

## Airy (Low Amplitude)

Wavelength is given by the following equations.

$$\text{Shallow water} \quad L = T\sqrt{gh} = CT \quad (84.1)$$

$$\text{Transitional water} \quad L = \frac{gT^2}{2\pi} \tanh \left( \frac{2\pi h}{L} \right) \quad (84.2)$$

$$\text{Deep water} \quad L_o = \frac{gT^2}{2\pi} = C_o T \quad (84.3)$$

where

$T$  = wave period

$g$  = acceleration due to gravity

$h$  = water depth

$C$  = wave celerity

Subscript  $o$  denotes deep water conditions.

## Cnoidal (Shallow Water, Long Waves)

The theory originally developed by Boussinesq [1877], has been studied and presented in more usable form by several researchers. Wavelength is given by

$$L = \sqrt{\frac{16d^3}{3H}} kK(k) \quad (84.4)$$

and wave period by

$$T\sqrt{\frac{g}{h}} = \sqrt{\frac{16y_t}{3H}} \frac{h}{y_t} \left[ \frac{kK(k)}{1 + \frac{H}{y_t k^2} \left( \frac{1}{2} - \frac{E(k)}{K(k)} \right)} \right] \quad (84.5)$$

where

$y_t$  = distance from the bottom to the wave trough

$k$  = modulus of the elliptic integrals

$K(k)$  = complete elliptic integral of the first kind

$E(k)$  = complete elliptic integral of the second kind

Cnoidal waves are periodic and of permanent form; thus  $L = CT$ .

SUBMARINE VESSEL

*Simon Lake*

*Patented April 20, 1897*

**#581,213**

Up to this time, many submarines had been described and some even built; including the Turtle, basically a water-tight barrel with a propeller, used once to plant a bomb under an enemy vessel during the American Revolution.

Lake's patent was the first to describe many of the features used in modern submarines such as compressed-air ballast for vertical submerging, an air lock for entering and leaving the vessel while it was submerged and an automatic control for maintaining the vessel at a selected depth while under power. The problem of locomotion while under water was addressed by reference to "chemical engines, storage batteries, and the like" which are means commonly used in today's small research submarines. Even described was the forerunner of the periscope for viewing the surface while the vessel was submerged. (© 1994, DewRay Products, Inc. Used with permission.)

## Stream Function

Stream function was developed by Dean [1977] and is of analytical form with the wavelength  $L$ ,

coefficients  $X(n)$ , and the value of stream function on the free surface  $\psi_\eta$  determined numerically. The expression for the stream function,  $\psi$ , for a wave system rendered stationary by a reference frame moving with the speed of the wave,  $C$ , is

$$\psi = \left( \frac{L}{T} - U \right) z + \sum_{n=1}^{NN} X(n) \sinh \left[ \frac{2\pi n}{L} (h + z) \right] \cos \left( \frac{2\pi n x}{L} \right) \quad (84.6)$$

with the coordinate  $z$  referenced to the mean water level;  $U$  is a uniform current.

Stream function (Table 84.1) provides values of wavelength  $L' = L/L_o$ ,  $\eta'_c = \eta_c/H$  (water surface elevation above mean water),  $\eta'_t = \eta_t/H$  (wave surface elevation below mean water),  $u'_c$  (horizontal dimensionless velocity at the crest),  $w'_m$  (maximum dimensionless vertical velocity),  $(F'_D)_m$  (maximum dimensionless drag force), and  $(F'_I)_m$  (maximum dimensionless inertia force).

**Table 84.1** Selected Summary of Tabulated Dimensionless Stream Function Quantities

## Stokian (Third Order)

Wavelength is given by

$$L = \frac{gT^2}{2\pi} \tanh\left(\frac{2\pi h}{L}\right) \left\{ 1 + \left(\frac{\pi H}{L}\right)^2 \left[ \frac{5 + 2 \cosh(4\pi h/L) + 2 \cosh^2(4\pi h/L)}{8 \sinh^4(2\pi d/L)} \right] \right\} \quad (84.7)$$

## 84.2 Sediment Processes

Along the coasts the ocean meets land. Waves, currents, tsunamis, and storms have been shaping the beaches for many thousands of years. Beaches form the first defense against the waves and are constantly moving on, off, and along the shore (littoral drift). [Figure 84.4](#) provides a definition for terms describing a typical beach profile. The shoreline behavior is very complex and difficult to understand; it cannot be expressed by equations because many of the processes are site-specific. Researchers have, however, developed equations that should be summarized. There are two basic sediment movements:

1. On- and offshore
2. Parallel to the shore and at an angle to the shore.

**Figure 84.4** Visual definition of terms describing a typical beach profile. (Source: Department of the Army. 1984. *Shore Protection Manual*, vols. I and II. Department of the Army, Corps of Engineers, Coastal Engineering Research Center, Waterways Experiment Station, Vicksburg, MS.)

## 84.3 Beach Profile

Information on beach profiles is essential in designing structural modifications (such as seawalls, revetments, and breakwaters, both connected and detached), pipeline crossings, and beach replenishment. Bruun [1954] indicated that many beach profiles (Fig. 84.5) can be represented by

$$h(x) = Ax^{2/3}$$

where  $h$  is the water depth at a distance  $x$  offshore, and  $A$  is a dimensional scale parameter.

**Figure 84.5** Beach profile scale factor,  $A$ , versus sediment diameter,  $D$ , in relationship  $h = Ax^{2/3}$ . (Source: Dean, R. G. 1991. Beach profiles. In *Handbook of Coastal and Ocean Engineering*, Volume 2, ed. J. B. Herbich. Gulf, Houston, TX. Copyright 1990 by Gulf Publishing Company, Houston, TX. Used with permission. All rights reserved.)

Dean [1977] showed that  $H_b/wT$  is an important parameter distinguishing **barred** profiles from nonbarred profiles (where  $H_b$  is breaking wave height,  $w$  is fall velocity of sediment in water, and  $T$  is wave period). This parameter is consistent with the following beach profiles in nature:

$$\begin{array}{lcl}
\text{Milder slope profiles} & \left\{ \begin{array}{l} \text{High waves} \\ \text{Short periods} \\ \text{Small sediment diameter} \end{array} \right. & \\
\text{Steeper profiles} & \left\{ \begin{array}{l} \text{Low waves} \\ \text{Long periods} \\ \text{Large sediment diameter} \end{array} \right. & 
\end{array}$$

$$\text{When } \frac{H_b}{wT} > 0.85, \text{ one can expect } \mathbf{\bar{b}ar} \text{ formation.} \quad (84.8a)$$

$$\text{When } \frac{H_b}{wT} < 0.85, \text{ a monotonic profile can be expected.} \quad (84.8b)$$

Later, on the basis of large laboratory data, Kriebel *et al.* [1986] found the value of 2.3 rather than 0.85 in Eqs. (84.8a) and (84.8b).

## 84.4 Longshore Sediment Transport

---

The longshore transport ( $Q$ ) is the volumetric rate of sand movement parallel to the shoreline. Much longshore transport occurs in the surf zone and is caused by the approach of waves at an angle to the shoreline.

Longshore transport rate ( $Q$ , given in unit volume per second) is assumed to depend upon the longshore component of wave energy flux,  $P_{ls}$  (Department of the Army, 1984):

$$Q = \frac{K}{(\rho_s - \rho)g\alpha} P_{ls} \quad (84.9)$$

where

$K$  = dimensionless empirical coefficient (based on field measurements) = 0.39

$\rho_s$  = density of sand

$\rho$  = density of water

$g$  = acceleration due to gravity

$\alpha$  = ratio of the volume of solids to total volume, accounting for sand porosity = 0.6

## General Energy Flux Equation

The energy flux per unit length of wave crest or, equivalently, the rate at which wave energy is transmitted across a plane of unit width perpendicular to the direction of wave advance,

is

$$P = EC_g \quad (84.10)$$

where  $E$  is wave energy density and  $C_g$  is wave group speed. The wave energy density is calculated by

$$E = \frac{\rho g H^2}{8} \quad (84.11)$$

where  $\rho$  is mass density of water,  $g$  is acceleration of gravity, and  $H$  is wave height.

If the wave crests make an angle  $\alpha$  with the shoreline, the energy flux in the direction of wave advance per unit length of beach is

$$P \cos \alpha = \frac{\rho g H^2}{8} C_g \cos \alpha \quad (84.12)$$

The longshore component of wave energy flux is

$$P_l = P \cos \alpha \sin \alpha = \frac{\rho g H^2}{8} C_g \cos \alpha \sin \alpha \quad (84.13)$$

or,

$$P_l = \frac{\rho g}{16} H^2 C_g \sin 2\alpha \quad (84.14)$$

## Threshold of Sand Movement by Waves

The threshold of sand movement by wave action has been investigated by a number of researchers [e.g., [Tsuchiya, 1991](#)]. [Figure 84.6](#) shows the modified Shields diagram, where  $\tau_{*c} = 1/\varepsilon \psi_i(D_{\nu*})$ , and  $\psi_i(D_{\nu*})$  is a function of sediment-fluid number only, plotted as a function of  $D_{\nu*}$ .

**Figure 84.6** Threshold of sand movement by waves with Shields, Sleath, and Tsuchiya empirical curves, as well as the theoretical curve. (Source: Tsuchiya, Y. 1991. Threshold of sand movement. In *Handbook of Coastal and Ocean Engineering, Volume 2*, ed. J. B. Herbich. Gulf, Houston, TX. Copyright 1990 by Gulf Publishing Company, Houston, TX. Used with permission. All rights reserved.)

The empirical formula shown by dashed lines is as follows:

$$\begin{aligned}
 \tau_{*c} &= 0.20 & \text{for } D_{v*} \leq 1 \\
 &= 0.20 D_{v*}^{-2/3} & \text{for } 1 \leq D_{v*} \leq 20 \\
 &= 0.010 D_{v*}^{1/3} & \text{for } 20 \leq D_{v*} \leq 125 \\
 &= 0.050 & \text{for } 125 \leq D_{v*}
 \end{aligned} \tag{84.15}$$

## 84.5 Coastal Structures

Wave forces act on coastal and offshore structures; the forces may be classified as due to nonbreaking, breaking, and broken waves. Fixed coastal structures include (a) wall-type structures such as **seawalls**, bulkheads, revetments, and certain types of breakwaters, (b) pile-supported structures such as piers and offshore platforms, and (c) rubble structures such as breakwaters, **groins**, and revetments.

### Seawalls

Forces due to nonbreaking waves may be calculated using Sainflou or Miche-Rundgren formulas. Employing the Miche-Rundgren formula, the pressure distribution is

$$p_1 = \left( \frac{1 + \chi}{2} \right) \frac{\gamma H_i}{\cosh(2\pi h/L)} \tag{84.16}$$

$\chi$  = wave reflection coefficient

$\gamma$  = unit weight of water

$H_i$  = incident wave height  
 $h$  = water depth  
 $L$  = wavelength

Figure 84.7 shows the pressure distribution at a vertical wall at the crest and trough of a clapotis.

**Figure 84.7** Pressure distributions for nonbreaking waves. (Source: Department of the Army. 1984. *Shore Protection Manual*, vols. I and II. Department of the Army, Corps of Engineers, Coastal Engineering Research Center, Waterways Experiment Station, Vicksburg, MS.)

Forces due to breaking waves may be estimated by Minikin and Goda methods. The Minikin method described by the Department of the Army [1984] estimates the maximum pressure (assumed to act on the SWL) to be:

$$p_m = 101\gamma \frac{H_b}{L_D} \frac{d_s}{D} (D + d_s) \quad (84.17)$$

where  $p_m$  is the maximum dynamic pressure,  $H_b$  is the breaker height,  $d_s$  is the depth at the toe of the wall,  $D$  is the depth one wavelength in front of the wall, and  $L_D$  is the wavelength in water depth  $D$ . The distribution of dynamic pressure is shown in Fig. 84.8. The pressure decreases parabolically from  $p_m$  at the WL to zero at a distance of  $H_b/2$  above and below the SWL. The force represented by the area under the dynamic pressure distribution is

$$R_m = \frac{p_m H_b}{3} \quad (84.18)$$

**Figure 84.8** Minikin wave pressure diagram. (Source: Department of the Army. 1984. *Shore Protection Manual*, vols. I and II. Department of the Army, Corps of Engineers, Coastal Engineering Research Center, Waterways Experiment Station, Vicksburg, MS.)

Goda's method [1985] assumes a trapezoidal pressure distribution (Fig. 84.9). The pressure extends to a point measured from SWL at a distance given by  $\eta^*$ :

$$\eta^* = 0.75(1 + \cos \beta) H_{\max} \quad (84.19)$$

in which  $\beta$  denotes the angle between the direction of wave approach and a line normal to the breakwater.

**Figure 84.9** Distribution of wave pressure on an upright section of a vertical breakwater. (Source: Goda, Y. 1990. Random wave interaction with structures. In *Handbook of Coastal and Ocean Engineering, Volume 1*, ed. J. B. Herbich. Gulf, Houston, TX. Copyright 1990 by Gulf Publishing Company, Houston, TX. Used with permission. All rights reserved.)

The wave pressure at the wall is given by

$$p_1 = \frac{1}{2}(1 + \cos \beta)(\alpha_1 + \alpha_2 \cos^2 \beta)\gamma H_{\max} \quad (84.20)$$

$$p_2 = \frac{p_1}{\cosh(2\pi h/L)} \quad (84.21)$$

$$P_3 = \alpha_3 p_1 \quad (84.22)$$

in which

$$\alpha_1 = 0.6 + 0.5 \left[ \frac{4\pi h/L}{\sinh(4\pi h/L)} \right]^2 \quad (84.23)$$

$$\alpha_2 = \min \left[ \frac{h_b - d}{3h_b} \left( \frac{H_{\max}}{d} \right)^2, \frac{2d}{H_{\max}} \right] \quad (84.24)$$

$$\alpha_3 = 1 - \frac{h'}{h} \left[ 1 - \frac{1}{\cosh(2\pi h/L)} \right] \quad (84.25)$$

## Breakwaters

Rubble-mound breakwaters are the oldest form of breakwaters, dating back to Roman times. The rubble mound is protected by larger rocks or artificial concrete units. This protective layer is usually referred to as **armor** or cover layer.

$$W = \frac{\gamma_r H^3}{K_D (S_r - 1)^3 \cot \theta} \quad (84.26)$$

where

$W$  = weight in newtons or pounds of an individual armor unit in the primary cover layer

$\gamma_r$  = unit weight (saturated surface dry) of armor unit in  $\text{N/m}^3$  or  $\text{lb/ft}^3$

$S_r$  = specific gravity of armor unit, relative to the water at the structure ( $S_r = w_r/w_\omega$ )

$\gamma_\omega$  = unit weight of water: freshwater =  $9800 \text{ N/m}^3$  ( $62.4 \text{ lb/ft}^3$ );

seawater =  $10\,047 \text{ N/m}^3$  ( $64.0 \text{ lb/ft}^3$ )

$\theta$  = angle of structure slope measured from horizontal in degrees

$K_D$  = stability coefficient that varies primarily with the shape of the armor units, roughness of the armor unit surface, sharpness of edges, and degree of interlocking obtained in placement

Figure 84.10 presents the recommended three-layer section of a rubble-mound breakwater. Note that underlayer units are given in terms of  $W$ , the weight of armor units.

**Figure 84.10** Rubble-mound section for wave exposure on both sides with moderate overtopping conditions. (Source: Department of the Army. 1984. *Shore Protection Manual*, vols. I and II. Department of the Army, Corps of Engineers, Coastal Engineering Research Center, Waterways Experiment Station, Vicksburg, MS.)

**Recommended Three-layer Section**

Automated coastal engineering system (ACES) describes the computer programs available for the design of breakwaters using Hudson and related equations.

Van der Meer [1987] developed stability formulas for plunging (breaking) waves and for surging (nonbreaking) waves. For plunging waves,

$$H_s / \Delta D_{n50} * \sqrt{\xi_z} = 6.2 P^{0.18} (S / \sqrt{N^{0.2}}) \quad (84.27)$$

For surging waves,

$$H_s / \Delta D_{n50} = 1.0 P^{-0.13} (S / \sqrt{N^{0.2}}) \sqrt{\cot \alpha} \xi_z^p \quad (84.28)$$

$H_s$  = **significant wave height** at the toe of the structure

$\xi_z$  = surf similarity parameter,  $\xi_z = \frac{\tan \alpha}{\sqrt{2\pi H_s / g T_z^2}}$

$T_z$  = zero up-crossing wave period

$\alpha$  = slope angle

$\Delta$  = relative mass density of the stone,  $\Delta = \rho_a / (\rho - 1)$

$\rho_a$  = mass density of the stone

$\rho$  = mass density of water

$D_{n50}$  = nominal diameter of the stone,  $D_{n50} = (W_{50} / \rho_a)^{1/3}$

$W_{50}$  = 50% value (median) of the mass distribution curve

$P$  = permeability coefficient of the structure

$S$  = damage level,  $S = A / D_{n50}^2$

$A$  = erosion area in a cross section

$N$  = number of waves (storm duration)

Influence of breakwater slope angle is depicted in Fig. 84.11.

## 84.6 Navigational Channels

The development of very large commercial craft (VLCC) and ultralarge commercial craft (ULCC) forced many government planners and port managers to evaluate existing channels. Navigational channels allow large vessels to reach harbors. Of paramount design consideration is the safety of vessels in a channel, particularly when passing [Herbich, 1992].

Vessel behavior in channels is a function of bottom suction, bank suction, interference of passing ships, waves, winds, and currents. Most major maritime countries have criteria regarding the depth and width of channels. The international commission ICORELS (sponsored by the Permanent International Association of Navigation Congresses\xd1 PIANC) recommends that general criteria for gross underkeel clearances can be given for drawing up preliminary plans:

- *Open sea area.* When exposed to strong and long stern or quarter swells where speed may be

**Figure 84.11** Influence of slope angle. (Source: Van der Meer, J. W. 1990. Rubble mounds—Recent modifications. In *Handbook of Coastal and Ocean Engineering, Volume 1*, ed. J. B. Herbich. Gulf, Houston, TX. Copyright 1990 by Gulf Publishing Company, Houston, TX. Used with permission. All rights reserved.)

high, the gross underkeel clearance should be about 20% of the maximum draft of the large ships to be received.

- *Waiting area.* When exposed to strong or long swells, the gross underkeel clearance should be about 15% of the draft.
- *Channel.* For sections exposed to long swells, the gross underkeel clearance should be about 15% of the draft.

The *Engineering Manual* [U.S. Army Corps of Engineers, 1983] provides guidance for the layout and design of deep-draft navigation channels. Table 84.2 provides the general criteria for channel widths.

**Table 84.2** General Criteria for Channel Widths

Location	Minimum Channel Width in Percent of Beam			
	Vessel Controllability			Channels with Yawing Forces
	Very Good	Good	Poor	
Maneuvering lane, straight channel	160	180	200	Judgment*
Bend, 26° turn	325	370	415	Judgment*
Bend, 40° turn	385	440	490	Judgment*
Ship clearance	80	80	80	100 but not less than 100 ft
Bank clearance	60	60 plus	60 plus	150

\*Judgment will have to be based on local conditions at each project.

## 84.7 Marine Foundations

Design of marine foundations is an integral part of any design of marine structures. The design criteria require a thorough understanding of marine geology; geotechnical properties of sediments at a given location; and wind, wave, currents, tides, and surges during maximum storm conditions. In the arctic areas information on fast ice and pack ice is required for the design of offshore structures (on artificial islands) and offshore pipelines.

A number of soil engineering parameters are required, as shown in Table 84.3. Many of the properties may be obtained employing standard geotechnical methods. Geotechnical surveys and mapping of seabed characteristics have reached a high degree of sophistication. High-resolution geophysical surveys determine water depth, seafloor imagery, and vertical profiles. Bottom-mapping systems include multibeam bathymetry, sea beam, side-scan sonars, and subbottom profilers (including shallow, medium, and deep penetration types).

**Table 84.3** Soil Engineering Parameters Normally Required for Categories of Geotechnical Engineering Applications

Application	Soil Classification	Grain Size	Atterberg Limits	Strength Properties				Common Properties			Subbottom Depth of Survey
				Clay		Sand		Clay		Sand	
				$S_u, S_r$	$\bar{c}, \phi'$	$\phi'$	$\phi$ or $S_u$	$C_v, k$	$C_c$	$C_c$	
Shallow foundation	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	1.5 to 2 × foundation width
Deadweight anchors	Yes	No	No	Yes	Yes	Yes	No	No	No	No	1.5 to 2 × anchor width
Deep pile foundations	Yes	Yes	Yes	Yes	Yes	Yes	No	Yes	Yes	No	1 to 1.5 × pile group width, below individual pile tips
Pile anchors	Yes	Yes	Yes	Yes	Yes	Yes	No	No	No	No	To depth of pile anchor
Direct-embedment anchors	Yes	Yes	No	Yes	Yes	Yes	Yes	Yes	No	No	To expected penetration of anchor, maximum 33 to 50 ft clay; 13 to 33 ft sand
Drag anchors	Yes	Yes	No	Yes	No	No	No	No	No	No	33 to 50 ft clay; 10 to 16½ ft sand for large anchors
Penetration	Yes	Yes	No	Yes	No	Yes	Yes	No	No	No	33 to 50 ft clay; 13 to 33 ft sand
Breakout	Yes	Yes	Yes	Yes	Yes	Yes	Yes	No	No	No	1 × object width plus embedment depth
Scour	Yes	Yes	No	Yes	No	No	No	No	No	No	3.3 to 16½ ft; related to object size and water motion
Slope stability	Yes	Yes	Yes	Yes	Yes	Yes	No	No	No	No	33 to 100 ft; more on rare occasions

Symbols:

$S_u$  = undrained shear strength

$S_r$  = sensitivity

$\bar{c}$  = drained cohesion intercept

$\phi'$  = drained friction angle

$\phi$  = undrained friction angle for sands rapidly sheared

$C_v$  = coefficient of consolidation

$k$  = permeability

$C_c$  = compression index

Source: Marine Board, National Research Council. 1989. *Our Seabed Frontier—Challenges and Choices*. National Academy Press, Washington, DC.

The geotechnical investigation is designed to include sediment stratigraphy; sediment types; and sediment properties, including density, strength, and deformational characteristics. Deployment systems employed for sampling in situ include self-contained units, drilling rigs, and submersibles. (Figure 84.12 shows the deployment systems.)

There are many in situ testing devices; these include the vane shear test, cone penetrometer test, pressure meter, shear vane velocity tools, temperature probes, natural gamma logger, and so forth [Young, 1991].

## 84.8 Oil Spills

The best method of controlling oil pollution is to prevent oil spills in the first place. This may include such techniques as rapid removal of oil from stricken tankers, continuous monitoring of oil wells, killing wild wells at sea, and containing oil spills under the water surface. Spilled oil, being lighter than water, floats on the water surface and spreads laterally. As oil is spilled, several regimes are generally assumed: gravity-inertial, gravity-viscous, and surface tension. In the early stage, generally less than one hour, the gravity-inertial regime, or inertial spread, dominates and is described by

**Figure 84.12** Deployment systems used for sampling, in situ, and experimental testings. (Source: Marine Board, National Research Council. 1989. *Our Seabed Frontier*<sup>3/4</sup>*Challenges and Choices*. National Academy Press, Washington, DC.)

$$R = k_4(\Delta g L t^2)^{1/4} \quad (84.29)$$

$R$  = radius of the oil slick

$k_4$  = nondimensional coefficient experimentally determined to be 1.14

$\Delta$  = the ratio of the absolute difference between the densities of sea water and the oil to that of seawater

$g$  = force of gravity

$L$  = original volume of oil spilled

$t$  = time

When the oil film thickness becomes equal to the viscous layer in the water, a transition occurs from the gravity-inertial regime to the gravity-viscous regime. This viscous spreading is described by

$$\text{Radius of oil slick} = R = k_5 \left( \frac{\Delta g L^2 t^{3/2}}{\nu^{1/2}} \right)^{1/6} \quad (84.30)$$

where  $k_5$  is the nondimensional coefficient determined to be about 1.45,  $\nu$  is the kinematic viscosity of water,  $\Delta$  is the ratio of the difference between density of seawater and oil,  $L$  is the original volume of spilled oil, and  $t$  is the time.

The last phase, the surface tension regime, occurs when the oil film thickness drops below a critical level, which is a function of the net surface tension, the mass densities of the oil and the water, and the force of gravity. The surface tension spread is described by

$$R = k_6 \left( \frac{\sigma^2 t^3}{\rho^2 \nu} \right)^{1/4} \quad (84.31)$$

$k_6$  = 2.30, experimentally determined

$\sigma$  = surface tension

$\rho$  = density of water

For large spills, on the order of 10 000 tons, inertial and viscous spreading will dominate for about the first week, with the surface tension spread controlling thereafter.

Although the exact mechanisms that cause the termination of spreading are unknown, the terminal areas of several oil slicks have been observed and used to determine an analytical relationship for the maximum area of a given oil spill based on the properties of the oil. This is described by

$$A_T = K_a \left( \frac{\sigma^2 V^6}{\rho^2 \nu D^3 s^6} \right)^{1/8} \quad (84.32)$$

$K_a$  = undetermined constant or order unit

$V$  = volume of oil that can be dissolved in this layer

$D$  = diffusivity

$s$  = solubility of the significant oil fractions in the water

In addition, the area covered by the oil slick is not allowed to exceed  $A_T$ ; therefore, spreading is terminated at the time

$$t = \left( \frac{V\rho}{s\sigma} \right)^{1/2} \left( \frac{\nu}{D} \right)^{1/4} \left( \frac{K_a}{\pi k_6^2} \right)^{2/3} \quad (84.33)$$

Oil may be set up by wind and current against a barrier; any containment device must take the setup estimates into account. There are a number of containment devices (barriers) that prevent oil from spreading. Most mechanical-type oil containment barriers fail in wave heights greater than 2 ft, when the wave steepness ratio is greater than 0.08, and in currents normal to the barrier greater than about 0.7 knots.

Oil may also be removed from the water surface by skimming devices. Most mechanical skimming devices have only been able to work in waves less than 2 to 3 ft in height, in moderate currents.

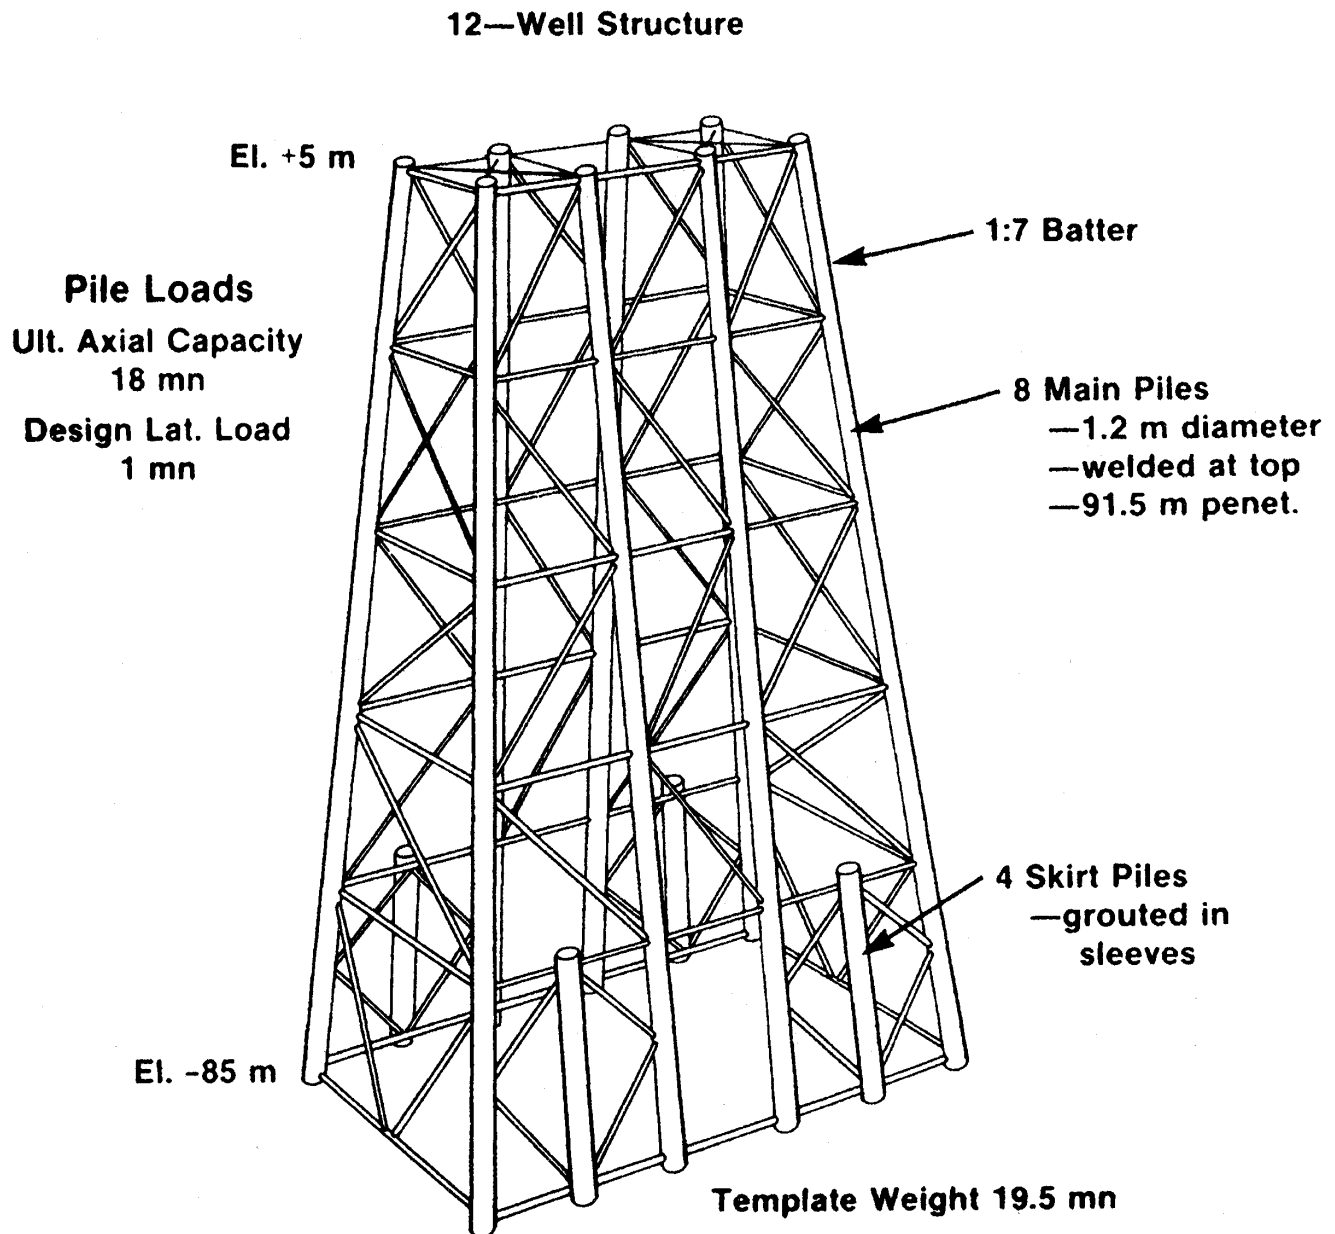

## 84.9 Offshore Structures

---

Many types of offshore structures have been developed since 1947, when the first steel structure was installed in 18 feet of water. Since that time over 4100 template-platforms have been constructed on the U.S. continental shelf in water depths less than 600 feet (Fig. 84.13).

Deep-water marine structures include gravity platforms, fixed platforms, guyed tower, tension-leg platform, and a buoyant compliant tower (Fig. 84.14).

**Figure 84.13** Template-type pile foundation structure. (Source: Young, A. G. 1991. Marine foundation studies. In *Handbook of Coastal and Ocean Engineering, Volume 2*, ed. J. B. Herbich. Gulf, Houston, TX. Copyright 1990 by Gulf Publishing Company, Houston, TX. Used with permission. All rights reserved.)

**Figure 84.14** Range of water depths for various types of deep-water marine structures. (Source: Marine Board, National Research Council. 1989. *Our Seabed Frontier*<sup>34</sup>*Challenges and Choices*. National Academy Press, Washington, DC.)

Wave forces on certain types of offshore platforms are computed by the Morrison equation, which is written as the sum of two individual forces, inertia and drag. The equation may be written as

$$f(t) = C_M \rho \frac{\pi}{4} D^2 \dot{u}(t) + \frac{1}{2} C_D \rho D |u(t)| u(t) \quad (84.34)$$

The force,  $f$ , as a function of time,  $t$ , is written as a function of the horizontal water particle velocity,  $u(t)$ , and the horizontal water particle acceleration,  $\dot{u}(t)$ , at the axis of the cylinder, and is dependent on the water density,  $\rho$ . The quantities  $C_M$  and  $C_D$  are defined as the inertia (or mass) coefficient and the drag coefficient, respectively.

The design and dynamic analysis of offshore platforms, which include jacket structures, topside structures, pile foundations, and dynamic analysis, may be found in Hsu [1991]; discussion of wave forces is given in Chakrabarti [1991].

## Defining Terms

**Armor unit:** A relatively large quarry stone or concrete shape that is selected to fit specified geometric characteristics and density. It is usually of nearly uniform size and usually large enough to require individual placement. In normal cases it is used as primary wave protection and is placed in thicknesses of at least two units.

**Artificial nourishment:** The process of replenishing a beach with material (usually sand)

obtained from another location.

**Attenuation:** (1) A lessening of the amplitude of a wave with distance from the origin. (2) The decrease of water-particle motion with increasing depth. Particle motion resulting from surface oscillatory waves attenuates rapidly with depth and practically disappears at a depth equal to a surface wavelength.

**Bar:** A submerged or emerged embankment of sand, gravel, or other unconsolidated material built on the sea floor in shallow water by waves and currents.

**Diffraction:** The phenomenon by which energy is transmitted laterally along a wave crest. When a part of a train of waves is interrupted by a barrier, such as a breakwater, the effect of diffraction is manifested by propagation of waves into the sheltered region within the barrier's geometric shadow.

**Dunes:** (1) Ridges or mounds of loose, wind-blown material, usually sand. (2) Bed forms smaller than bars but larger than ripples that are out of phase with any water-surface gravity waves associated with them.

**Ebb current:** The tidal current away from shore or down a tidal stream, usually associated with the decrease in height of the tide.

**Fetch:** The area in which seas are generated by a wind having a fairly constant direction and speed. Sometimes used synonymously with *fetch length* or *generating area*.

**Flood current:** The tidal current toward shore or up a tidal stream, usually associated with an increase in the height of the tide.

**Groin:** A shore protection structure built (usually perpendicular to the shoreline) to trap littoral drift or retard erosion of the shore.

**Harbor oscillation (harbor surging):** The nontidal vertical water movement in a harbor or bay. The vertical motions are usually low, but when oscillations are excited by a tsunami or storm surge, they may be quite large. Variable winds, air oscillations, or surf beat also may cause oscillations. See **seiche**.

**Hurricane:** An intense tropical cyclone in which winds tend to spiral inward toward a core of low pressure, with maximum surface wind velocities that equal or exceed 33.5 meters per second (75 mph or 65 knots) for several minutes or longer at some points. *Tropical storm* is the term applied if maximum winds are less than 33.5 meters per second.

**Mean high water (MHW):** The average height of the high waters over a 19-year period. For shorter periods of observations, corrections are applied to eliminate known variations and reduce the results to the equivalent of a mean 19-year value.

**Probable maximum water level:** A hypothetical water level (exclusive of wave run-up from normal wind-generated waves) that might result from the most severe combination of hydrometeorological, geoseismic, and other geophysical factors and that is considered reasonably possible in the region involved, with each of these factors considered as affecting the locality in a maximum manner. This level represents the physical response of a body of water to maximum applied phenomena such as hurricanes, moving squall lines, other cyclonic meteorological events, tsunamis, and astronomical tide, combined with maximum probable ambient hydrological conditions such as wave setup, rainfall, runoff, and river flow. It is a water level with virtually no risk of being exceeded.

**Refraction:** (1) The process by which the direction of a wave moving in shallow water at an angle

to the contours is changed: The part of the wave advancing in shallower water moves more slowly than that part still advancing in deeper water, causing the wave crest to bend toward alignment with the underwater contours. (2) The bending of wave crests by currents.

**Scour:** Removal of underwater material by waves and currents, especially at the base or toe of a shore structure.

**Seawall:** A structure separating land and water areas, primarily designed to prevent erosion and other damage due to wave action.

**Seiche:** (1) A standing wave oscillation of an enclosed water body that continues, pendulum fashion, after the cessation of the originating force, which may have been either seismic or atmospheric. (2) An oscillation of a fluid body in response to a disturbing force having the same frequency as the natural frequency of the fluid system. Tides are now considered to be seiches induced primarily by the periodic forces caused by the sun and moon.

**Significant wave:** A statistical term relating to the one-third highest waves of a given wave group and defined by the average of their heights and periods. The composition of the higher waves depends upon the extent to which the lower waves are considered.

**Wave spectrum:** In ocean wave studies, a graph, table, or mathematical equation showing the distribution of wave energy as a function of wave frequency. The spectrum may be based on observations or theoretical considerations. Several forms of graphical display are widely used.

Citizens Gas and Coke Utility in Indianapolis, Indiana, which operates as the public Department of Utilities for the City, completed the construction of a \$35 million ammonia destruct/desulfurization facility. The ammonia destruct facility, the first phase of the project, was completed in 1990 and has eliminated more than 5000 pounds of ammonia per day that previously was discharged into the city's wastewater treatment plants. The ammonia destruct system is over 90% efficient. The ammonia molecule is destroyed at high temperature using nickel catalyst, and even the resulting hydrogen gas is used as an energy source for the Citizens Gas and Coke Utility coke oven batteries.

The second-phase of the project, the desulfurization plant, was completed in 1994. The plant eliminates over 4000 tons of hazardous waste each year. 99.99% pure elemental sulfur is recovered for sale. Shown above is the sulfur recovery section of the plant.

The ammonia destruct facility was the first of its kind in the Western Hemisphere, and coupled with its sister desulfurization facility, represents the only combination ammonia destruct/desulfurization facility like it in the world. (Photo Courtesy of Citizens Gas and Coke Utility.)

THE U.S. HAS LONG SINCE PASSED from being a "frontier society." In those times, the land, air, and water resources at our disposal seemed almost infinite. As this country moved through the Industrial Revolution, we utilized those resources as if they were, indeed, infinite in scope and automatically self-healing. Today we realize our natural resources are neither infinite in size nor totally self-healing from the insults of the pollutants we emit into the atmosphere, discharge into our water courses, or bury in our land. We are quickly realizing that the things we do on this earth in manufacturing, process operations, and in our daily lives must now have a component specifically related to minimizing the impact of these activities on the environment.

We must use the latest technologies to protect the atmosphere, our water resources, and the land we live on. Moreover, we must incorporate into our thinking an "environmental management system" (EMS) approach to everything we do. In process and manufacturing operations, we can no longer design from "cradle to grave"; rather, our design ethic must include a "cradle to cradle" concept. In other words, the product or process design pathway must include an environmental decision block where consideration is given to such things as use of nonhazardous materials; recycling or reuse of waste streams; and reuse of piece parts, fasteners, and so on. Ultimately,

everything we do and use will be given an end-use consideration, and the disposal concept will no longer exist. Cost savings will drive this new thinking. Companies now involved in EMS and this new way of designing are reporting significant cost savings as opposed to the expected negative economic impact of traditional environmental considerations.

On the horizon is a new international standard referred to as ISO 14 000, which is now in the development stage by a number of countries, including the U.S. This new standard, when it is published, will mandate a total EMS approach to the development of exported products and processes. Ideally, in the years to come, an environmental ethic will permeate everything we do, not just in consumer recycling, but in the way commercial and industrial products and processes are designed, manufactured, used, and disposed of—or, I should say, reused.

Microbial Contamination • Chemical Contamination • Aesthetic Aspects of Water Quality

## 85.2 Drinking Water Regulations

Total Coliform Rule • Surface Water Treatment Rule • Lead and Copper Rule • Future Regulations

## 85.3 Water Treatment Processes

Coagulation • Sedimentation • Filtration • Disinfection

**Appiah Amirtharajah**

*Georgia Institute of Technology*

**S. Casey Jones**

*Georgia Institute of Technology*

The goal of drinking water treatment is to provide a water supply that is both safe and pleasing to consume. To meet this goal, conventional water treatment plants utilize the physicochemical processes of coagulation, sedimentation, filtration, and disinfection. The following sections will review the important aspects of water quality, drinking water regulations, and the main processes in conventional water treatment.

## 85.1 Water Quality

---

### Microbial Contamination

Microorganisms present in water supplies can cause immediate and serious health problems. Infections by bacteria, viruses, and protozoa usually cause gastrointestinal distress; however, some, such as the bacteria *Vibrio cholerae*, can result in death. The protozoa *Giardia lamblia* and *Cryptosporidium* form chlorine resistant cysts, and just a few cysts can cause disease. Beyond these, a vast number of pathogenic organisms exist, and water suppliers cannot feasibly monitor for all of them. Therefore, they monitor for **indicator organisms** instead. The total coliform group of bacteria is the most common indicator. Unfortunately, some pathogens (e.g., viruses and protozoa) are more resistant to conventional water treatment processes than are total coliforms.

## Chemical Contamination

### Inorganic Contaminants

Toxic metals and other inorganic compounds contaminate water supplies from both human-made and natural sources. Nitrates, common in groundwaters, cause methemoglobinemia or "blue-baby syndrome" in infants. Fluoride, added by many water suppliers in small doses to prevent tooth decay, causes a weakening of the bones called *skeletal fluorosis* at concentrations above 4 mg/L. Radon, a naturally occurring radionuclide, may cause lung cancer from long-term exposures in the air after being released from water.

### Organic Contaminants

Most organic contaminants are either volatile organic chemicals (VOCs) or synthetic organic chemicals (SOCs). Dissolved VOCs transfer to the gas phase when exposed to the atmosphere. They are typically found in groundwaters that have been contaminated by leaks from industrial storage facilities. Examples include trichloroethylene (TCE) and tetrachloroethylene (PCE), both probable carcinogens. SOCs are more soluble in water and include pesticides and pollutants from leaking underground gasoline storage tanks, such as benzene and toluene. The health effects of SOCs range from central nervous system damage to cancer.

## Aesthetic Aspects of Water Quality

### Color and Turbidity

Inorganic metals such as iron and organic compounds such as natural organic matter (NOM) cause color. In addition to being aesthetically undesirable, color in the form of NOM is a precursor to the formation of **disinfection by-products (DBPs)**, which may cause cancer. Turbidity is the cloudiness of a water and is determined by measuring the amount of light scattered by suspended particles in water. The unit of turbidity is the nephelometric turbidity unit (NTU). Although not a direct threat to health, turbidity decreases the efficiency of disinfection, and particles that cause turbidity can transport harmful chemicals through a treatment plant.

### Taste and Odor

Zinc, copper, iron, and manganese can be detected by taste at concentrations of 1 mg/L. Hydrogen sulfide, a common contaminant in groundwaters, is detectable at concentrations of 100 ng/L. Many tastes and odors in surface waters result from biological activity of filamentous bacteria and blue-green algae. They produce geosmin and methylisoborneol (MIB), which cause an earthy or musty smell. Both are detected at concentrations of 10 ng/L [[Tate and Arnold, 1990](#)].

### Alkalinity

**Alkalinity** is a measure of the buffering capacity of a water. Alkalinity determines the magnitude of pH changes during coagulation and affects the solubility of calcium carbonate in the distribution system. In natural waters the carbonate system dominates alkalinity. In such systems, bicarbonate ( $\text{HCO}_3^-$ ), carbonate ( $\text{CO}_3^{2-}$ ), and hydroxide ( $\text{OH}^-$ ) ions are the major species of alkalinity.

## Temperature and pH

Temperature and pH affect coagulation, disinfection, and corrosion control. Equilibrium constants and reaction rates vary with temperature. The hydrogen ion concentration, measured as pH, is an important chemical species in these processes. Furthermore, the density and viscosity of water vary with temperature; thus, it is an important variable in the design of mixing, flocculation, sedimentation, and filtration process units.

## 85.2 Drinking Water Regulations

In the U.S., the Environmental Protection Agency (EPA) sets standards to regulate drinking water quality. Typically, the EPA establishes a maximum contaminant level goal (MCLG) and a maximum contaminant level (MCL) for each contaminant. An MCLG is the level at which no adverse health effect occurs. An MCL is set as close to the MCLG as is economically and technically feasible. A primary MCL is a legally enforceable standard based on a potential health risk. A secondary MCL is a nonenforceable standard based on a potential adverse aesthetic effect. [Table 85.1](#) lists some MCLs of important drinking water contaminants.

**Table 85.1** Some Drinking Water Standards

Contaminant	MCL <sup>1</sup>	Sources
Arsenic	0.05	Geological, pesticide residues; industrial waste and smelter operations
Asbestos	7 mfl <sup>2</sup>	Natural mineral deposits; also in asbestos/cement pipe
Benzene	0.005	Fuel (leaking tanks); solvent commonly used in manufacture of industrial chemicals, pharmaceuticals, pesticides, paints, and plastics
Cadmium	0.005	Natural mineral deposits; metal finishing; corrosion product plumbing
Chromium	0.1	Natural mineral deposits; metal finishing; textile, tanning, and leather industries
Mercury	0.002	Industrial/chemical manufacturing; fungicide; natural mineral deposits
Nitrate (as N)	10	Fertilizers, feedlots, sewage; naturally in soil, mineral deposits
Polychlorinated biphenyls (PCBs)	0.0005	Electric transformers, plasticizers; banned in 1979
Radium 226/228	5 pCi/L <sup>3</sup>	Radioactive waste; geological/natural
Tetrachloroethylene (PCE)	0.005	Dry cleaning; industrial solvent
Toluene	1	Chemical manufacturing; gasoline additive; industrial solvent
Trichloroethyle (TCE)	0.005	Waste from disposals of dry cleaning materials and manufacturing of pesticides, paints, waxes, and varnishes; paint stripper; metal degreaser

<sup>1</sup>Maximum contaminant level, in milligrams per liter unless otherwise noted.

<sup>2</sup>Million fibers per liter, with fiber length greater than 10  $\mu\text{m}$ .

<sup>3</sup>Picocurie (pCi) is the quantity of radioactive material producing 2.22 nuclear transformations per minute.

Source: U.S. Environmental Protection Agency, 1991. *Fact Sheet: National Primary Drinking Water Standards*.

In 1974 the U.S. Congress enacted the Safe Drinking Water Act (SDWA), which was the first law to cover all public drinking water utilities in the U.S. In 1986 Congress amended the SDWA, and, as a result, in 1989 the EPA promulgated the Surface Water Treatment Rule (SWTR). The SWTR established standards for all water treatment plants that use surface water as a source. Subsequently, the EPA also modified the standards for total coliforms, lead, and copper.

## Total Coliform Rule

The total coliform rule set the MCLG for total coliforms at zero. The MCL is currently based on a presence-absence test. Utilities must monitor the distribution system for total coliforms taking a specified number of samples based on the population served by the utility. No more than 5.0% of the samples taken per month should be positive for total coliform. Small systems taking fewer than forty samples per month can have no more than one positive sample.

## Surface Water Treatment Rule

### Turbidity

Filtered water turbidity must never exceed 5 NTU and should meet the MCL in 95% of the samples taken either continuously or every four hours. The MCL is either 0.5 or 1.0 NTU depending on the type of filter used. For conventional and direct filtration the MCL is 0.5 NTU.

### Disinfectant Residual

The disinfectant concentration or residual entering the distribution system cannot be less than 0.2 mg/L for more than four hours. A disinfectant residual must be detectable in 95% of the samples taken monthly at consumers' taps for two consecutive months.

### Treatment Techniques

Instead of setting an MCL for the pathogens *Giardia lamblia* and viruses, the U.S. EPA specified a treatment technique, that is, disinfection and possibly filtration. To ensure the required disinfection, utilities must determine *CT* values, where *C* is the concentration of disinfectant and *T* is the contact time between disinfectant and water. The *CT* value required for *Giardia lamblia* corresponds to 99.9% (3 log) removal or inactivation, and for viruses it corresponds to 99.99% (4 log) removal or inactivation. Filtration must be practiced unless the utility demonstrates that adequate treatment occurs without it and that the water source is free from significant contamination. Conventional filtration plants receive a *CT* credit of 2.5 log removal for *Giardia lamblia* and 2.0 log removal of viruses.

## Lead and Copper Rule

The EPA also specified a treatment technique for lead and copper. However, in this case, the treatment technique need not be implemented unless an action level is exceeded. Action levels of 0.015 mg/L for lead and 1.3 mg/L for copper are set at the consumer's tap. If these action levels are exceeded during an extensive sampling program, the utility must perform a corrosion control study to determine the best technique to minimize the corrosivity of the water entering the distribution system.

## Future Regulations

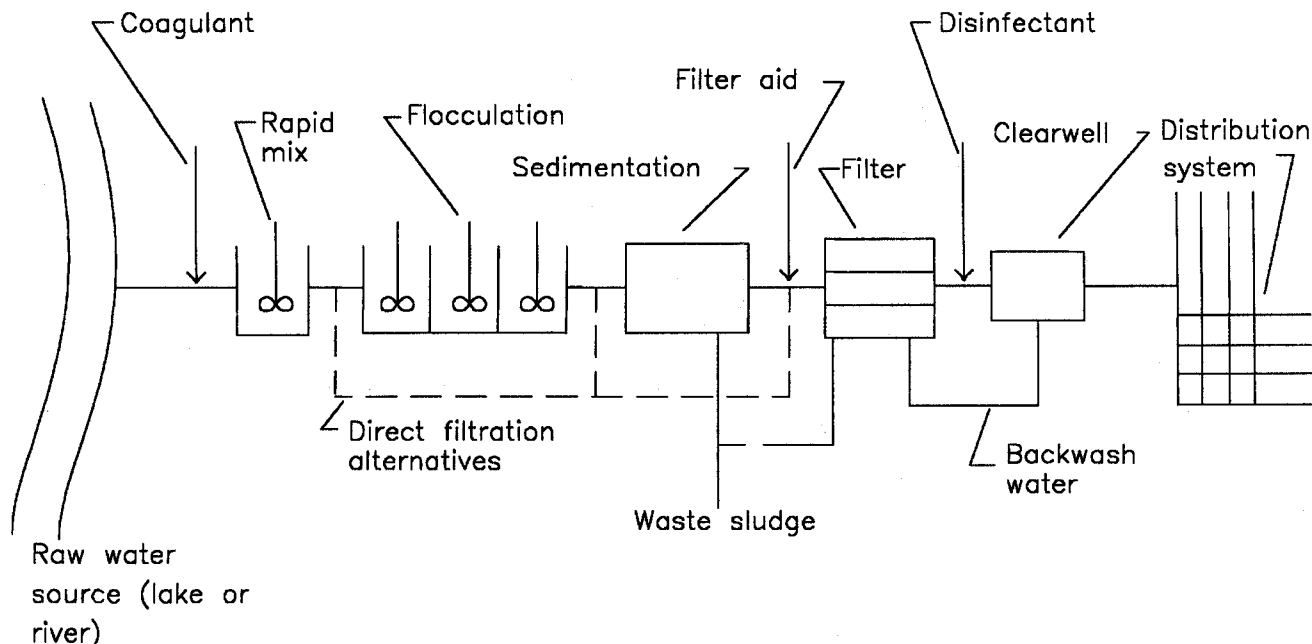

At present, no regulation exists regarding the protozoa *Cryptosporidium*, in part because of a lack of technical information about the organism. The EPA is in the process of collecting this information. Regulations are also expected in the near future for DBPs. The EPA is expected to lower the MCLs for total trihalomethanes (THMs) from 0.10 mg/L to 0.08 mg/L and to set MCLs for total haloacetic acids at 0.04 mg/L. In addition, removals of total organic carbon, a precursor to DBP formation, are to be specified under an Enhanced Surface Water Treatment Rule.

## 85.3 Water Treatment Processes

---

Figure 85.1 shows the treatment processes in a conventional surface water treatment plant. After being withdrawn from a source (lake or river), raw water is a suspension of small, stable colloidal particles whose motions are governed by molecular diffusion. In coagulation these particles are destabilized by the addition of a coagulant during rapid mixing. Flocculation promotes the collisions of these unstable particles to produce larger particles called *flocs*. In sedimentation, these flocs settle under the force of gravity. The particles that do not settle are removed during filtration. A disinfectant such as chlorine is then added, and, after a certain amount of contact time, the treated water is distributed to consumers. Direct filtration plants omit the sedimentation and occasionally the flocculation processes. These plants are suitable for raw waters with low to moderate turbidities and low color. The following sections describe the underlying theory and design of each of the major processes: coagulation, sedimentation, filtration, and disinfection.

**Figure 85.1** Schematic of a conventional water treatment plant.

## Coagulation

In coagulation, small particles combine into larger particles. Coagulation consists of three separate and sequential processes: coagulant formation, particle destabilization, and interparticle collisions. The first two steps occur during rapid mixing, whereas the third occurs during flocculation. In natural waters, particles (from 10 nm to 100  $\mu\text{m}$  in size) are stable, because they have a negative surface charge.

### Mechanisms of Destabilization

The possible mechanisms of particle destabilization are double layer compression, polymer bridging, **charge neutralization**, and **sweep coagulation**. In water treatment the last two mechanisms predominate; however, when organic polymers are used as coagulants, polymer bridging can occur. In charge neutralization the positively charged coagulant, either the hydrolysis species of a metal salt (alum or ferric chloride) or polyelectrolytes, adsorbs onto the surface of the negatively charged particles. As a result, the particles have no net surface charge and are effectively destabilized. In sweep coagulation a metal salt is added in concentrations sufficiently high to cause the precipitation of a metal hydroxide (e.g., aluminum hydroxide). The particles are enmeshed in the precipitate, and it "sweeps" the particles out of the water as it forms and settles.

### Solution Chemistry

With metal salt coagulants, the mechanism of coagulation is determined by the coagulant dose and the pH of the equilibrated solution. The most common coagulant is alum  $[\text{Al}_2(\text{SO}_4)_3 \cdot 14.3 \text{ H}_2\text{O}]$ . The alum coagulation diagram, shown in Fig. 85.2, indicates the regions where each mechanism dominates. A similar diagram exists for ferric chloride [Amirtharajah and O' Melia, 1990].

Important considerations in using the alum coagulation diagram are that the boundaries of the restabilization zone vary with the surface area of the raw water particles and that significant concentrations of NOM rather than turbidity can control the alum dose required for effective treatment.

**Figure 85.2** The alum coagulation diagram that defines the mechanism of coagulation based on pH and alum dose. (Source: Amirtharajah, A. and Mills, K. M. 1982. Rapid mix design for mechanisms of alum coagulation. *J. AWWA*. 74(4):210–216.)

### Rapid Mix Design

At a fundamental level the rapid-mixing unit provides encounters between molecules and particles in the source water and the coagulant species. These encounters are controlled by the hydrodynamic parameters and geometry of the mixer, molecular properties of the source water, and the kinetics of the coagulation reactions. Research indicates that coagulation by sweep coagulation is insensitive to mixing intensity. Although its applicability is questionable on theoretical grounds, the **G-value** is widely used to represent mixing intensity in both rapid mix and flocculation units. The G-value is computed as

$$G = \sqrt{\frac{P}{\mu V}} = \sqrt{\frac{\varepsilon}{\nu}} \quad (85.1)$$

where  $G$  is the velocity gradient ( $\text{s}^{-1}$ ),  $P$  is the *net* power input to the water (W),  $\mu$  is the dynamic viscosity of water ( $\text{Ns/m}^2$ ),  $V$  is the mixing volume ( $\text{m}^3$ ),  $\varepsilon$  is the rate of energy dissipation per mass of fluid ( $\text{W/kg}$ ), and  $\nu$  is the kinematic viscosity ( $\text{m}^2/\text{s}$ ). Mixing time,  $t$ , is an important design parameter, and it can vary from less than one second in some in-line mixers to over a minute in back-mix reactors. In general, short times ( $< 1$  s) are desired for the charge neutralization mechanism and longer times (10 to 30 s) for sweep coagulation.

### Flocculator Design

In flocculation, physical processes transform smaller particles into larger aggregates or flocs. Interparticle collisions cause the formation of flocs, and increased mixing with increased velocity gradients accelerates this process. However, if the mixing intensity is too vigorous, turbulent shear forces will cause flocs to break up. Studies of the kinetics of flocculation [Argaman and Kaufman, 1970] indicate that a minimum time exists below which no flocculation occurs regardless of mixing intensity and that using tanks in series significantly reduces the overall time required for the same degree of flocculation. Figure 85.3 illustrates these two conclusions. In current designs,  $G$ -values are tapered from one tank to the next with the highest  $G$ -value in the first tank and decreasing in each successive compartment.  $G$ -values are between 60 and  $10 \text{ s}^{-1}$ , and total detention times are close to 20 minutes.

### Sedimentation

During sedimentation, gravity removes the flocs produced during the preceding flocculation process. These flocs continue to aggregate as they settle, and, as a result, experimental techniques are required to describe their settling behavior. Rectangular sedimentation basins are the most common in water treatment practice. Designs are based on the overflow rate, which is the flow rate divided by the surface area. The overflow rate indicates the settling velocity of the discrete (nonflocculant) particles that are removed with 100% efficiency. Typical overflow rates are 1.25 to 2.5 m/h. Plate and tube settlers are often added to the last two thirds of a basin to increase the overflow rate by a factor of 3.

### Filtration

In the U.S., the most common filters are dual-media filters, in which water flows by gravity through a porous bed of two layers of granular media. The top layer is anthracite coal, and the bottom layer is sand. Filters are operated until one of two criteria is exceeded—the effluent turbidity standard or the allowable head loss through the filter. The filters are cleaned by backwashing to remove the particles that have been collected on the filter media.

The removal of particles in a dual-media filter occurs within the pores of the filter and is mediated by transport mechanisms that carry small particles across fluid streamlines to distances

**Figure 85.3** A graph illustrating the benefit of tanks in series for flocculation. (Source: Argaman, Y. and Kaufman, W. J. 1970. Turbulence and flocculation. *ASCE J. Sanitary Engineering Div.* 96(SA2):223–241.)

close to the filter grains (also called *collectors*). When particles are very close to the collectors, short-range surface forces cause the collector to capture the particle. The dominant transport mechanisms in water filtration are diffusion and sedimentation. Diffusion is transport resulting from random Brownian motion by bombardment of the particle by molecules of water. Diffusion is increasingly important for particles less than 1  $\mu\text{m}$  in size. Sedimentation is due to the force of gravity and the associated settling velocity of the particle, which causes it to cross streamlines and reach the collector. This mechanism becomes increasingly important for particles greater than 1  $\mu\text{m}$  in size (for a size range of 5 to 25  $\mu\text{m}$ ). The combination of these two mechanisms results in a minimum net transport efficiency for a size of approximately 1  $\mu\text{m}$ . It is interesting to extrapolate this result to two important microbial contaminants. Cysts of *Giardia lamblia*, with dimensions of 10 to 15  $\mu\text{m}$ , are probably removed by the sedimentation mechanism, whereas *Cryptosporidium*, with a dimension close to 3 to 5  $\mu\text{m}$ , is probably close to the minimum net transport efficiency. Unfortunately, a theory of filtration that is sufficiently general and predictive does not yet exist. Therefore, designers must rely on empirical evidence from pilot-scale tests for guidance.

### **Chemical Pretreatment**

Evidence clearly shows that chemical pretreatment for particle destabilization is the most important variable affecting filtration efficiency. Plant-scale studies have shown that filtration rates between 5 and 15 m/h can treat water equally well given adequate chemical pretreatment.

### **Initial Degradation and Filter Ripening**

Just after backwashing, filters typically have poor effluent quality, and the quality improves during the course of the run. This improvement with time is called *filter ripening*. Studies have shown that greater than 90% of the particles passing through a well-operated filter do so during the initial stages of filtration. If the duration of filter ripening is short, then the initial filter effluent can be wasted until the effluent turbidity reaches a desired level. Particles removed during a filter run function as collectors themselves, resulting in filter ripening.

### **Rate Changes**

Any rate changes during filtration cause a significant deterioration of the effluent quality. The degradation in quality can be quantitatively correlated directly with the magnitude of the rate change and inversely with the duration of the rate change. This fact forms the basis for the superiority of variable declining-rate filters over the traditional constant-rate filters. In variable declining-rate filters the rate through the filter is controlled by the hydraulics of the filter; therefore, clean filters have a higher rate than dirty ones. However, in constant-rate filters, the rate is controlled by a mechanically actuated valve in the effluent piping. Each time the valve opens, the rate through the filter changes slightly, possibly causing a poorer effluent quality. With well-destabilized suspensions, the difference in effluent quality from these systems is minimal [Amirtharajah, 1988].

### **Polymers**

Polyelectrolytes can assist in improving effluent quality when added in small amounts as a filter

aid (0.1–1.0 mg/L) just prior to filtration. Polymers cause the attachment forces to be stronger, and, therefore, backwashing is more difficult. Polymers are important in direct-filtration plants where sedimentation and possibly flocculation are not included. However, polymers are not a substitute for adequate pretreatment.

### **Backwashing**

In the U.S., filters have traditionally been backwashed by fluidizing the filter media for a specific period of time. However, very few particle contacts occur between fluidized particles. Hence, particulate fluidization with water alone is an intrinsically weak process. Air scour with subfluidization water wash causes abrasions between particles throughout the depth of the bed. Surface wash causes collisions at the top of the bed. Both processes are effective auxiliaries for cleaning. When polymers are used, air scour or surface wash is necessary.

### **Disinfection**

A variety of disinfectants are available in water treatment, including chlorine, chloramines, chlorine dioxide, and ozone. In the U.S., however, chlorine is the most common disinfectant. Chlorine gas is added to water to form hypochlorous acid (HOCl). At pHs between 6 and 9, HOCl dissociates to form the hypochlorite ion ( $\text{OCl}^-$ ) and hydrogen ion ( $\text{H}^+$ ). HOCl has the greatest disinfection power. The extent of disinfection in a water treatment plant is determined by computing *CT* values as mentioned in section 85.2. The *CT* value required varies with chlorine concentration, pH, and temperature.

Although increasing the *CT* value may provide a large factor of safety against microbial contamination, disinfection causes the formation of disinfection by-products (DBPs), which are suspected carcinogens. DBPs result from reactions between disinfectants and NOM, which is ubiquitous in natural waters. The most common DBPs from chlorine are the THMs: chloroform, bromodichloromethane, dibromochloromethane, and bromoform. Other technologies such as membranes and adsorption will be used in the future, together with the traditional water treatment processes, to reduce the threat from both microorganisms and DBPs.

### **Defining Terms**

**Alkalinity:** The ability of a water to resist changes in pH. Includes the following species: carbonate, bicarbonate, and hydroxide.

**Charge neutralization:** A mechanism of coagulation in which positively charged coagulants adsorb to the surface of negatively charged colloids. The resulting colloids, with no net surface charge, are effectively destabilized.

**Disinfection by-products (DBPs):** By-products that result from the reactions of disinfectants such as chlorine with the natural organic matter that is present in all natural waters. DBPs such as trihalomethanes are suspected carcinogens.

**G-value:** A measure of mixing intensity in turbulent mixing vessels. Used in the design of both rapid mix and flocculation units.

**Indicator organisms:** Easily detectable organisms that act as a surrogate for water-borne

pathogens. Although not pathogenic themselves, indicators are present in the same environs as pathogens in larger concentrations.

**Sweep coagulation:** A mechanism of coagulation in which particles are enmeshed in a precipitate of metal hydroxide, such as aluminum hydroxide.

*University of Central Florida*

Air pollution is defined as contamination of the atmosphere with solid particles, liquid mists, or gaseous compounds in concentrations that can harm people, plants, or animals, or reduce environmental quality. Particulate matter (PM) constitutes a major class of air pollution. Ambient (outdoor) air quality standards exist for particulate matter less than  $10\ \mu\text{m}$  (PM-10), and many industries have emission limits on total PM. Particles have various shapes, different chemical and physical properties, and a wide range of sizes—from less than  $0.01\ \mu\text{m}$  to over  $100\ \mu\text{m}$  in **aerodynamic diameter**. The major gaseous pollutants that are emitted into the air include sulfur oxides, nitrogen oxides, carbon monoxide, and volatile organic compounds (such as petroleum fuels and organic chemicals). Major sources of air pollution include combustion processes (especially fossil fuel power plants), motor vehicles, and the materials processing and petrochemical industries.

## **86.1 Control of Particulate Matter**

---

Control of PM involves separation and removal of the PM from a flowing stream of air. A control device is chosen based on the size and properties (density, corrosivity, reactivity) of the particles, the chemical and physical characteristics of the gas (flow rate, temperature, pressure, humidity, chemical composition), and the collection efficiency,  $E$ , desired. The calculation of  $E$  is based on the fraction of mass removed:

$$E = (M_i - M_e)/M_i \quad (86.1)$$

where  $E$  is the collection efficiency (fraction),  $M$  is the mass flow rate of the pollutant (g/s), and  $i$

and  $e$  are subscripts indicating the input or exit stream. The efficiency of most devices is a strong function of particle size, decreasing rapidly as particle size decreases.

A key operating parameter of most control devices is the pressure drop ( $\Delta P$ ). In general, to increase efficiency of a device, more energy must be expended, which often shows up as  $\Delta P$  through the system. But moving the air through that  $\Delta P$  can account for a major portion of the operating cost. The fan power required is given by

$$W = Q\Delta P/\eta \quad (86.2)$$

where  $W$  is the power (kW),  $Q$  is the volumetric flow rate ( $\text{m}^3/\text{s}$ ),  $\Delta P$  is the pressure drop (kPa), and  $\eta$  = fan/motor efficiency.

Cyclones are moderate-efficiency mechanical separators that depend on centrifugal force to separate PM from the air stream. These precleaners are typically much less expensive than the more efficient devices discussed herein: electrostatic precipitators, fabric filters, and wet scrubbers [Cooper and Alley, 1994].

## Electrostatic Precipitators

An electrostatic precipitator (ESP) applies electrical force to separate PM from the gas stream. A high voltage drop is established between the electrodes (many sets of large plates in parallel, with vertical wires in between). The particles being carried by the gas flowing between the electrodes acquire a charge, and then are attracted to an oppositely charged plate, while the cleaned gas flows through the device. The plates are cleaned by rapping periodically, and the dust is collected in hoppers in the bottom of the device.

The classic Deutsch equation (first published in 1922) is used for preliminary design and performance evaluation:

$$E = 1 - \exp(-wA/Q) \quad (86.3)$$

where  $w$  is the drift velocity,  $A$  is the collection area, and  $Q$  is the gas volumetric flow rate, all in a consistent set of units.

In design, this equation is used to estimate the total plate area needed, and thus the size and cost of the ESP. The drift velocity,  $w$ , is a key parameter, and is a function of many variables (including the particle's diameter and resistivity, the electrical field strength, and the gas viscosity). Ranges of values of some operating and design parameters are given in Table 86.1.

The resistivity of the dust is a measure of its resistance to electrical conduction. Resistivity is very important to the design and operation of an ESP because (1) for different dusts, it can range over many orders of magnitude, and (2) for a given ESP, an increase in dust resistivity can decrease the drift velocity markedly, reducing the collection efficiency. Resistivity is also quite dependent on operating conditions. For example, for coal fly ash, the resistivity is a strong function of temperature and sulfur content of the coal (see Fig 86.1).

**Table 86.1** Ranges of Values for Key ESP Parameters

Parameter	Range of Values
Drift velocity $w_e$	1.0–10 m/min
Channel width $D$	15–40 cm
Specific collection area (plate area/gas flow)	0.25–2.1 m <sup>2</sup> /(m <sup>3</sup> /min)
Gas velocity $u$	1.2–2.5 m/s (70–150 m/min)
Aspect ratio $R$ (duct length/height)	0.5–1.5 (not less than 1.0 for $\eta > 99\%$ )
Corona power ratio $P_c/Q$ (corona power/gas flow)	1.75–17.5 W/(m <sup>3</sup> /min)
Corona current ratio $I_c/A$ (corona current/plate area)	50–750 $\mu\text{A}/\text{m}^2$
Power density versus resistivity	
Ash Resistivity, ohm-cm	Power Density, W/m <sup>2</sup>
$10^4$ – $10^7$	43
$10^7$ – $10^8$	32
$10^9$ – $10^{10}$	27
$10^{11}$	22
$10^{12}$	16
$10^{13}$	10.8
Plate area per electrical set $A_s$	460–7400 m <sup>2</sup>
Number of electrical sections $N_s$	
a. In the direction of gas flow	2–8
b. Total	1–10 bus sections/(1000 m <sup>3</sup> min)

**Figure 86.1** Variations of resistivity of coal fly ash. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control<sup>3</sup>/4A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

ESPs can be designed for efficiencies above 99% on many types of dry dusts or wet fumes, and can handle large volumes of air with very low  $\Delta P$  (less than 1 in. H<sub>2</sub>O). However, they tend to have high capital costs and take up a lot of space. The capital cost is a quantitative function of the plate area [Vatavuk, 1990].

## Fabric Filtration

A fabric filter (or baghouse) operates on the age-old principle of filtering air through a cloth to remove dust. The air passes through the cloth, leaving the dust behind and providing a clean air stream. The dust builds up as a loosely packed mat on the cloth until removed by shaking or blowing; the dust is then collected in hoppers. There are three main types of baghouses (classified by cleaning method): shaker, reverse-air, and pulse-jet. The first two types have parallel compartments; each compartment is taken off-line, cleaned, and returned to service sequentially while the filtering continues in the other compartments. The pulse-jet baghouse has only one compartment and the bags are cleaned in sequence by blasts of high-pressure air while filtration occurs.

The efficiency of a fabric filter system is extremely high and is almost independent of particle size because of the mat of dust that builds up on the cloth. However, as the thickness of the dust mat increases, so does the pressure drop. The baghouse  $\Delta P$  can be related to key operating variables through the filter drag model:

$$\Delta P/V = K_1 + K_2 W \quad (86.4)$$

where  $V$  is the filtering velocity (m/min),  $W$  is the fabric area dust density (g/m<sup>2</sup>), and  $K_1$  and  $K_2$  are empirical constants.  $V$  is defined simply as the volumetric gas flow rate divided by the on-line fabric area. The filtering velocity is a key design parameter; some values are shown in Table 86.2.

**Table 86.2** Recommended Filtering Velocities in Baghouses

Type of Dust	Filtering Velocity, m <sup>3</sup> /m <sup>2</sup> or m/min	
	Shaker or Reverse-Air	Pulse-Jet
Carbon, graphite, sugar, paint pigments	0.6–0.7	1.6–2.4
Glass, gypsum, limestone, quartz	0.8–0.9	3.0–3.5
Leather, tobacco, grains	1.0–1.1	3.8–4.2

Baghouses often achieve efficiencies above 99.9% on many types of dry dusts, are fairly flexible to operating changes, and can handle large volumes of air with reasonable pressure drops (6–12 in. H<sub>2</sub>O). However, they cannot handle highly humid gases, they have high capital costs, and they take up a lot of space. The capital cost is related quantitatively to the fabric area [Vatavuk, 1990].

## Wet Scrubbing

A wet scrubber employs the principle of impaction and interception of the particles by droplets of water. The larger, heavier droplets are then easily separated from the gas. Later, the particles are separated from the water stream, and the water treated prior to reuse or discharge. Spray chambers and venturi scrubbers are shown in Fig. 86.2.

**Figure 86.2** Common types of wet scrubbers. (a),(b) Spray chambers. (c) venturi scrubber with cyclone separator. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control—A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

During design, the collection efficiency of scrubbers can be related to a number of gas and liquid parameters through specific equations [Cooper and Alley, 1994]. Some of the most important variables include the liquid-to-gas ratio, the particle diameter, and, in a venturi, the gas velocity (which is directly related to pressure drop). In high-efficiency venturis,  $\Delta P$  can exceed 60 in. H<sub>2</sub>O. Extrapolating the performance of existing scrubbers can be done successfully using the contacting power approach. Contacting power is the energy expended per unit volume of gas treated and is related to collection efficiency through the following equation:

$$E = 1 - \exp [a(P_T)^b] \quad (86.5)$$

where  $P_T$  is the contacting power, kW/1000 m<sup>3</sup>/hr, and  $a$  and  $b$  are empirical constants.

Scrubbers have been used on a wide variety of dry or wet PM with efficiencies as high as 99%, while removing some soluble gases as well. Successful use of wet scrubbers also requires (1) good humidification of the gases prior to entering the scrubber, and (2) good separation of the water mist before exhausting the scrubbed gases. The disadvantages include potential for corrosion and the production of a liquid effluent that must be further treated. Capital costs of scrubbers have been related to the gas scrubbing capacity [Peters and Timmerhaus, 1991].

## 86.2 Control of Gaseous Pollutants

---

The most widely used processes for gaseous pollution control are absorption, adsorption, and incineration. The selection of the most practical process for a specific control application is based primarily on the chemical and physical properties of the pollutant to be removed. Some of the properties include vapor pressure, chemical reactivity, toxicity, solubility, flammability, and corrosiveness.

The following sections describe the design basics for each process and some typical applications. This section will refer to gases and vapors where gases are defined as substances far removed from the liquid state and vapors are substances existing near condensation conditions.

### Absorption Processes

Absorption refers to the transfer of a material from a gas or vapor mixture to a contacting liquid, which in most cases is either water or an aqueous alkaline or acidic solution. The contacting process is typically carried out in a cylindrical tower partially filled with an inert packing to provide a large wetted surface to contact the incoming gas stream. The process is shown schematically in Fig. 86.3, where  $V$  and  $L$  designate the flow rates in mol/h of the vapor and liquid streams. The concentrations of the liquid streams in mol fraction are designated by  $x$  and the vapor phase concentrations are designated by  $y$ . The height of the packed section is shown as  $Z_t$  and subscripts indicate the location of the variable,  $t$  referring to the top of the tower and  $b$  the bottom. The height of the packed bed is a function of the rate of transfer of material (which we will refer to as the solute) from the gas phase to the liquid phase. The transfer rate is dependent on the concentration driving force across the gas-liquid interface, which is approximated by  $(y - y^*)$ , where  $y^*$  is the

mol fraction of the solute in the gas phase that would be in equilibrium with the solute concentration in the bulk liquid phase. The following relationship referred to as the operating line for the tower is developed from an overall material balance around the tower by substituting the solute-free liquid and gas flow rates,  $L'$  and  $V'$ .

$$\frac{y}{1-y} = \frac{L'_m}{V'_m} \left( \frac{x}{1-x} \right) + \left[ \frac{y_b}{1-y_b} - \frac{L'_m}{V'_m} \left( \frac{x_b}{1-x_b} \right) \right] \quad (86.6)$$

where  $L'_m = L(1-x)$  and  $V'_m = V(1-y)$ . The operating line provides a relationship between the solute concentrations in the bulk liquid and gas phases. The overall driving force in the packed bed is shown graphically in Fig. 86.4, where the operating line is the upper curve and the lower line is the equilibrium line for the solute at the operating temperature and pressure of the tower ( $y^*$  vs.  $x$ ). These two lines will be linear only at low solute concentrations (lean gas mixtures), which fortunately is the case in many air pollution control applications.

**Figure 86.3** Schematic diagram of packed tower. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control<sup>3</sup>A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

**Figure 86.4** Operating and equilibrium lines. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control<sup>3</sup>4A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

The basic design equation for the height of the packed bed is

$$\left( \frac{K_y a}{G_{my}} \right) Z_t = \int_{y_t}^{y_b} \frac{dy}{(1-y)(y-y^*)} \quad (86.7)$$

The reciprocal of the term in parentheses, the overall mass transfer rate divided by the molar gas phase flux, is referred to as  $H_y$ , the height of a transfer unit based on the overall gas phase driving force. The value of the integral may then be thought of as the number of transfer units,  $N_{ty}$ . Hence,

Eq. (86.7) may also be written as

$$Z_t = (N_{ty})(H_y) \quad (86.8)$$

For the case of linear operating and equilibrium lines, the integral can be replaced with

$$\int_{y_t}^{y_b} \frac{dy}{(1-y)(y-y^*)} = \frac{y_b - y_t}{\Delta y_{LM}} \quad (86.9)$$

where

$$\Delta y_{LM} = (y - y^*)_{LM} = \frac{(y_b - y_b^*) - (y_t - y_t^*)}{\ln \left[ \frac{(y_b - y_b^*)}{(y_t - y_t^*)} \right]}$$

The value of  $H_y$  may be calculated from empirical relations that are presented in many texts or from experimental plots provided by manufacturers of tower packings. Typically,  $H_y$  values range from 1.0 to 3.0 feet.

The diameter of an absorption tower must be such that the gas and liquid velocities will provide good phase contact, but at the same time will not result in a gas pressure drop sufficient to cause liquid hold-up or flooding. Flooding–gas velocity correlations are also provided by suppliers of tower packing and are discussed in detail by McCabe *et al.* [1985] and Cooper and Alley [1994].

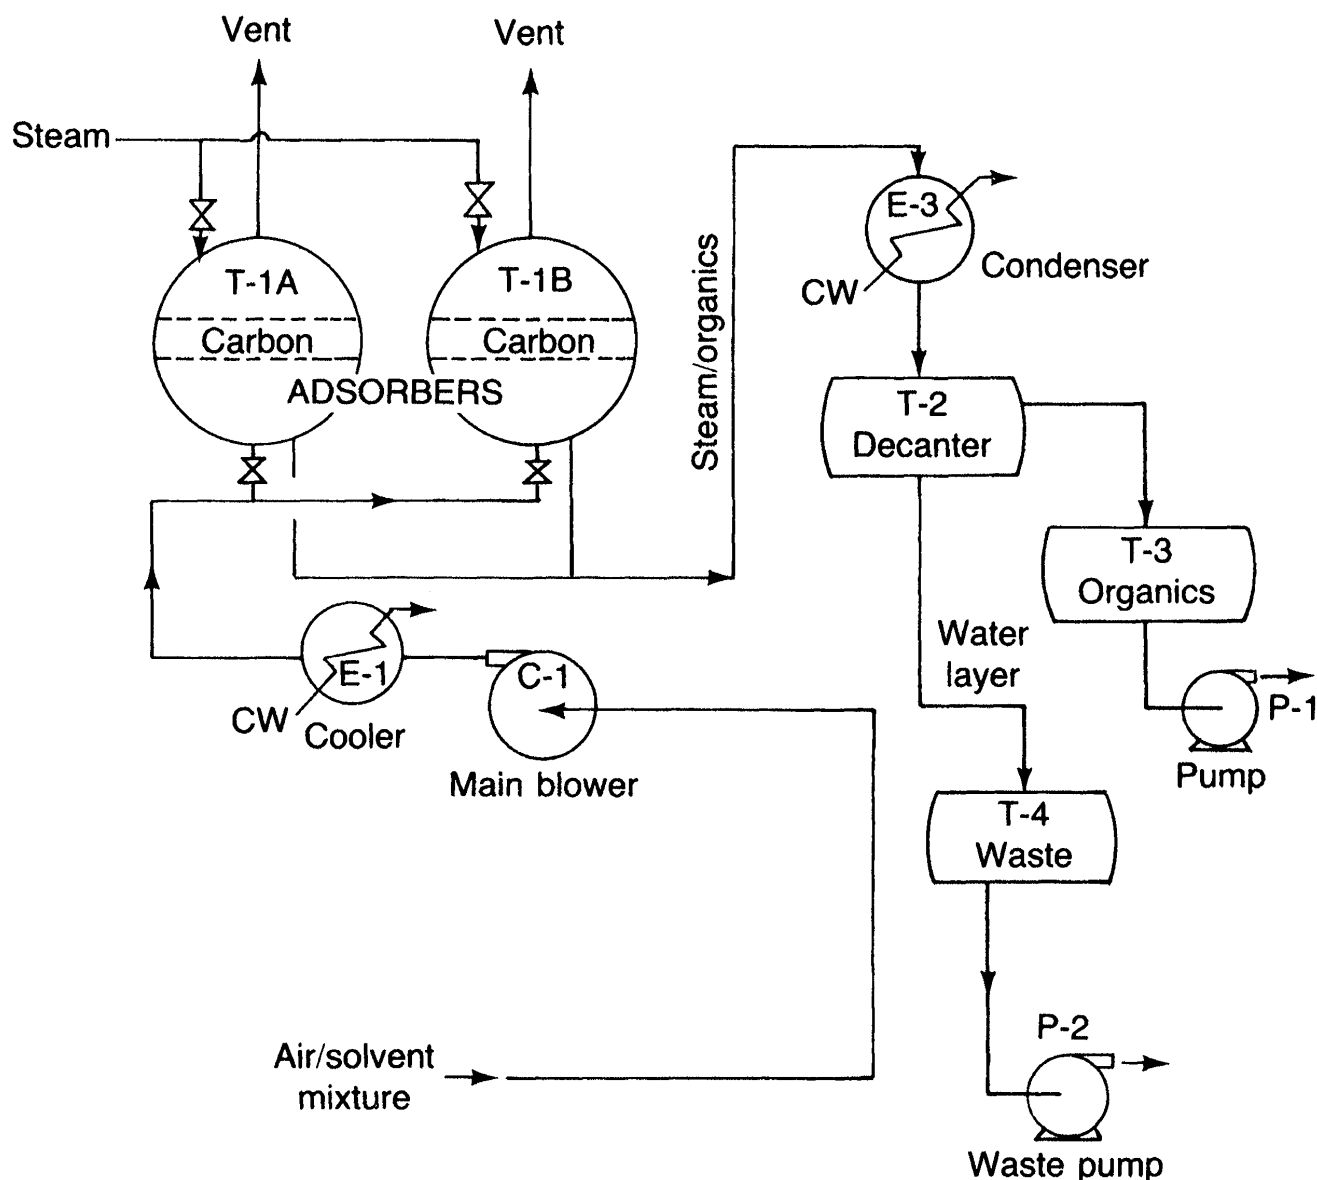

Tower costs are estimated based on the total weight of the tower shell plus 10 to 20% additional for manholes and fittings. To this is added the packing cost. Costing procedures for towers and auxiliaries are presented in detail by Peters and Timmerhaus [1991]. Major operating costs include blower power, spent absorbent liquid disposal, and (in the case of acid gas treatment) chemical costs.

In many applications gas absorbers are utilized to recover valuable chemicals from exhaust streams, which reduces the load on subsequent pollution control equipment. Examples of this application include recovery of light hydrocarbon ends from wellhead gas and recovery of HCl gas in hydrochloric acid production. Strictly air pollution control applications include removal of oxides of sulfur and nitrogen, chlorine, and ammonia.

## Adsorption

The removal of low-concentration gases and vapors from an exhaust stream by the adherence of these materials to the surface of a porous solid adsorbent is referred to as adsorption. Adsorbents used in air pollution applications include activated carbon, alumina, bauxite, and silica gel. Activated carbon (most frequently used) is prepared by partially oxidizing lignite, bituminous coal, and petroleum coke. A typical fixed-bed system employing carbon as the adsorbent is shown schematically in Fig. 86.5.

**Figure 86.5** Flow sheet for a fixed-bed system. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control<sup>3</sup>A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

This system incorporates two horizontal cylindrical vessels, each containing a bed of granular activated carbon supported on a heavy screen. An air-solvent or air-pollutant mixture from a plant source flows through a cooler and then into one carbon bed while the other bed is being regenerated. A monitor-controller located in the vent stack detects a preset maximum concentration (breakthrough) and switches the incoming exhaust stream to the other bed, which has completed a regeneration cycle. The bed undergoing regeneration is contacted with saturated steam, which drives off the adsorbed material and carries it to a condenser, where it is condensed along with the steam. If the adsorbed material is insoluble in water, the condensed mixture goes to a decanter and is separated for final disposal.

When a material is adsorbed it may be weakly bonded to the solid (physical adsorption) or it may react chemically with the solid (chemisorption). Physical adsorption permits economical regeneration of the adsorbent and is practical in air pollution control applications such as solvent recovery and the removal of low-concentration odorous and toxic materials. The design of fixed-bed physical adsorption systems is described below.

The actual adsorption onto a carbon bed occurs in a concentration zone called the adsorption zone, as shown in Fig. 86.6. The zone is bounded by saturated carbon upstream and clean carbon downstream. Unlike the steady state conditions in an absorption tower, adsorption is an unsteady state process in which the mass transfer driving force goes to zero as the carbon bed becomes saturated with respect to the partial pressure of the adsorbate (material adsorbed) in the gas stream.

**Figure 86.6** The adsorption wave and breakthrough curve. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control<sup>3</sup>4A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

The quantity of adsorbent in each bed is based on the saturation capacity for the adsorbate at the operating conditions of the adsorber. The operating adsorbent capacity is normally supplied by the manufacturer of the adsorbent or estimated by using 30% of the saturation capacity, as shown on

the capacity curve (isotherm) illustrated in Fig. 86.7.

**Figure 86.7** Adsorption isotherms for activated carbon. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control<sup>3</sup>4A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

For a two-bed system each bed must contain sufficient adsorbent to adsorb all solvent or pollutant in the incoming gas stream while the other bed is being regenerated, usually a period of 0.5 to 1.0 hour. The cross-sectional area of each bed is determined by assuming that the superficial velocity of the gas in the bed is in the range of 70 to 100 ft/s. The system blower power is based on the pressure drop through the bed, fittings, and condenser. In most applications, the expended bed is regenerated by passing low pressure-saturated steam through it at a rate of 0.3 to 0.5 pounds of steam per pound of carbon. The size of the condenser is based on 70 to 80% of this heat load. Cooper and Alley [1994] present examples of typical fixed-bed adsorber design.

Vatavuk [1990] reported that the purchased equipment cost (PEC) of packaged adsorber systems containing up to 14 000 pounds of carbon can be estimated by

$$PEC = 129(M_C)^{0.848} \quad (86.10)$$

where

PEC = purchase cost, 1988 dollars

$M_C$  = mass of carbon, pounds

Typical grades of carbon utilized in adsorbers cost from two to three dollars per pound and have a normal service life of five to seven years. The major utility costs are for steam, blower power, and cooling water. Average blower horsepower requirement is 6–8 hp/1000 SCFM of gas throughput.

Carbon adsorption has been shown to be applicable for the control of many types of gaseous pollutants, including volatile organic compounds (VOC), chlorinated solvents, and odorous materials.

## Incineration Processes

Incineration of polluted exhaust streams offers an effective but costly means of controlling a wide variety of contaminants, including VOCs, which constitute a major fraction of the total annual emissions in the U.S. and play an important role in the **photochemical smog** process. A pollution control incinerator, also referred to as an afterburner or thermal oxidizer, is shown schematically in Fig. 86.8. The incoming polluted air is injected into the flame mixing chamber, heated, and held in the reaction chamber until the desired pollutant destruction efficiency is obtained.

**Figure 86.8** Schematic diagram of a vapor incinerator. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control<sup>34</sup>A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

The process design of an incinerator requires specification of an operating temperature and a residence time in the reaction chamber. Typical operating condition ranges to provide the required "three T's" of combustion are temperature (1000–1500°F), residence time (0.3–0.5 s), and turbulence (mixing velocity 20–40 ft/s). Burner fuel requirements are estimated from a steady state enthalpy balance, as shown in Eq. (86.11):

$$0 = \dot{M}_{PA} h_{PA} + \dot{M}_G h_G + \dot{M}_{BA} h_{BA} - \dot{M}_E h_E + \dot{M}_G (-\Delta H_c)_G + \sum \dot{M}_{VOC_i} (-\Delta H_c)_{VOC_i} X_i - q_L \quad (86.11)$$

where

- $\dot{M}$  = mass flow rates, kg/min or lbm/min
- $h$  = specific enthalpy, kJ/kg or Btu/lbm
- $-\Delta H_c$  = net heat of combustion (lower heating value), kJ/kg or Btu/lbm
- $X_i$  = fractional conversion of  $\text{VOC}_i$
- $q_L$  = rate of heat loss from the incinerator, kJ/min or Btu/min

In most designs the heat generated by combustion of the pollutant is ignored, but at concentrations in the 1000 ppm range, this heat may be roughly 10% of the burner heat requirement. Insurance regulations limit the combustible pollutant concentration entering the incinerator to 25% of the **lower explosion limit (LEL)**.

To reduce the required operating temperature in the reaction chamber, the combustion mixture may be passed over a catalyst bed, which greatly increases the pollutant oxidation rate. Typically, the catalyst is either palladium or platinum, although Cr, Mn, Co, and Ni are used. The catalyst is deposited on an alumina support or wire screen which is placed just downstream of the burner mix chamber. The total amount of catalyst surface area required is in the range of 0.2 to 0.5 ft<sup>2</sup> per SCFM of waste gas. Typical operating temperature for catalytic incinerators is in the range of 600 to 900°F.

Combustion kinetics are extremely complicated and often incinerator design is based on empirical data or the results of pilot scale tests. The application of simplified kinetic reaction models to incinerator design is described by Cooper and Alley [1994].

The choice between a thermal or catalytic incinerator is in most cases a trade-off between capital and operating cost. The installed cost of a catalytic unit will normally be 40 to 70% higher than a thermal unit, but will require 30 to 50% less fuel for the same waste gas throughput. Offsetting this saving, however, is the service life of the catalyst, which is usually four to six years. Fuel costs for both units may be lowered by incorporating heat recovery equipment in the overall design. The cost of a packaged thermal unit handling up to 30 000 SCFM with facilities for 50% heat recovery may be estimated with the following equation [Vatavuk, 1990]:

$$P = \$4920Q^{0.389} \quad (86.12)$$

where

- $P$  = manufacturer's f.o.b. price, 1988 dollars
- $Q$  = waste gas flow rate, SCFM

The cost of catalytic units (not including the catalyst) equipped for 50% heat recovery may be found from [Vatavuk, 1990]

$$P = \exp(11.7 + 0.0354Q) \quad (86.13)$$

where

- $P$  = manufacturer's f.o.b. price, 1988 dollars

$Q$  = waste gas flow rate, thousands of SCFM

Catalyst costs in 1988 were \$3000 per cubic foot for precious metals and \$600 per cubic foot for common metals.

Both catalytic and thermal incinerators find widespread use in the chemical process industries, in coating and film printing operations, and in food processing. Recent VOC emission regulations should promote increased sales of these units.

This photograph, taken in 1994, clearly illustrates the consequences of acid rain and pollution in the Shenandoah forests of Virginia. It is not possible to tell exactly where the pollution originated because air streams can carry weather fronts hundreds of miles before dumping the precipitation. It is, however, more common to find this type of damage in forests near industrial areas. Although the effect of acid rain is easily visible in forests, acid rain is less visible but extremely detrimental to agricultural crops and human health.

The entire eastern seaboard in the U.S. is experiencing acid rain to some degree. Effects of acid rain are not isolated, but can be seen all over the world. Europe, particularly the vast area of southern Scandinavia, eastern England, Northern France, Germany, and sweeping east through the former Eastern Block countries, have also been greatly affected.

Due to regulation in the U.S., this damaging trend has been slowly reversing over the past 20 years. Discussion in Congress of deregulation threatens the improvements already made. (Photo courtesy of Noam Lior, University of Pennsylvania.)

## Defining Terms

**Aerodynamic diameter:** The diameter of a unit density sphere ( $\rho_p = \rho_w = 1000 \text{ kg/m}^3$ ) that has the same settling velocity as the particle in question.

**Contacting power:** The quantity of energy dissipated per unit volume of gas treated.

**Lower explosion limit:** The lowest concentration of a flammable gas, vapor, or solid in air that will provide flame propagation throughout the mixture.

**Photochemical smog:** An air pollution condition resulting from a series of photochemical reactions involving various volatile organic compounds and oxides of nitrogen in the lower atmosphere.

The practice of collecting and treating wastewater prior to disposal is a relatively recent undertaking. Although remains of sewers have been found in ancient cities, the extent of their use for wastewater carriage is not known. The elaborate drainage system of ancient Rome was not used for waste disposal, and wastes were specifically excluded from the sewerage systems of London, Paris, and Boston until well after the turn of the nineteenth century.

The invention of the flush toilet in the nineteenth century drastically changed waste disposal practices. To cope with the drastically increased volume of liquid waste, cities began to use natural drainage systems and storm sewers for wastewater carriage. The first "modern" sewerage system for wastewater carriage was built in Hamburg, Germany, in 1842 and included many of the principles that are still in use today. Construction of combined sewers was commonplace in large cities during the latter half of the nineteenth century. Since storm drain systems naturally ended at watercourses, waterborne wastes were discharged directly to streams, lakes, and estuaries without treatment. Gross pollution often resulted, and health problems were transferred from the sewered community to downstream users of the water.

The treatment of wastewater lagged considerably behind its collection. Treatment was considered necessary only after the self-purification capacity of the receiving waters was exceeded and nuisance conditions became intolerable. Various treatment processes were tried in the late 1800s and early 1900s, and by the 1920s wastewater treatment had evolved to those processes in common use today. Design of wastewater treatment facilities remained empirical, however, until mid-century. In the last 30 to 40 years, great advances have been made in understanding wastewater treatment, and the original processes have been formulated and quantified. The science of wastewater treatment is far from static, however. Advanced wastewater treatment processes are currently being developed that will produce potable water from domestic wastewater. Problems

associated with wastewater reuse will no doubt challenge the imagination of engineers for many years to come.

Philosophies concerning the treatment and ultimate disposal of wastewater have evolved over the years. Operating under the original assumption that the "solution to pollution is dilution," the assimilative capacity of streams was utilized before treatment was deemed necessary. For many years, little, if any, treatment was required of small communities located on large streams, whereas a high level of treatment was required by large cities discharging to small streams. In more recent times the policy has shifted to require a minimum level of treatment of all waste discharges, regardless of the capacity of the receiving stream. Under current practice in the U.S., all dischargers are given a permit stating the maximum amount of each pollutant that they are allowed to discharge. Discharge permits are no longer intended to just protect the self-purification capacity of the streams but are focused on maintaining a high level of quality in all receiving streams.

Where extensive treatment of wastewater is necessary to meet stringent discharge permits, the quality of the treated effluent may approach or exceed that of the receiving stream. This effluent should be considered a valuable water resource, particularly where water is scarce. Regulatory agencies encourage utilization of these wastewaters for irrigation, non-body contact recreational activities, groundwater recharge, some industrial processes, and other nonpotable uses.

## 87.1 Wastewater Characteristics

Wastewaters are usually classified as industrial wastewater or municipal wastewater. Industrial wastewater with characteristics compatible with municipal wastewater may be discharged to the municipal sewers. Many industrial wastewaters require pretreatment to remove noncompatible substances prior to discharge into the municipal system.

Water collected in municipal wastewater systems, having been put to a wide variety of uses, contains a wide variety of contaminants. Quantitatively, constituents of wastewater may vary significantly, depending upon the percentage and type of industrial waste present and the amount of dilution from infiltration/inflow into the collection system. The most significant components of wastewater are usually suspended solids, biodegradable organics, and pathogens. The source and environmental significance of contaminants commonly found in wastewater are shown in [Table 87.1](#).

**Table 87.1** Wastewater Contaminants

Contaminant	Source	Environmental Significance
Suspended solids	Domestic use, industrial wastes, erosion by infiltration/inflow	Cause sludge deposits and anaerobic conditions in aquatic environment
Biodegradable organics	Domestic and industrial waste	Cause biological degradation, which may use up oxygen in receiving water and result in undesirable conditions

Pathogens	Domestic waste	Transmit communicable diseases
Nutrients	Domestic and industrial waste	May cause eutrophication
Refractory organics	Industrial waste	May cause taste and odor problems; may be toxic or carcinogenic
Heavy metals	Industrial waste, mining, etc.	Are toxic; may interfere with effluent reuse
Dissolved inorganic solids	Increases above level in water supply by domestic and/or industrial use	May interfere with effluent reuse

---

Source: Peavy, H. S., Rowe, D. R., and Tchobanoglous, G. 1985. *Environmental Engineering*. McGraw-Hill, New York.

**Suspended solids** are primarily organic in nature and are composed of some of the more objectionable material in sewage. Body wastes, food waste, paper, rags, and biological cells form the bulk of suspended solids in wastewater. Even inert materials such as soil particles become fouled by adsorbing organics to their surface. Removal of suspended solids is essential prior to discharge or reuse of wastewater.

Although suspended organic solids are biodegradable through hydrolysis, biodegradable material in wastewater is usually considered to be **dissolved solids** of organic origin. Soluble organics in domestic wastewater are composed chiefly of proteins (40 to 60%), carbohydrates (25 to 50%), and lipids (approximately 10%). Proteins are chiefly amino acids, whereas carbohydrates are compounds such as sugars, starches, and cellulose. Lipids include fats, oil, and grease. All of these materials contain carbon that can be converted to carbon dioxide biologically, thus exerting a **biochemical oxygen demand**. Proteins also contain nitrogen, and thus a nitrogenous oxygen demand is also exerted. The biochemical oxygen demand (BOD) test is therefore used to quantify biodegradable organics.

All forms of waterborne **pathogens** may be found in domestic wastewater. These include bacteria, viruses, protozoa, and helminths. These organisms are discharged by persons who are infected with the disease. Although pathogens causing some of the more exotic diseases may not be present in viable form, it is a safe assumption that a sufficient number of pathogens are present in all untreated wastewater to represent a substantial health hazard. Fortunately, few of the pathogens survive wastewater treatment in a viable state.

Traditional wastewater treatment processes are designed to reduce suspended solids, biodegradable organics, and pathogens to acceptable levels prior to disposal. Additional wastewater treatment processes may be required to reduce levels of nutrients if the wastewater is to be discharged to a delicate ecosystem. Processes to remove refractory organics and heavy metals and to reduce the level of inorganic dissolved solids may be required where wastewater reuse is anticipated.

## 87.2 Terminology in Wastewater Treatment

---

The terminology used in wastewater treatment is often confusing to the uninitiated person. Terms such as *unit operations*; *unit processes*; *reactors*; *systems*; and *primary*, *secondary*, and *tertiary treatment* frequently appear in the literature, and their usage is not always consistent. The

meanings of these terms as used in this chapter are discussed in the following paragraphs.

Methods used for treating municipal wastewaters are often referred to as either **unit operations** or **unit processes**. Generally, unit operations involve contaminant removal by physical forces (screening, sedimentation, and filtration), whereas unit processes are conversion processes involving biological and/or chemical reactions.

The term *reactor* refers to the vessel, or containment structure, along with all of its appurtenances, in which the unit operation or unit process takes place. Although unit operations and processes are natural phenomena, they may be initiated, enhanced, or otherwise controlled by altering the environment in the reactor. Reactor design is a very important aspect of wastewater treatment and requires a thorough understanding of the unit processes and unit operations involved.

A wastewater treatment system is composed of a combination of unit operations and unit processes designed to reduce certain constituents of wastewater to an acceptable level. Many different combinations are possible. Although practically all wastewater treatment systems are unique in some respects, a general grouping of unit operations and unit processes according to target contaminants has evolved over the years. Unit operations and processes commonly used in wastewater treatment are listed in [Table 87.2](#) and are arranged according to conventional grouping.

**Table 87.2** Unit Operations, Unit Processes, and Systems for Wastewater Treatment

Contaminant	Unit Operation, Unit Process, or Treatment System
Suspended solids	Sedimentation
	Screening and comminution
	Filtration variations
	Flotation
	Chemical-polymer addition
	Coagulation/sedimentation
	Land treatment systems
Biodegradable organics	Activated-sludge variations
	Fixed-film; trickling filters
	Fixed-film; rotating biological contactors
	Lagoon and oxidation pond variations
	Intermittent sand filtration
	Land treatment systems
	Physical-chemical systems
Pathogens	Chlorination
	Hypochlorination
	Ozonation
	Land treatment systems
Nutrients	
Nitrogen	Suspended-growth nitrification and denitrification variations
	Fixed-film nitrification and denitrification variations

	Ammonia stripping
	Ion exchange
	Breakpoint chlorination
	Land treatment systems
Phosphorus	Metal-salt addition
	Lime coagulation/sedimentation
	Biological-chemical phosphorus removal
	Land treatment systems
Refractory organics	Carbon adsorption
	Tertiary ozonation
	Land treatment systems
Heavy metals	Chemical precipitation
	Ion exchange
	Land treatment systems
Dissolved inorganic solids	Ion exchange
	Reverse osmosis
	Electrodialysis

Source: Peavy, H. S., Rowe, D. R., and Tchobanoglous, G. 1985. *Environmental Engineering*. McGraw-Hill, New York.

Municipal wastewater treatment systems are often divided into primary, secondary, and tertiary subsystems. The purpose of **primary treatment** is to remove suspended solid materials from the incoming wastewater. Large debris may be removed by screens or may be reduced in size by grinding devices. Inorganic solids are removed in grit channels, and much of the organic suspended solids is removed by sedimentation. A typical primary treatment system (Fig. 87.1) should remove approximately one half of the suspended solids in the incoming wastewater. The BOD associated with these solids accounts for about 30% of the influent BOD.

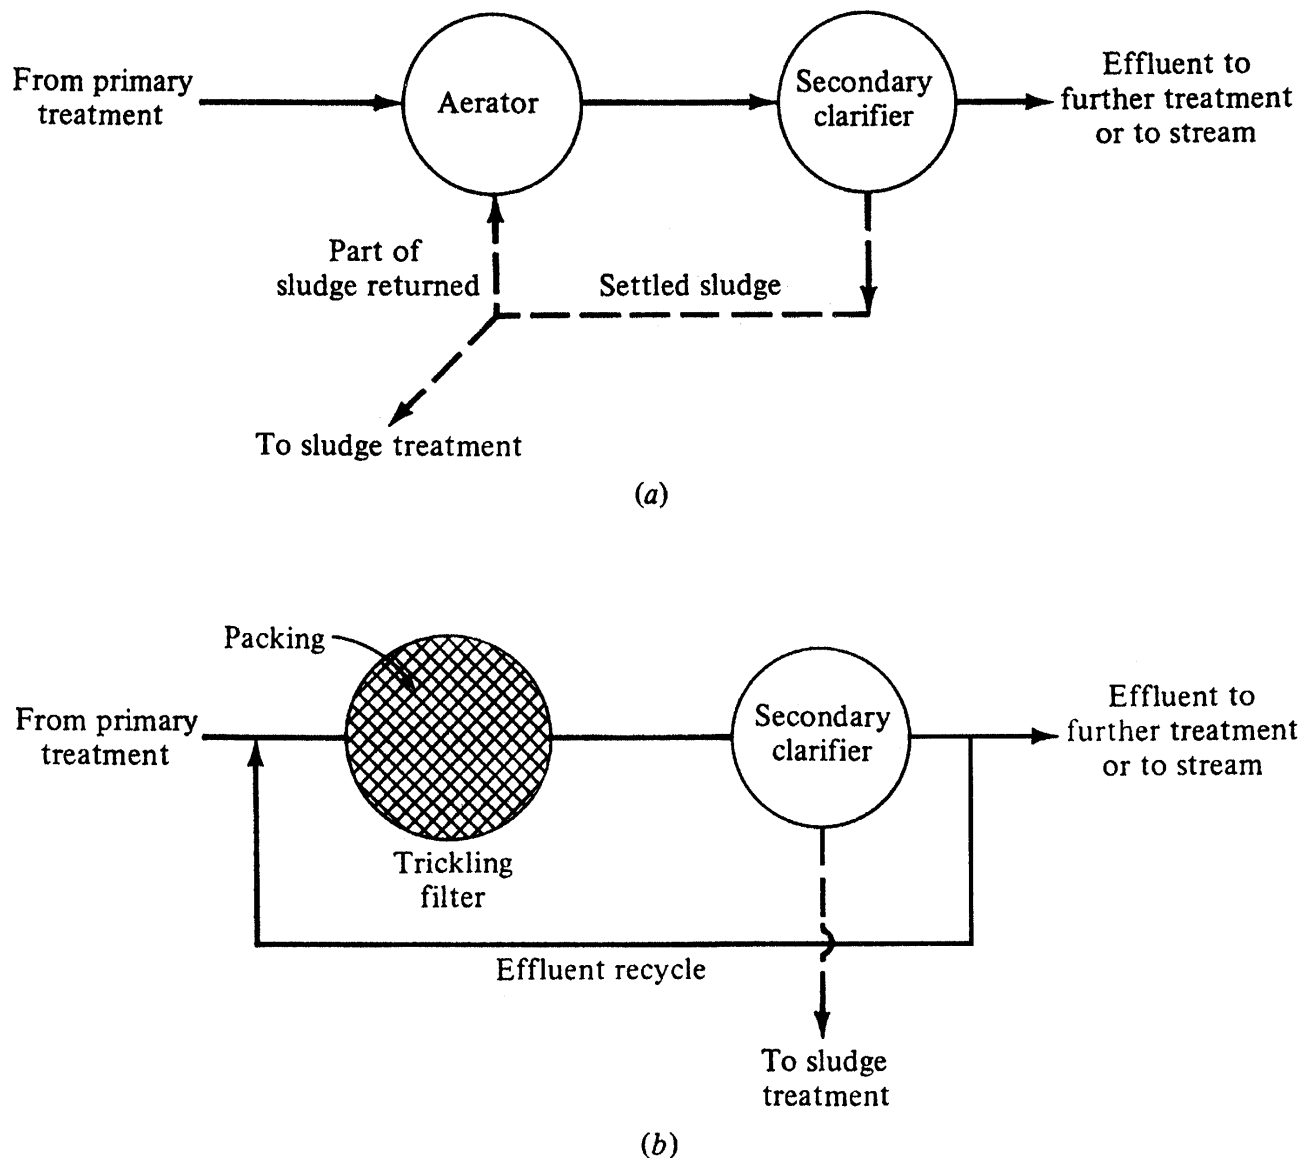

**Figure 87.1** Typical primary treatment system. (Source: Peavy, H. S., Rowe, D. R., and Tchobanoglous, G. 1985. *Environmental Engineering*. McGraw-Hill, New York.)

**Secondary treatment** usually consists of biological conversion of dissolved and colloidal

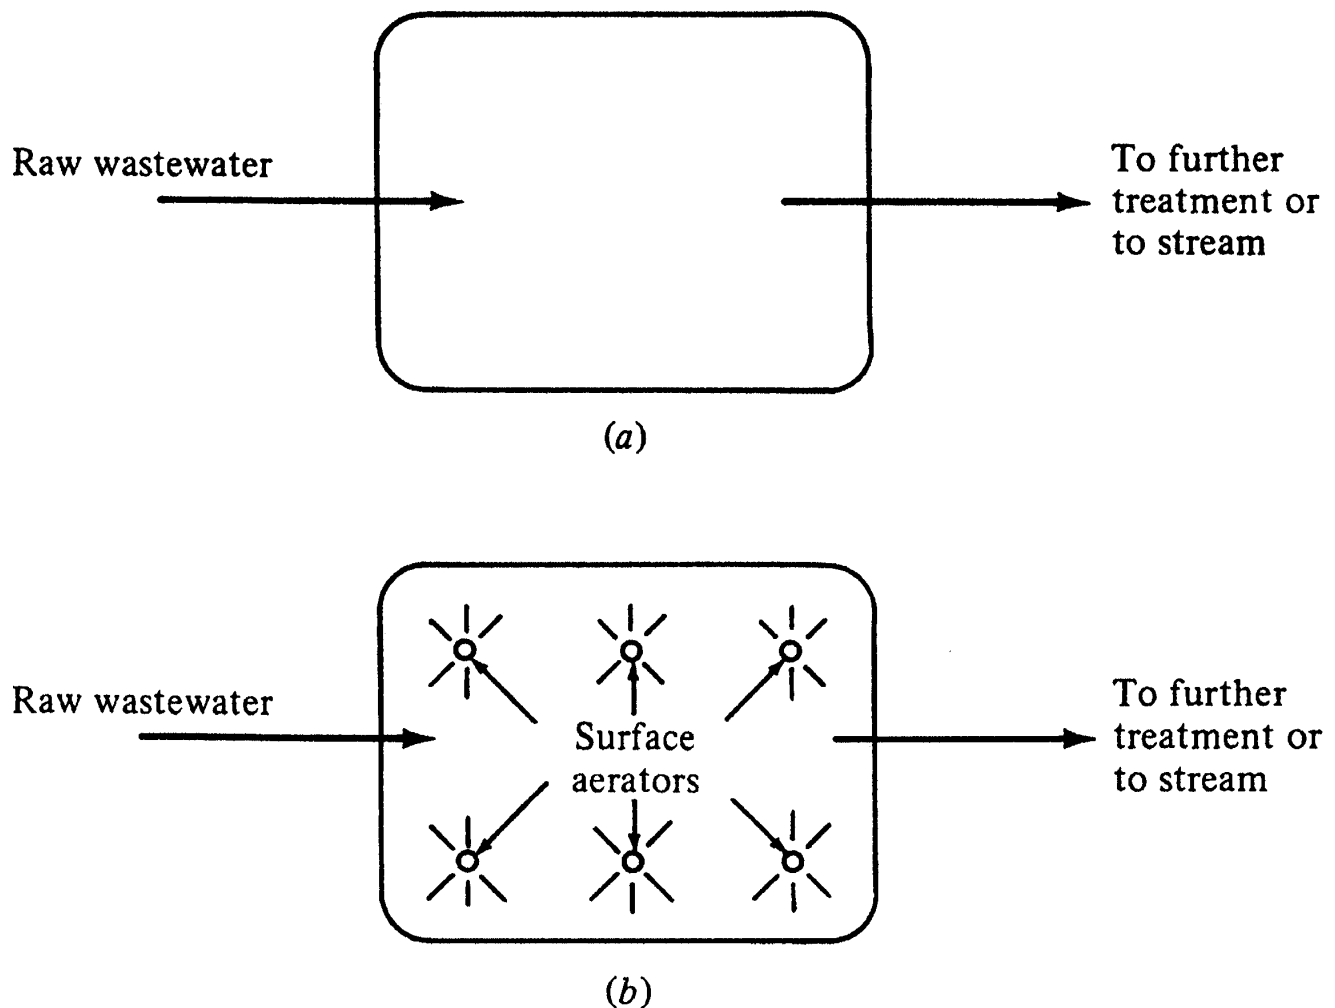

organics into biomass that can subsequently be removed by sedimentation. Contact between microorganisms and the organics is optimized by suspending the biomass in the wastewater or by passing the wastewater over a film of biomass attached to solid surfaces. The most common suspended biomass system is the activated-sludge process shown in Fig. 87.2(a). Recirculating a portion of the biomass maintains a large number of organisms in contact with the wastewater and speeds up the conversion process. The classical attached-biomass system is the trickling filter shown in Fig. 87.2(b). Stones or other solid media are used to increase the surface area for **biofilm** growth. Mature biofilms peel off the surface and are washed out to the settling basin with the liquid underflow. Part of the liquid effluent may be recycled through the system for additional treatment and to maintain optimal hydraulic flow rates.

**Figure 87.2** Typical secondary treatment systems: (a) activated sludge system and (b) trickling filter system. (Source: Peavy, H. S., Rowe, D. R., and Tchobanoglous, G. 1985. *Environmental Engineering*. McGraw-Hill, New York.)

Sometimes primary and secondary treatment can be accomplished together, as shown in Fig. 87.3. The oxidation pond [Fig. 87.3(a)] is a large impoundment that most nearly approximates treatment by natural systems, with oxygen being supplied by algal photosynthesis and surface reaeration. This oxygen seldom penetrates to the bottom of the pond, and the solids that settle are decomposed by anaerobic bacteria (bacteria that require no oxygen). In an aerated lagoon system [Fig. 87.3(b)] oxygen is supplied by mechanical aeration, and the entire depth of the pond is aerobic. The small quantity of excess sludge that is produced is retained in the bottom sediments. Due to large space requirements, oxidation ponds are only feasible for small communities.

**Figure 87.3** Primary and secondary treatment by ponds: (a) oxidation pond and (b) aerated pond.  
(Source: Peavy, H. S., Rowe, D. R., and Tchobanoglous, G. 1985. *Environmental Engineering*. McGraw-Hill, New York.)

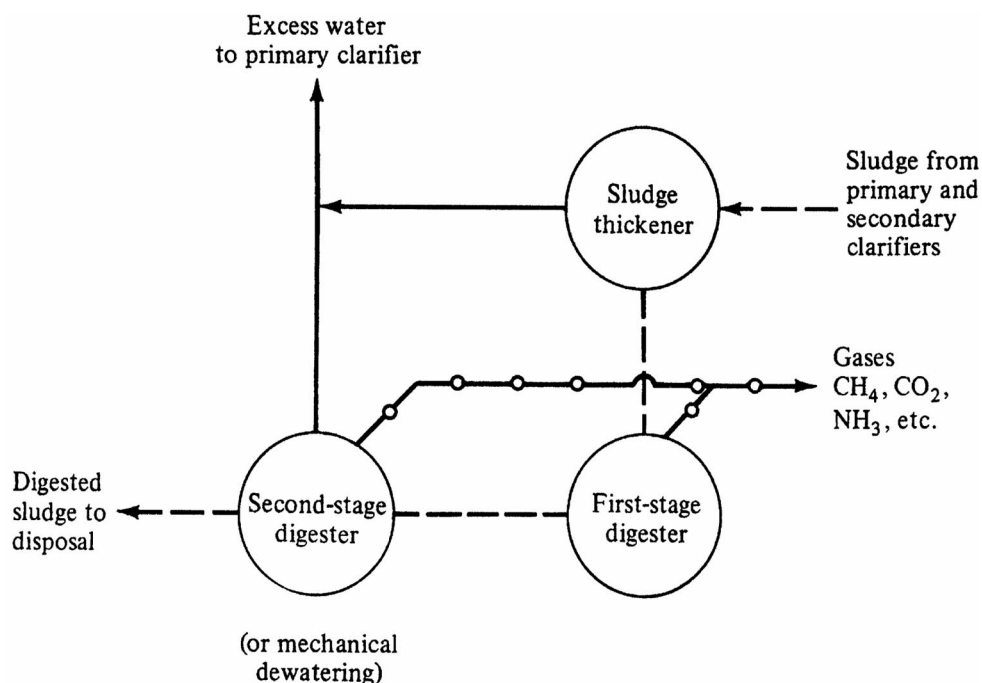

In most cases, secondary treatment of municipal wastewater is sufficient to meet effluent standards. In some instances, however, additional treatment may be required. **Tertiary treatment** most often involves further removal of suspended solids and/or the removal of nutrients. Solids removal may be accomplished by filtration, and phosphorus and nitrogen compounds may be removed by combinations of physical, chemical, and biological processes.

## 87.3 Sludge

A careful inspection of Figs. 87.1 through 87.3 leads to an interesting observation. The "removal" processes in wastewater treatment are essentially concentrating, or thickening, processes. Suspended solids are removed as sludges, and dissolved solids are converted to suspended solids and subsequently become removable sludges. Primary and secondary treatment, followed by sludge thickening, may concentrate the per capita contribution of organic material (represented by 250 mg/L of suspended solids and 200 mg/L BOD in 375 L of municipal wastewater) to 2.0 L of sludge containing 50 000 mg/L of solids. Most of the objectionable material initially in the wastewater is concentrated in the sludges and must be disposed of in a safe and environmentally acceptable manner. The majority of the expenses, effort, and problems of wastewater treatment and disposal are associated with the sludges.

Wastewater sludges are usually combined, thickened, and treated by two-stage anaerobic biological processes, as shown in Fig. 87.4. The results are gaseous end products, principally methane ( $\text{CH}_4$ ) and carbon dioxide ( $\text{CO}_2$ ), and liquids and inert solids. The methane has significant heating value and may be used to meet part of the power requirements of the treatment plant. The liquids contain large concentrations of organic compounds and are recycled through the treatment plant. The solid residue has a high mineral content and may be used as a soil conditioner and fertilizer on agricultural lands. Other means of solids disposal may be by incineration or by landfilling.

**Figure 87.4** Sludge thickening and treatment system. (Source: Peavy, H. S., Rowe, D. R., and Tchobanoglous, G. 1985. *Environmental Engineering*. McGraw-Hill, New York.)

## 87.4 Advanced Wastewater Treatment

---

The quality of effluent provided by secondary treatment may not always be sufficient to meet discharge requirements. This is often the case when large quantities of effluent are discharged into small streams or when delicate ecosystems are encountered. In these instances, additional treatment to polish the effluent from secondary systems will be required, or an alternative method of wastewater disposal must be found.

Additional treatment often involves the removal of nitrogen and phosphorus compounds, plant nutrients associated with eutrophication. Further treatment may be required to remove additional suspended solids, dissolved inorganic salts, and **refractory organics**. Combinations of the above processes can be used to restore wastewater to potable quality, although at considerable expense. Referred to as *reclamation*, this complete treatment of wastewater can seldom be justified except in water-scarce areas where some form of reuse is mandated.

The term **advanced wastewater treatment** is frequently used to encompass any or all of the above treatment techniques, and this term would seem to imply that advanced treatment follows conventional secondary treatment. This is not always the case, as some unit operations or unit processes in secondary or even primary treatment may be replaced by advanced treatment systems. The targets of most advanced wastewater treatment processes and operations are dissolved nutrients and suspended solids.

### Nutrient Removal

Excess nutrients can be very troublesome in natural water systems because they stimulate growth of algae and other aquatic plants. Although the quantities of nutrients contributed by wastewater discharges may be less than those contributed by agricultural runoff and other sources, the point-source nature of wastewater discharges makes them more amenable to control techniques. Thus, wastewater treatment plants that discharge to water bodies that are delicately balanced with respect to nutrient loads may have nutrient limitations imposed on their effluent. The nutrients most often of interest are nitrogen and phosphorous compounds.

### Solids Removal

Removal of suspended solids, and sometimes dissolved solids, may be necessary in advanced wastewater treatment systems. The solids removal processes employed in advanced wastewater treatment are essentially the same as those used in the treatment of potable water, although application is made more difficult by the overall poorer quality of the wastewater.

As an advanced treatment process, suspended solids removal entails the removal of particles and flocs too small or too lightweight to be removed in gravity settling operations. These solids may be carried over from the secondary clarifier or from tertiary systems in which solids were precipitated.

Several methods are available for removing residual suspended solids from wastewater. Removal by centrifugation, air flotation, mechanical microscreening, and granular-media filtration have all been used successfully. In current practice, granular-media filtration is the most commonly used process. Basically, the same principles that apply to filtration of particles from potable water

apply to the removal of residual solids in wastewater. However, differences in operational modes for wastewater filtration versus potable water filtration may range from slight to drastic.

Although applied less frequently than suspended solids removal processes, dissolved solids removal is sometimes necessary in the treatment of wastewaters. Both secondary treatment and nutrient removal decrease the content of dissolved organic solids in wastewater. Neither process, however, completely removes all dissolved organic constituents, and neither process removes significant amounts of inorganic dissolved solids. Further treatment will be required where substantial reductions in the total dissolved solids of wastewater must be made.

Ion exchange, microporous membrane filtration, adsorption, and chemical oxidation can be used to decrease the dissolved solids content of water. These processes were developed to prepare potable water from a poor-quality raw water. Their use can be adapted to advanced wastewater treatment if a high level of pretreatment is provided. The removal of suspended solids is necessary prior to any of these processes. Removal of the dissolved organic material (by activated carbon adsorption) is necessary prior to microporous membrane filtration to prevent the larger organic molecules from plugging the micropores.

Advanced wastewater treatment for dissolved solids removal is complicated and expensive. Treatment of municipal wastewater by these processes can be justified only when reuse of the wastewater is anticipated.

## **87.5 Wastewater Disposal and Reuse**

---

An insignificant volume of the influent wastewater accompanies sludges and other materials disposed of during wastewater treatment processes. The bulk of the wastewater remains to be disposed of after the treatment processes have been completed. Ultimate receptors of treated wastewaters include surface water and groundwater bodies, land surfaces, and, in some instances, the atmosphere. Recognition of the value of wastewater as a water resource has resulted in an increase in the reuse of treated effluent, particularly in water-scarce regions.

The most common method of wastewater disposal is by dilution in surface waters. As previously discussed, treatment processes are applied to make the wastewater compatible with the natural water system to which it is discharged. Other practices include land disposal and, in arid climates, evaporation to the atmosphere. Land application may involve irrigation, in which the water is incorporated in plants and/or transpired to the atmosphere, or infiltration, in which the water is percolated through the soil and is ultimately discharged to groundwater. Land disposal practices are generally seasonal in nature and generally require large storage facilities for off-season flows.

Under some circumstances, wastewater reuse may be an appropriate method of disposing of treated effluent. In water-scarce areas, wastewater may constitute a major portion of the available resource. Where delicate ecosystems necessitate stringent effluent requirements, reuse of the wastewater may help to offset the cost of advanced wastewater treatment, or a reuse that will accept a lower level of treatment may obviate the expense of advanced treatment prior to

discharge. Wastewater is currently being reused for several purposes, including creation or enhancement of recreational facilities, industrial water supplies, groundwater recharge, and even direct reuse in potable supplies.

## 87.6 Future of Wastewater Treatment and Reuse

---

Many areas of the world are presently experiencing water shortages, or expect to experience them in the foreseeable future. In these areas, wastewaters must be considered a valuable resource and be integrated into the available water supply.

The principal concerns involving the reuse of wastewater are public health and public acceptance. From a public health standpoint, there must be reasonable assurance that pathogenic microorganisms and toxic chemicals are reduced to concentrations that pose acceptable health risks. Thus, wastewater treatment processes and operations must be upgraded and/or developed to consistently treat wastewater to a higher level of purity, and at an affordable cost. Professionals in the wastewater industry, in engineering practice, and in academia are currently active in this pursuit. The development of new technology, new materials, and better analytical techniques to measure results creates challenges and opportunities to which professionals in the wastewater field will be responding well into the foreseeable future.

In addition to technological advances, public acceptance is also a necessary element of wastewater reuse. Experience at the Santee project in California—in which treated wastewater was used to enhance a recreational resource—indicates that public acceptance is greatly enhanced by informing and involving the public at all stages of planning and implementation of wastewater reuse. Following this lead, the city of Denver has launched a massive drive for public acceptance of wastewater recycling. Nonpotable reuse of effluent from a demonstration plant is planned, with extensive research on health and toxicological studies being performed. Concurrently, a public education program has been designed to gain public acceptance of eventual reuse in the potable system, should the health studies show this to be practical. These programs are to continue for 10 to 15 years and, if successful, will result in the construction of a full-scale plant from which reuse will include direct recycle to the potable system. The city of San Diego, California, is presently embarking on a similar project.

Other projects have chosen to limit the utilization of reclaimed wastewater to nonpotable uses for the present time. In California, Los Angeles and Orange counties conducted an extensive market analysis and identified a long-term nonpotable reuse potential of  $1.15 \cdot 10^6 \text{ m}^3/\text{d}$  of treated wastewater. These uses include irrigation of public property, various industrial uses, and groundwater recharge. The uses require varying levels of treatment and, thus, varying costs depending on the water quality acceptable to each user. At the project's initiation, a combination of users that optimized the cost of treatment and delivery of the wastewater was selected. This type of approach has considerable merit when the demand for treated wastewater exceeds the supply.

As demand for water increases, more consideration will necessarily be given to fitting the quality of the water to the intended use. Currently, water distributed through public systems is of potable quality, although less than one half the water distributed through these systems is used in a manner necessitating potable water quality. Thus, the opportunity for the use of water of less-than-potable

quality is abundant, and reclaimed wastewater could conceivably be used in many instances where potable water is now being used. This would require separate delivery and plumbing systems, an expensive but not technologically complicated procedure, along with an extensive public education program.

## Defining Terms

**Advanced wastewater treatment:** Processes or operations used to "polish" wastewater after conventional treatment. Generally aimed at specific contaminants.

**Biochemical oxygen demand:** The amount of oxygen that is required for microorganisms to convert the organic material in wastewater to carbon dioxide and other stable end products.

**Biofilm:** A community of microorganisms that attach themselves to surfaces in thick, slimy layers.

**Dissolved solids:** Ions of elements and or compounds that are held by or within the molecular structure of water. The residue that is left when a filtered sample of water is evaporated to dryness.

**Pathogen:** Microorganisms that are capable of causing disease in humans.

**Primary treatment:** The initial set of wastewater treatment operations that are intended to remove or alter suspended solids from wastewater.

**Refractory organics:** Organic material that is not readily biodegradable due to its molecular structure or toxicity to microorganisms.

**Secondary treatment:** A set of processes and operations whose purpose is to convert dissolved organics to biological solids and to remove those solids from the wastewater stream. Usually follows primary treatment.

**Suspended solids:** Material that is held in suspension by the buoyant or turbulent forces of water. Can be removed by filtering through a standard filter paper.

**Tertiary treatment:** Removal of nutrients—usually compounds of phosphorous and nitrogen—from wastewater. Usually follows secondary treatment.

**Unit operations:** The removal of substances from wastewater by physical forces, for example, settling, filtration, and so on.

**Unit processes:** The conversion of dissolved substances to suspended material so that it can be more readily removed from wastewater.

**Ross E. McKinney***Consulting Engineer*

**Solid wastes** are primarily a problem for urban and industrial areas. Although solid wastes have been a problem for urban centers since the beginning of time, it was the rapid growth of the industrial society that generated the current problems. As the standard of living increased, the consumption of goods produced solid wastes that created environmental pollution when discarded without proper treatment. Recently, the industrialized countries began to examine solid wastes and to develop methods for reducing their production as well as processing them for return to the environment without creating pollution. Although progress has been made, more is required.

---

**88.1 Regulations**

---

The primary solid waste regulations are at the local government level. One of the primary functions of local government is to protect the health of its citizens. Solid waste collection and processing is primarily a public health problem that can only be managed at the local level. Most communities have developed ordinances to handle solid waste storage, collection, and processing.

Local government derives its authority from state government. Since solid wastes are public health problems, many states have placed their solid waste regulations under state departments of health. In recent years a number of states have moved control of solid wastes to departments of environmental pollution control or departments of natural resources. The authority for all solid waste regulations resides in each state legislature, with the development of detailed regulations assigned to the appropriate state agency.

In 1965 the federal government became involved in solid waste legislation when Congress passed the first federal solid waste legislation as an addendum to the 1965 Federal Air Pollution

legislation. The primary purpose of this federal legislation was to reduce the number of open burning dumps that were creating air pollution and to determine the status of state solid waste programs. The Resource Recovery Act was passed by Congress in 1970 to assist in the development of new systems for processing solid wastes and recovering materials for reuse. This was followed by the Resource Conservation and Recovery Act of 1976 (RCRA). The most important components of this legislation were Subtitle C, which dealt with hazardous solid wastes, and Subtitle D, which dealt with sanitary landfills. Problems with buried hazardous wastes resulted in Congress's passing the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA), also known as the Superfund Act. RCRA was amended by Congress in 1980 and in 1984. The 1984 amendments were designated the Hazardous and Solid Waste Amendments. In 1986 the Superfund Amendments and Reauthorization Act (SARA) passed Congress. Congress has had recent difficulty passing new legislation, but it has allowed existing legislation to continue, permitting the federal EPA to develop regulations covering the areas of concern. As a net result, it is essential to keep informed on the continuous stream of regulations published in the *Federal Register*.

Overall, federal regulations provide national policies in solid wastes, whereas the state regulations are designed to implement the federal regulations. However, it must be recognized that ultimate control of solid waste operations is at the local level. It is at the local level that federal and state policies and regulations are converted to action. For the most part, regulations are being developed in response to public perception of environmental problems and the two are not always in a logical sequence.

## 88.2 Characteristics

---

One of the more interesting aspects of solid waste management is the simple fact that very little real data exists on current solid waste characteristics. It is too difficult to collect detailed data on solid waste characteristics for even the largest cities to gather data. A few detailed studies have been made when the economic considerations for specific solid waste-processing systems were high enough to justify determination of solid waste characteristics. Most engineers use the data generated by the U.S. EPA [EPA, 1990] as the basis for solid waste characteristics. The EPA data represent approximate characteristics based on a material flow methodology developed at Midwest Research Institute in 1969. The EPA composition data are a reasonable estimate on a national basis. It should be recognized that solid waste characteristics vary with the section of the country, the seasons of the year, and economic conditions.

The EPA Office of Solid Waste recognized that solid wastes were composed of many different materials, making composition analyses difficult if a common set of criteria were not used. As a result, a broad classification of ten categories was used. Although several subcategories have been added for specific projects, the ten categories have gained widespread acceptance. Table 88.1 gives the percentage of total solid wastes for the ten categories as estimated by the EPA for the year 1988 [EPA, 1990]. It was estimated that 83% of the solid wastes was combustible and 17% noncombustible. The combustible characteristics of solid wastes are important when solid wastes are to be processed by incineration, whereas the general solid waste characteristics are used for evaluating solid waste recycling and solid waste reduction projects. It should be noted that the EPA

solid waste characteristics are based on an "as collected" basis, which includes about 20% moisture and 5% ash from the combustible organics. Only about 58% of the solid wastes are combustible organics, with 22% noncombustible ash. Variations in moisture content are very important when evaluating solid waste characteristics for incineration.

**Table 88.1** Characteristics of Solid Wastes Generated in 1988

Type of Waste	Percentage of Total Solid Waste
Paper and paperboard	40.0
Glass	7.0
Metals	8.5
Plastics	8.0
Rubber and leather	2.6
Textiles	2.2
Wood	3.6
Food wastes	7.3
Yard wastes	17.6
Other wastes	3.2

## 88.3 Generation

Data on solid waste generation are a little better than data on solid waste characteristics, since more communities have gathered data on the weight of solid wastes handled than on solid waste analyses. However, it should be recognized that weight data may not be much better than characterization data. Accurate weight data require checking the scales at regular intervals to ensure accuracy. It is also important to weigh trucks both before and after unloading to determine the real weight of the solid wastes. Use of a truck tare weight to minimize the number of weighings will often result in high values. The key to proper evaluation of generation data is regular collection and weighing of solid wastes from the same areas of the community.

Generation data are generally reported in pounds per person per day. With a uniform generation rate it is easy to determine the total solid waste production for various sizes of communities. The EPA data on solid waste generation [EPA, 1990] indicated a change from 2.66 lb/person/day in 1960 to 4.00 lb/person/day in 1988. It has been found that solid waste generation is primarily a function of economic conditions. During recessions solid waste generation decreases. With rapid economic growth the production of solid wastes increases. Concern over the generation of solid wastes has resulted in changes in the packaging of materials. Smaller packages and lighter packaging have contributed to the decrease in weight of packaging materials. Increased advertising has generated more pages of newspapers and magazines that quickly become outdated. Careful evaluation of social conditions indicates that there is a limit to how much solid waste a person can actually generate on a daily basis. A study for the Institute for Local Self-Reliance [Platt *et al.*, 1990] found that residential solid waste generation for 15 cities ranged from 1.9 to 5.5

lb/person/day with a median of 3.3 lb/person/day. Unfortunately, the economics of some solid wastes projects depend upon a reasonable estimation of the solid waste generation rate. The ease of collecting solid waste generation data should allow engineers to obtain sufficient data prior to the design of any solid waste project.

## 88.4 Collection

---

Solid wastes must be collected where they are generated. This means that a system must be developed to go to every building in the community at some time frequency. Currently, residential solid wastes can be conveniently collected once weekly. A few communities employ twice weekly collection. Commercial buildings may require more frequent collection, depending on the rate of generation and the size of the storage container. Restaurants often require daily collection.

Every solid waste generator must have a suitable storage container to hold the solid wastes between collection. Residences tend to use individual containers, each having a maximum capacity of 30 gallons to minimize the weight in any single container. Recently, large plastic containers with wheels have been used in some communities. The householder is able to wheel the solid wastes from the garage to the curb for pickup without difficulty. Special mechanisms on the collection trucks allow the solid waste collector to transfer the solid wastes from the wheeled container to the collection truck with a minimum of effort. Apartment buildings, office buildings, and commercial establishments produce larger quantities of solid wastes than residences and require larger solid waste containers. Storage containers range in size from 1 to 10 yd<sup>3</sup>. Small storage containers can be dumped into rear-loading collection trucks or side-loading trucks, whereas large storage containers require front-loading collection trucks.

Solid wastes weigh between 200 and 250 lb/yd<sup>3</sup> in loose containers. Collection trucks use hydraulic compaction to maximize the quantity of solid wastes that can be collected before dumping. Although it is possible to compact solid wastes to 600–700 lb/yd<sup>3</sup>, most collection trucks average 500 lb/yd<sup>3</sup> after compaction. Rear-loading compaction trucks range in size from 9 to 32 yd<sup>3</sup>, with 20 yd<sup>3</sup> trucks being the most commonly used for residential collection. Side-loading compaction trucks range from small, 6 yd<sup>3</sup>, to large, 35 yd<sup>3</sup>. Front-loading compaction trucks range from 22 to 42 yd<sup>3</sup>, with 30 and 35 yd<sup>3</sup> trucks being most widely used for commercial routes. Roll-off units are used by industrial and special commercial accounts having large quantities of nonputrescible solid wastes. Roll-off units range in size from 10 to 30 yd<sup>3</sup> and may be attached to stationary compaction units to increase the capacity of the roll-off unit. When the roll-off unit is full, the collection truck pulls the roll-off unit onto the truck frame for transport to the processing site. The collection trucks all have special unloading mechanisms to remove the compacted solid wastes at the desired processing site.

Collection crew size depends upon the specific collection pattern of each community. One-person crews are used for some side-loading residential collections, roll-off collections, and some front-loading commercial collections. Two-person crews are used in which one person is the driver and the other person is the collector. The two-person crews are quite common in areas where collection can only be made on one side of the street at a time. Three-person crews are most common in residential collection from both sides of the street. Four-person crews have been used

in large communities. The size of collection crews and collection trucks depends on the size of the collection routes and the time allotted for collection activities. Time-motion studies are very important for evaluating the crew collection efficiency, whereas good operation and maintenance records are important for evaluating the drivers and determining equipment replacement.

## 88.5 Transfer and Transport

---

Transport from the collection route to the solid waste processing site is an important parameter affecting the cost of operations. It is part of the rest time for collectors. If the transport distance is too long, valuable collection time can be lost. As a result, transfer stations have been constructed in large cities to permit smaller collection trucks to unload and return to collection routes. The solid wastes in the transfer station are placed into larger transfer trucks, 50 to 70 yd<sup>3</sup> capacity, for transport to the final processing site. The large transfer trucks normally have only a single driver, reducing the labor costs. Transfer stations are economical only in very large cities and require special design for efficient traffic flow. Small transfer stations where individuals bring their solid wastes in their own automobiles or trucks have been used in rural areas.

Recently, large cities have examined transporting solid wastes by rail for final processing. Rail transport is very expensive and has been used only in crowded areas where several communities are contiguous and no processing site can be found in any of the communities. Barge transport has also been used to move large quantities of solid wastes more economically. Transport of solid wastes from one area to other distant areas has created social and political problems that have limited long-distance transport of unprocessed solid wastes.

## 88.6 Processing and Resource Recovery (Recycling)

---

Solid waste processing has moved from incineration and open dumps to burial in sanitary landfills to partial recycling. **Incineration** has been the primary processing system for solid wastes in large cities over the past 100 years. The British pioneered incineration with energy recovery at the end of the last century, but it has been in only the last two decades that many energy recovery incineration systems have been constructed in the U.S. Poor designs and poor operations limited the use of energy recovery incineration even though they were quite successful in Europe. Incineration has application only in the very crowded areas of the country where heat energy can be easily used by adjacent industrial operations. It is important to understand that incineration simply converts combustible solid wastes to gaseous wastes that must be discharged to the atmosphere for final disposal and the noncombustible solid wastes to **ash** that must be returned to the land. Because of the potential for air pollution, the EPA has required extensive air pollution control equipment for solid waste incinerators, increasing the capital and operating costs. The U.S. Supreme Court has indicated that municipal solid waste ash must pass the hazardous waste criteria or be treated as hazardous waste. The high cost of incineration has limited its use to highly populated areas that produce large quantities of solid wastes on a continuous basis. Even in these areas, social and political pressures have limited the use of incineration for processing solid wastes.

Sanitary landfilling is the engineered burial of solid wastes. Fundamentally, sanitary landfills are sound processing systems for municipal solid wastes. The two most common forms of sanitary landfills are **trench landfills** and **area landfills**. Both methods employ heavy equipment to compact the solid wastes to at least 1000 lb/yd<sup>3</sup>. Unfortunately, inadequate designs and improper operations have combined to create a poor public image for sanitary landfills. The major problems with sanitary landfills have been (1) the failure to apply adequate soil cover on the compacted solid waste at the end of each day, allowing solid wastes to blow over the landfill surface and odors to escape; and (2) allowing water to enter the landfill, creating leachate and methane gas. Leachate passing through the sanitary landfill has contaminated groundwater as well as surface waters in some locations. Methane gas formation has produced fires in a few landfills, creating concern in the media over the safety of the sanitary landfills. The simplicity of sanitary landfills has made them the most popular form of solid waste processing with local government. The failure of local government to operate sanitary landfills properly has led the EPA to develop more complex regulations under Subtitle D of RCRA. Leachate and gas collection systems—as well as water barriers and sampling systems to prove that leachate and gas are not leaving the landfill and creating environmental pollution—will be required in the future. The cost of sanitary landfill processing of solid wastes will increase significantly as the EPA develops more stringent operational requirements.

**Reuse and recycling** have long been important as a solid waste processing system. Most countries with limited economic bases do not have serious solid waste problems. These countries use and reuse all their resources as a necessity. As countries grow economically, their production of solid wastes increases. In 1970 the U.S. demonstrated that current solid wastes could be recycled. Unfortunately, recycling of solid wastes was not as cost-effective as using raw materials and did not gain much acceptance. Environmental groups brought pressure on various industrial groups to begin recycling. The aluminum can industry developed the best recycling system and survived the challenge from environmentalists. The plastic industry recognized the dangers that adverse media exposure posed and began to develop methods for plastic recycling. Glass was easily recycled but it was too heavy to ship very far and was made from an abundant material widely available in nature. Office paper was the easiest paper product to recycle. Corrugated cardboard was also recyclable. Newspapers were abundant but had to be used at a lower product level or de-inked for fiber recovery. The problem with lower product formation was that ultimately the material had to be processed back into the environment. De-inking was expensive and produced water pollution with concentrated solids that had to be processed before being returned to the environment.

The EPA established a Municipal Solid Waste Task Force in 1988 to develop a national agenda for solid wastes [EPA, 1989]. With the help of various environmental organizations they published *The Solid Waste Dilemma: An Agenda for Action*. They called for a national goal of a reduction of 25% in solid wastes by source reduction/recycling by 1992. It was recognized that 17% of the solid wastes was composed of yard wastes that could be removed and composted for reuse. This fact meant that only 8% more solid waste reduction was necessary in the form of metal cans, glass bottles, and newspapers. A number of state legislatures quickly accepted the 25% reduction goal and eliminated the discharge of yard wastes to sanitary landfills. Local communities had to eliminate collection of yard wastes or establish separate collections and composting programs. A

few states legislated mandatory recycling. Unfortunately, mandating recycling created a sudden increase in recyclables that overwhelmed the markets, driving the prices down and increasing the costs. Unfortunately, the excess solid wastes were processed into sanitary landfills rather than being recycled. It was quickly learned that even the commodity of solid waste was governed by supply and demand economics. Distortion of economics by government leads to chaos rather than to a positive solution. The basic problem has been excessive social and political pressure for an instant solution to problems that require time and patience to resolve. However, some progress has been made with partial recycling of some solid waste components. A recent survey by Lisa Rebasca in *Waste Age* [1994] indicated that 40 states had data on recycling rates. The rates of recycling ranged from 3 to 56% with a median of 14%.

## 88.7 Final Disposal

---

There is no doubt that solid waste **reduction**, reuse, and recycling is the best method for processing solid wastes. The major issue is the same as it was in 1970—economics. Society has not learned how to reduce the production of solid wastes while maintaining an economically viable operation. Solving the problem of solid waste involves determining what materials should not be produced and how to efficiently employ people in meaningful endeavors. Reuse and recycling is more attractive since work is required to reprocess the waste materials into useful products. It should be recognized that all materials come from the earth and most materials are still available in the solid wastes. Recycling is the ultimate solid waste process, with wastes being converted back to raw materials for manufacture to new products to benefit all people. The strength of democratic societies lies in their ability to adapt to current conditions with a minimum of wasted effort. Until complete recycling systems are developed that can economically process solid wastes, storage will continue to be the final disposal of solid wastes. Storage may take many forms, including burial below the ground surface or above the ground surface, as in a sanitary landfill. When society needs the buried materials, the sanitary landfills will become the mines for future generations. Few people recognize that the future of current societies depends on their ability to process solid wastes back into the environment without creating serious pollution problems. The processing of polluted air and polluted water results in the production of solid wastes that must be returned to the environment. Survival does not depend on the heads of state or various legislative bodies, but, ultimately, on the action of a few individuals at the local level. Those dedicated individuals who collect and process all the solid wastes that society produces provide the environment that makes life worth living and allows the rest of society to do the things it finds most enjoyable. The future is bright because the solid waste profession has met all the challenges to date.

### Defining Terms

**Area landfill:** A landfill constructed by placing the solid waste against a natural hill, compacting the solid waste to 1000 lb/yd<sup>3</sup>, and covering with a minimum of 2 ft soil for final cover. The next cell is constructed by placing the solid waste against the previous cell and raising the land surface to the top of the landfill.

**Ash:** Residual inorganic material remaining after incineration.

**Incineration:** Controlled burning of mixed solid wastes at a temperature of 1800°F for a sufficient time to oxidize 99% of the organic matter in the solid waste.

**Solid wastes:** All solid materials that have no significant economic value to the owner and are discarded as wastes.

**Trench landfill:** A landfill constructed by digging a trench 10 to 15 ft deep and 20 to 30 ft wide, filling it with solid waste, compacting the solid waste to 1000 lb/yd<sup>3</sup>, and covering with a minimum of 2 ft soil for final cover.

**Waste recycling:** The reuse of solid waste materials after separation and reprocessing to new products.

**Waste reduction:** The reduction in the production of solid wastes, primarily by reducing the production and consumption of goods by society.

**Waste reuse:** The direct reuse (without major processing) of solid wastes by members of society.

## 90.1 Regulations

---

Among the federal and state regulations related to soil contamination and cleanup, the Comprehensive Environmental Response Compensation Liability Act (CERCLA, or Superfund) and the Resource Conservation and Recovery Act (RCRA) Corrective Action are most important. CERCLA, which was enacted in 1980, is the first comprehensive set of federal laws addressing releases of hazardous substances into the environment [U.S. EPA, 1990a]. The main objective of CERCLA is to establish an organized and cost-effective mechanism for responding to releases of hazardous materials, or to abandoned or uncontrolled hazardous waste sites, that present a serious threat to human health and environment. To accomplish this, CERCLA mandates two types of responses: an emergency response action for handling major chemical spills or incidents requiring immediate action and a remedial response capability for undertaking the long-term cleanup of hazardous waste disposal sites. The regulatory framework developed to guide these responses became the National Contingency Plan (NCP), which first outlined the level of cleanup necessary at Superfund sites and established basic procedures pertaining to discovery and treatment of hazardous waste sites. The federal Superfund cleanup process begins with the EPA or state agency conducting a preliminary assessment of a suspected site. If the results show that hazardous

substances have possibly been released to the environment, the agency will conduct a site inspection. Based on this information the agency determines whether the site is added to the National Priority List (NPL). Once the site is on the NPL, the following procedures are followed: (1) remedial investigation (RI)/feasibility study (FS), (2) public comment period, (3) record of decision (ROD), and (4) remedial design (RD)/**remedial action** (RA) [Hopper, 1989].

Whereas the Superfund regulation relates to the past hazards and cleanup requirements for hazardous waste sites, the RCRA amendments of 1984 focus on the cleanup of operating manufacturing facilities and the control of hazardous waste releases. RCRA imposes regulatory standards and permit requirements for ongoing hazardous waste management activities. Discretion is left to federal/state agencies on a site-specific basis to determine if, when, and what corrective actions are required. A facility that treats, stores, or disposes hazardous wastes may be required to initiate a corrective action to prevent a release of hazardous substances to the environment. Corrective action must address all releases of hazardous substances in the entire facility. The steps in RCRA corrective action include: (1) RCRA facility assessment, (2) RCRA facility investigation, (3) identification of remedies, (4) implementation of remedies, and (5) operation and maintenance [U.S. EPA, 1990a]. Table 90.1 lists acronyms commonly used in regulation for soil and remediation of soil.

**Table 90.1** Acronyms Used in Soil Remediation

ARAR	Applicable or relevant and appropriate requirements
CERCLA	Comprehensive Environmental Response Compensation and Liability Act
HRS	Hazardous ranking system (EPA's system for ranking the priority of cleanup sites)
MCL	Maximum contaminant level, enforceable standards under the Safe Drinking Water Act
NCP	National Contingency Plan
NPL	National Priority List, a list of sites eligible for federal cleanup
PRPs	Potentially responsible parties, who may be held liable for cleanup costs pursuant to CERCLA
RA	Remedial action
RCRA	Resource Conservation and Recovery Act
RD	Remedial design
RI/FS	Remedial investigation/feasibility study
ROD	Record of decisions
SARA	Superfund Amendment Reauthorization Act
SITE	Superfund Innovative Technology Evaluation
TCLP	Toxicity characteristics leaching procedure
TSCA	Toxic Substance Control Act

# 90.2 Treatment Technologies

As of 1991, landfilling and containment [U.S. EPA, 1992a] accounted for about 37% of all the remedial actions specified in Superfund RODs. The obvious drawbacks of landfilling are that the process does not eliminate the contamination or the liability associated with it and that the number of available sites for landfilling is constantly being reduced. Therefore, there are great incentives for developing alternatives to landfilling. The other 63% of the remedial actions, specified in the 1991 RODs, included both well-demonstrated and innovative technologies. The distribution of the nonlandfilling remedial actions for 1991, grouped by technology type, is shown in Fig. 90.1. The most commonly used technologies are thermal processes such as incineration, followed by solidification/stabilization and soil vapor extraction. The selection of a technology depends most on the physicochemical properties of the contaminant and soil, the local hydrogeology, and the amount of soil requiring treatment. Table 90.2 summarizes treatment technologies investigated for remediation of Superfund sites.

**Figure 90.1** Alternative treatment technologies through 1991. (Source: U.S. EPA, 1992.)

**Table 90.2** Treatment Technologies Investigatedfor Remediation of Superfund Sites

Technology	Contaminants
Soil vapor stripping	VOCs, <sup>1</sup> SVOCs, <sup>2</sup>
Thermal desorption	VOCs, SVOCs, PCBs, pesticides, <sup>3</sup> metals <sup>4</sup>
Soil washing	Metals, dioxins, PAHs, <sup>5</sup> PCBs, pesticides
Solvent extraction	PCBs, VOCs, SVOCs,

In situ flushing	VOCs, SVOCs, PAHs, metals
Solidification	Metals, pesticides, SVOCs, VOCs
Bioremediation	PAHs, SVOCs, VOCs
Dechlorination	PCBs, SVOCs, dioxins, pesticides

Examples of each classification are as follows:

<sup>1</sup>TCE, TCA, DCE, DCA, PCE, BTEX, TX, MEK, acetone, benzene carbon tetrachloride, chloroform, isopropyl alcohol, Freon, methylene chloride, styrene, vinyl chloride

<sup>2</sup>PCP, DNT, Aniline, Bis 2-ethyl hexyl phthalate, chlorobenzene, dimethylphenol, ethyl benzene, naphthalene, phenol, polychlorinated phenols

<sup>3</sup>DDT, DDE, DDD, ethyl and methyl parathion,, silvex, Toxaphene

<sup>4</sup>Arsenic, cadmium, chromium, copper, lead, mercury, nickel, silver

<sup>5</sup>Benzo anthracene, benzo pyrene, cresol, creosote, petroleum hydrocarbon

## 90.3 Landfilling and Containment

Landfilling and containment are the most widely used "treatments" for contaminated soil and account for about a third of all remedial actions. Although neither of these approaches decontaminate the soil, they do attempt to reduce the risk of the pollutants coming in contact with people or the surrounding environment. Ironically, about 25% of today's Superfund sites are former landfills. Modern landfills are usually lined with a clay layer or synthetic impermeable geomembrane that prevents leaching of contamination into the local groundwater. Landfills are classified as either *secured hazardous waste landfills* or *sanitary landfills*. Most contaminated soil that is intended for landfilling will be put in secured hazardous waste landfills.

Containment implies installation of impermeable barriers around the contaminated region. Examples of barriers are trenches backfilled with a bentonite slurry (slurry walls) or lined with a synthetic geomembrane. The top of the contaminated site is usually capped with a clay layer. The obvious difficulty in containment is installing a barrier beneath the contaminated region. In some cases the contaminated soil must be excavated and the empty hole lined with a barrier material before the contaminated soil is backfilled into the hole.

## 90.4 Soil Vapor Extraction

Soil vapor extraction (SVE) or soil vapor stripping is an **in situ** process in which several wells are sunk into and around the contaminated soil. In the simplest applications, air blowers attached to well heads create a partial vacuum within the wells, causing air and vapors in the surrounding soil to flow towards the wells and out of the soil. Volatile contaminants in the soil vapor are removed with the vapors and are usually treated above ground by thermal oxidation or adsorption on activated carbon. As the contaminant vapors are removed, liquid contaminant present in the soil evaporates to maintain equilibrium between the liquid and vapor phases of the contaminant. Thus liquid contaminants are removed from the soil by purging the contaminant's vapor phase until the liquid has completely evaporated.

Many variations of SVE exist that improve performance and extend the range of applicability of

the process. In some cases positive pressure is applied to wells to help control the flow direction. Heated air or steam can be injected into some wells to warm the soil and thereby increase the vapor pressure of volatile compounds. Increasing the temperature can dramatically increase the rate and degree of contaminant removal.

SVE is applicable to sites that have high soil permeability ( $K_h > 10^{-9} \text{ m}^2$ , or 1 cm/s) and are contaminated with volatile organic compounds (VOCs), as listed in Table 90.2. The vapor pressure of the contaminants should be greater than about 0.5 torr for effective performance. SVE is not appropriate for semivolatile compounds such as PCBs and many pesticides. Drier soils are easier to clean than soils with high moisture content, but the process has been applied to partially saturated soils. The performance and cost estimate of soil vapor extraction and other processes are shown in Table 90.3.

**Table 90.3** Performance and Cost of Remediation Technologies

Contaminants	Performance		Operating Condition	Cost Estimate
	Before	After (% removal)		
Soil Vapor Extraction				
Hydrocarbons	70 ppm	0.002 ppm	Steam enhanced	\$35–40/ton
Carbon tetrachloride			Ambient condition	
Benzene, TCE, PCE, DCA, MEK		Tot. VOC < 10 ppm Avg. VOC < 1 ppm	Continuous operation	
TCE		(95%)		\$40/ton(\$10–150/ton)
TCE, TetCE		(85 to 99% CVOC)  (55% SVOC)	Steam: 450°F & 450 psi,  hot air: 300°F & 250 psi	\$250–350/yd <sup>3</sup>
Thermal Desorption				
VOC	32 000 ppm	4.5 ppm	T = 160°C, heated screw	
TCE	1000 ppm	0.1 ppm	T = 300°F, t = 6–8 min	
PCB	1.04–2.3%	< 2 ppm	T = 1000°F	\$185/ton
Coal tars, wood preservatives		(Nearly 100%)	T = 260 to 815°C	\$260–1000/ton
PCB, PAH, pesticides		(99.9999%)	T = 850°C	
PCB		(99.99%)	Heated up to 1850°F	\$800/ton
Solidification/Stabilization				
Chromium		TCLP < 0.5 ppm		\$73/ton
PCB, organics	PCB: very low	TCLP: ND	In situ	
Organics, heavy metals	Pb: 2.2%; oil & grease: 25%;	TCLP = Pb: 100ppb; oil & grease: 4	Cement, fly ash,chloranan	\$40–60/ton for metals;\$75–100/ton

Hydrocarbons, metals	VOC: 100 ppm	ppm TCLP = organics < detection limit Ba: 2 mg/L	additives Emulsified asphalt	for organics \$88–100/ton for organics
Pb, Cd, As, Sb	Pb: total = 1.2% TCLP = 620 mg/L	TCLP: 0.4 mg/L	Dry, wet additives	\$67/ton
Bioremediation				
PAHs	800–2000 ppm	10–80 ppm	Time = 3–6 months	
PAH (creosote)	13 000 ppm	500 ppm	Slurry with 30% soil nutrients & surfactants	\$350/yd <sup>3</sup>
Gasoline, diesel, Jet-A, JP-4	88 000 ppm	(BTEX > 30%)	Microaerophilic bacteria micronutrients	\$25–50/yd <sup>3</sup>
Waste oil Toxaphene	470 ppm	(TPH > 80%) 180 ppm	Anaerobic, pH = 8.3–9.8	
Soil Washing				
Hg, PAH, organic Pesticides		(90%)	Flotation	\$125–200/ton
Hydrocarbons	15 000 ppm	(85–99%)	Surfactants, biosurfactants	\$250/ton \$40–140/ton
As, Cr	As: 2–6200 ppm Cr: 4–6200 ppm Cr: 4–6200 ppm	As < 1 ppm Cr: 627 ppm Cr: 627 ppm	Ambient, pH = 2–9

## 90.5 Thermal Treatments

There are many techniques that use heat to remediate soil, and they vary widely in the manner in which the soil is heated and the temperatures at which they operate. At one end of the spectrum is in situ steam stripping, described in the previous section as an SVE technique. In this process the soil temperature may be increased 20 to 40°C, which greatly assists the evaporation of volatile organics but does not destroy them. At the other extreme is incineration, which typically involves heating excavated soil with burning fuel in a furnace. For incinerators permitted to treat PCB-contaminated soil, for instance, temperatures must reach 1000°C with residence times of at least two seconds. Incineration can treat soils contaminated with organics and volatile metals like mercury and arsenic. The ash resulting from incineration may or may not be hazardous, depending primarily on its heavy metal content.

Another widely used **ex situ** thermal treatment is low-temperature thermal desorption. In this process, excavated soil is heated to 300 to 600°C so that volatile and semivolatile contaminants are vaporized. At these temperatures only partial destruction of some organic compounds is expected, and vapor treatment therefore is necessary. Usually the off-gases are either condensed and concentrated or passed through a thermal oxidizer to destroy the remaining organics. Carbon

adsorption and wet scrubbers are often used as polishing steps.

Thermal treatments account for about 36% of nonlandfilling remedial actions (Fig. 90.1). The advantage of thermal treatments is that they are robust. If the temperature is hot enough and the residence time long enough, any organic contaminant can be either volatilized, pyrolyzed, or oxidized. In ex situ processes like incineration and low-temperature desorption, the required operating conditions can be carefully controlled. However, ex situ thermal processes require excavation and handling of the soil, both steps adding expense and complexity to the process. In situ thermal processes generally require less complex machinery but also have less control of the operating conditions. In addition to steam-assisted SVE, in situ processes are being developed that make use of radio frequency and electric resistance heating for removal of VOCs and SVOCs.

## 90.6 Stabilization

---

Soil stabilization is the process of mixing the soil with an additive, such as a cement or grout, so that contaminants are bound in the resulting mixture and cannot leach out to the surrounding environment. Stabilization has been used to treat soils contaminated with heavy metals and organics such as PCBs. In the case of organics contaminants, special additives with high organic affinity must be added to the stabilizing mixture. Usually the soil is excavated and processed above ground before being put back into its original location. The additives may compose about 20 to 30% of the volume of the resulting mixture so that significantly more space is required for the treated soil.

There are also techniques for mixing the stabilizing agents directly into the soil without excavation. This is accomplished using machinery such as the Mectool, which is a large auger attached to a drill rig. As this auger is driven down through the soil, stabilizing agents are pumped through the auger blades and mixed with the soil.

## 90.7 Bioremediation

---

Many organic compounds or contaminants are degraded by microorganisms present in the soil, producing environmentally benign compounds. Biodegradation of contaminants can occur naturally if the soil has a proper mix of microorganisms, nutrients, and other environmental conditions such as pH, molecular oxygen, concentration, and temperature. Natural restoration (i.e., simply waiting for the site to improve, with minor site manipulation) is the most cost-effective way to decontaminate sites, if it is applicable. Sites should be investigated for the potential of natural restoration by determining the rate of contaminant degradation and formation of by-products or intermediates, and their environmental impacts.

*Bioremediation* refers to enhancement of biodegradation by altering conditions to increase its rate and effectiveness. Most applications of bioremediation make use of naturally occurring microorganisms that can use the organic contaminants as a food or energy source under favorable conditions. Applying bioremediation to a site usually entails manipulating the conditions in order to stimulate microbial activity. Examples of techniques used to stimulate biodegradation include injecting air into the soil to promote aerobic activity, supplying nutrients to promote growth of the microbial population, and increasing the temperature to stimulate microbial

metabolism.

Bioremediation is only appropriate for certain organic contaminants and depends on the hydrogeology of the site. As with most other in situ processes, bioremediation works best in sandy soils. In such soils there is enough transport of water and vapors to provide nutrients and oxidizing and reducing agents to microbes and to remove microbial wastes.

## 90.8 Soil Washing

---

Soil washing processes can take on many forms. In ex situ processes the soil is usually prepared for washing by grinding and size fractionation. Because large soil particles have a relatively small surface area per mass, they adsorb small amounts of contaminants; therefore, size fractionation often greatly reduces the volume of soil that needs to be washed. The washing process can be done with water alone or with water plus **surfactants**, organic solvents, or acids. Surfactants and organic solvents are used to remove organic contaminants, and acids are used to remove metals. In situ soil washing is a less common technique that involves pumping a washing solution into injection wells and extracting it at production wells installed in the contaminated soil.

Soil washing works best with soils that have low surface-area-to-mass ratios, such as sandy soils. Clay soils present problems in terms of desorbing the contaminants and separating the fine particles from the washing solution.

## 90.9 Emerging Technologies

---

Several technologies are being developed that may solve problems that present technologies cannot address. For radioactive and mixed radioactive/hazardous waste soils, in situ **vitrification** may be able to destroy the organic contaminants and encapsulate the radioactive compounds in glassy material. For low permeability soils in which SVE and bioremediation cannot work, in situ **electrokinetic** processes have been shown to remove metals and water-soluble organics [Shapiro, 1993]. In situ chemical destruction techniques are also being developed, such as a method to destroy TCE in groundwater as it flows through an installed permeable wall made of iron particles.

### Defining Terms

**Electrokinetic:** A process in which water and dissolved materials are caused to move soil as a result of an applied electric field.

**Ex situ:** A process conducted on excavated soil.

**In situ:** A process conducted in place, without excavation of soil.

**PCBs:** Polychlorinated biphenyls, dielectric compounds previously used in high-voltage electrical equipment such as transformers and capacitors.

**Remedial action:** Specific steps taken to decontaminate a site.

**Surfactants:** Surface active chemicals, typically found in soaps, that assist solubilization of nonpolar organic materials in water.

**SVOCs:** Semivolatile organic compounds, which slightly volatilize at room temperature.

Examples are shown in [Table 90.2](#).

**Vitrification:** Process of heating soil to sufficient temperature to cause melting of silica minerals and produce a glass-like material.

**VOCs:** Volatile organic compounds, which readily volatilize at room temperature. Examples are shown in [Table 90.2](#).

The processes of surface runoff and infiltration into the ground are normally effective in removing excess water from the land. Where these processes are impeded, wetland habitats, with their moist or permanently saturated soils, may develop. Plant life in wetlands is highly specialized in order to cope with excess water, lack of oxygen, and frequently a scarcity of nutrients in the soil. The rural economy of wetland areas is also distinctive, based on drainage and careful water level control or on the cultivation of wetland crops such as rice and freshwater fish and the production of traditional materials such as reed and peat. The conservation of wetland areas requires an understanding of their hydrology.

WATER RESOURCES ENGINEERING encompasses a number of fields associated with design, construction, and management activities related to water resources. Basic to all these fields are hydraulics and hydrology, which are concerned with the flow of water in the human-made and natural environments, respectively.

Records of different applications of hydraulics go back to antiquity. There are ancient Egyptian pictographs of water bailers and of siphoning. The principles of hydrostatics and flotation began with the early Greek Archimedes. The elements of hydraulics of open channels were known to the Romans, who used the techniques very efficiently in their aqueducts, such as the famous Pont du Gard in southern France and the Cloaca Maxima or main sewer of ancient Rome. But we have to look to the Renaissance to find the beginnings of experimental hydraulics.

Leonardo da Vinci is well known for his drawings of eddy formations, profiles of free overfalls, and flows over weirs, for example. Our understanding of the velocity of flow from orifices is due to the 17th-century Italian Toricelli. Also in that century the Frenchman Pascal developed the hydraulic press, which he called the machine for multiplying forces. In the next century Daniel Bernoulli dealt with the dynamics of fluids; the well-known theorem that bears his name is concerned with the different forms of energy in a steadily moving incompressible fluid.

Toward the end of the 18th century experimenters such as Borda and Venturi worked on devices for the measurement of flow in pipes. The classical form of a contraction followed by an expansion is known as the Venturi tube. In the second half of the 19th century the Englishman Osborne Reynolds developed the criterion that today is known as the Reynolds number and that distinguishes between laminar and turbulent flows. Robert Manning, who served as president of the Irish Institution of Civil Engineers in the latter part of the 19th century, is well known for the formula for the velocity of flow in open channels, which is named after him.

Counterparts to the Venturi tube for measurement in open-channel flow were developed in the 20th century. One of these is the Parshall flume. The merging of experimental hydraulics and fluid mechanics occurred in this century, and substantial developments have taken place in universities and laboratories of the U.S. Compared with hydraulics, hydrology is a much more recent science. This is not to say that there were no concerns in earlier times about the flow of water in the natural environment. In fact, Nilometers were in use in 3000 B.C. to record the fluctuations of the Nile. However, accurate understanding of the hydrologic cycle is very recent, and the principles were not fully accepted until the 19th century.

Although the equations for surface flow were formulated by de Saint Venant in 1871, their practical solution had to wait until the 1960s, with the advent of the digital computer. Darcy's experiments with flow through sand columns, published in 1856, form the basis of our understanding of groundwater flow. The extension of Darcy's law to unsaturated flow was presented by Richards in 1931.

Recent advances in hydrology are concerned with the transport of solutes in the natural environment. In groundwater this transport takes place by advection, diffusion, and mechanical dispersion. Chemical reactions can take place between the solute and the rock or soil medium.

Of course, one very important phase of transport is that of sediments. Suspended sediment can move by convection and turbulent diffusion and is sometimes associated with the transport of pollutants. The evaluation of bed load transport is more empirical. The name of Hans Einstein, son of Albert Einstein, is associated with the transportation of bed load. Under the direction of Vito Vanoni, the ASCE published in 1975 a comprehensive manual and report on engineering practice with regard to sedimentation.

It is hoped that the placement of several of the key names in their historical context will whet the reader's interest in pursuing the following chapters.

## Barbara Hauser

*Bay de Noc Community College*

Hydraulics deals with the principles that govern the behavior of liquids at rest and in motion. This is the study of the mechanics of water and its control by man. Hydraulics deals with pressurized systems and open channel flow, and includes principles of pressure and force, energy theorem, **flow** calculations and measurement, friction losses, pumps, and pumping applications.

## 91.1 Flow Characteristics

---

*Laminar flow* occurs at extremely low **velocity**; water molecules move in straight parallel lines called *laminae*, which slide upon each other as they travel, evidenced in groundwater flow; friction losses are minimal. *Turbulent flow*, normal pipe flow, occurs because of roughness encountered on the inner conduit walls. Outer layers of water are thrown into the inner layers; movement in different directions and at different velocities generates turbulence. *Steady state flow* occurs if at any one point flow and velocity are unchanging. Hydraulic calculations almost always assume steady state flow. *Uniform flow* occurs when the magnitude and direction of velocity do not change from point to point.

## 91.2 Equation of Continuity

---

At a given flow, water velocity is dependent upon the cross-sectional area of the conduit. This statement expresses the most basic hydraulic equation, the equation of continuity:

$$Q = AV \quad (91.1)$$

where  $Q$  is the flow in cfs,  $A$  is the cross-sectional area in  $\text{ft}^2$ , and  $V$  is the velocity in  $\text{ft/s}$ .

## 91.3 Pressure Characteristics

---

### Unit Pressure

Water **pressure** is due to its weight ( $62.4 \text{ lb/ft}^3$ ) and the depth of water above the point of measurement (equating pressure to depth,  $0.433 \text{ psi/ft}$  water depth, or  $2.31 \text{ ft}$  water depth/psi).

Water pressure does not affect liquid density, and *Pascal's law* states that the pressure at any one point in a static liquid is exerted with equal intensity in all directions.

### Pressure Measurement

The *piezometer* is an open-ended vertical tube inserted at the point of pressure measurement, and is impractical for measuring anything but the smallest pressures. The *manometer* is a modification of the piezometer with internal liquid fill of a higher specific gravity, bent into a U shape for easy reading. When connected to two separate sources of pressure, the unit yields a differential reading.

The *pressure gage*, called a *Bourdon tube*, may read feet, psi, or inches of mercury. It provides a direct, easy-to-read, static connection to the source of pressure (Fig. 91.1).

**Figure 91.1** Pressure gage.

The earth's atmosphere, about 200 miles deep, exerts a pressure of 14.7 psi or the equivalent of 34 ft water pressure upon the surface of the earth at sea level, the standard reference point for all pressure measurements. *Gage pressure* (psig) is the pressure read on a gage above or below atmospheric. *Absolute pressure* (psia) includes atmospheric pressure in the reading and is employed when calculating pumping suction **heads**.

## Total Pressure

**Force** is registered in pounds, and is calculated as follows:

$$\begin{aligned}\text{Force} &= \text{Pressure} \times \text{Area} & (91.2) \\ \text{lb} &= \text{lb/ft}^2 \times \text{ft}^2\end{aligned}$$

## Components of Pressure

*Pressure head* (PH) is due to the depth of the water and is measured as feet of water or registered on a pressure gage. *Velocity head* (VH) is the distance the water can move due to velocity energy; it does not register on a pressure gage, but can be captured by a pitot gage (described later) and is calculated as follows:

$$\text{VH} = \frac{V^2(\text{ft/s})^2}{2g(\text{ft/s}^2)} \quad (91.3)$$

*Elevation head* ( $Z$ ) is pressure due to elevation above the point of reference, measured as feet of water or registered on a pressure gage.

## Bernoulli's Theorem

In a fluid system employing steady state flow, the theoretical total energy is the same at every point in the path of flow, and the energies are composed of pressure head, velocity head, and elevation head ( $Z$ ). Expressed in terms of actual energy change between two points in a dynamic system where a pressure decrease or head loss (HL) occurs,

$$\text{PH}_1 + \text{VH}_1 + \neg_1 \neq \text{PH}_2 + \text{VH}_2 + \neg_2 + \text{ZHL} \quad (91.4)$$

## 91.4 Effects of Pressure<sup>3</sup>/<sub>4</sub>Dynamic Systems

---

*Water hammer* (hydraulic shock) is the momentary increase in pressure that occurs in a moving

water system when there is a sudden change in direction or velocity of the water. **Suppressors** are installed where water hammer is encountered frequently in order to minimize shock and protect piping and appurtenances. *Surge*, a less severe form of hammer, is a slow-motion mass oscillation of water caused by internal pressure fluctuations in the system; it can be controlled by surge suppressors or spring-loaded pressure relief valves. *Thrust*, caused by an imbalance of pressures, is the force that water exerts on a pipeline as it turns a corner. Its intensity is directly proportional to water **momentum** and acts perpendicular to the outside corner of the pipe, affecting bends, tees, reducers, and dead ends, pushing the coupling away from both sections of pipeline. To calculate total pounds of thrust,

$$\text{Thrust} = 2TA \times \sin \frac{1}{2}\theta \quad (91.5)$$

where  $T$  is the test pressure of system in psf, plus 100 psi for hammer, and  $A$  is the cross-sectional area of fitting.

For pipes using push-on or **mechanical joints**, thrust restraint is desired. *Thrust blocks* are concrete blocks cast in place onto the pipe and around the outside corner of the turn. Block-bearing face must be large enough so that its pressure does not exceed soil-bearing strength (variable, <1000-10 000 lb/ft<sup>2</sup>, depending on soil type) (Fig. 91.2).

**Figure 91.2** Thrust blocks.

To calculate bearing face area of the thrust block:

$$\text{Area} = \frac{\text{Total thrust (lb)}}{\text{Bearing strength of soil (lb/ft}^2\text{)}} \quad (91.6)$$

In locations where it is difficult to use thrust blocks, *restrained joint pipe* is an alternative. Extra locking rings stabilize the joint under thrust conditions and transfer the load from the pipe directly to the surrounding soil.

## 91.5 Pressure Loss

*Major head loss* occurs because of friction dropping pressure along the conduit length. *Minor head loss* is caused by extra turbulence at bends, fittings, and diameter changes in the pipeline. In open channel systems, slope equates to the amount of pipe incline, as feet of drop per foot of pipe length; it is designed to be just enough to overcome friction losses so that velocity will remain constant. In closed conduit systems under pressure, the pipe is taken as horizontal unless otherwise indicated, and slope relates directly to the loss of pressure per foot of pipe:

$$\text{Slope} = \frac{\text{Head loss}}{\text{Length}} \quad (91.7)$$

## Head Loss<sup>3/4</sup>Physical Components

Interior pipe roughness is dependent upon pipe material and increases with corrosion and age, designated by the *C* factor, the roughness coefficient ([Table 91.1](#)).

**Table 91.1** Hazen-Williams Roughness Coefficient (*C*) Value

Type of Material	<i>C</i> Value
Asbestos cement	140
Brass	140
Brick sewer	100
Cast iron:	
10 yr. old	110
20 yr. old	90
Ductile iron (cement lined)	140
Concrete:	
Smooth	140
Rough	110
Copper	140
Fire hose (rubber lined)	135
Galvanized iron	120

Glass	140
Lead	130
Masonry conduit	130
Plastic	150
Steel:	
Coal-tar enamel lined	150
Unlined	140
Riveted	110
Vitrified	120

---

Length, velocity head, and diameter (inversely) also affect pressure loss. A widely used formula for flow, velocity, or head loss calculation in a closed pipe system, derived from these physical components, was developed by Hazen and Williams:

$$Q = 0.435 \times C \times d^{2.63} \times s^{0.54} \quad (91.8)$$

For field use, a **nomograph** has become popular ([Fig. 91.3](#)).

Variations of this formula are easily recognizable, and with any of them approximate values can be measured or calculated for flow, velocity, slope, or length. Accuracy is limited, however, by the roughness coefficient  $C$ , which can only be estimated based on pipe type and age and a knowledge of water quality.

## Compound Pipe Systems

When pipes are laid in series, flow is continuous through the system and head losses in the component segments are additive. Pipes laid in parallel split flow among the components; head loss in each is identical and is the same as the total head loss. Indirect solutions may be obtained by the equivalent pipe method, creating a single pipe with head loss equivalent to that in the compound set.

## Minor Head Loss

For determination of minor head loss, a standard nomograph is often used, with which each fitting is converted to an equivalent length of straight pipe of the same diameter. Head loss calculations using the new length of pipe will include both major and minor losses ([Fig. 91.4](#)).

Figure 91.3 Hazen-Williams alignment chart.

**Figure 91.4** Resistance of valves and fittings to flow of fluids.

A few minor losses may be expressed in terms of velocity head ( $V^2/2g$ ). Useful in calculations where Bernoulli's theorem is in use and a velocity head value is readily at hand, this method directly converts to head loss (ordinary exit:  $HL = 1VH$  ; ordinary entrance:  $HL = 0.5VH$  ; Borda entrance:  $HL = 1VH$  ).

## 91.6 Open Channel Flow

---

In conduits where the water has a free surface exposed to atmospheric pressure, velocity head is the energy driving flow. The channel must be physically sloped enough to overcome friction losses so that velocity is maintained. In a properly sloped channel, at steady state flow, the water surface is parallel to the channel bottom and the hydraulic grade line follows. Energy loss is negated by the slope of the channel, and water depth remains constant throughout. In an open channel with a horizontal bottom, the water encounters friction and decreases in velocity, "piling up" behind; it produces the pressure head needed as a greater depth at the upstream end, and the slope of the water surface registers its progressive loss downstream. If the channel is sloped more than is necessary to overcome friction losses, velocity will increase and water depth will decrease; the steep slope creates extra velocity head. A stream bed that slopes sharply, then levels off, will carry water at a shallow depth where the slope is steep and velocity is high. Downstream, the water will be deeper, and the velocity slower (Fig. 91.5).

**Figure 91.5** Hydraulic jump.

In locations where waters of two different velocities meet, a short section of deeper water occurs; water level rises at the point of velocity change before the surface evens out again; there is extra turbulence at this point, and the water traps air and expands. Called *hydraulic jump*, the phenomenon occurs dramatically at dams and flumes, less so as shoreline waves or those created in a ship's wake, or as ripples that form when a stone is thrown into water.

*Manning's formula* is widely used for calculation of velocity or flow in open

channels:

$$V = \frac{1.486}{n} \times R^{0.66} \times s^{0.5} \quad (91.9)$$

Manning's formula employs a roughness coefficient,  $n$ , which is specialized for materials of which open channels are constructed (Table 91.2). In this equation, diameter has been replaced by hydraulic radius ( $R$ ), making the formula flexible enough to adapt to all cross-sectional areas.  $R$  is a measure of the efficiency with which the conduit transmits water and is determined by dividing the cross-sectional area of the water by the wetted perimeter.

$$R = \frac{\text{Wetted area}}{\text{Wetted perimeter}} \quad (91.10)$$

For pipes less than full, wetted area and wetted perimeter are difficult to ascertain, and a hydraulic elements curve is an indirect but accurate method of obtaining the desired value based on its percentage of the full pipe value (Fig. 91.6).

**Figure 91.6** Hydraulic elements curve.

**Table 91.2** Manning Roughness Coefficient (*n*) Value

## 91.7 Flow Measurement

### Orifice Meter

An orifice meter is a flat steel plate with a precisely sized small diameter hole at the center that is installed between flanges in a pipeline; the pressure differential created across the orifice is measured by gages upstream and at the orifice discharge. Derived from Bernoulli's formula, calculation is based upon change in velocity head passing through the orifice:

$$Q = C_d A \sqrt{(PH_1 - PH_2) \times 2g} \quad (91.11)$$

$C_d$  = coefficient of discharge (0.6-0.9)

$A$  = area of the orifice ( $\text{ft}^2$ )

$\text{PH}_1$  = pressure head upstream

$\text{PH}_2$  = pressure head at discharge

## Venturi Meter

The Venturi meter is the most accurate and widely used closed conduit pressure differential meter—a constricted tube, with converging section, throat, and longer diverging outlet section. Gages are placed just upstream from the convergence and at the throat; flow is smooth through the unit, and head loss is minimal ( $C_d = 0.98$ ).

$$Q = C_d A \sqrt{\frac{(\text{PH}_1 - \text{PH}_2)}{1 - (d_2/d_1)^4} \times 2g} \quad (91.12)$$

## Pitot Gage

The Pitot gage is a flowmeter that relies on a direct measurement of velocity head. A pressure gage with a double sensing unit (or a differential manometer) is installed into the pipeline. One end is bent backwards into the flow to capture velocity head as well as pressure head. The differential reading is velocity head, which can be converted to flow.

## Magnetic Flowmeter

A magnetic flowmeter consists of a set of magnetic coils that surround the pipe, creating an electromagnetic field; an opposed pair of electrodes mounted at right angles register the induced voltage (converted to a current signal), which is directly proportional to the velocity of the water passing through the unit.

## Ultrasonic Meter

The transmissive type of ultrasonic meter sends ultrasonic beams through the pipe from opposite transmitter/receivers mounted at a diagonal to the flow stream; beam differential is directly proportional to water velocity. The reflective type sends a single sonic beam into the water from a transmitter mounted on the pipe; the beam bounces off solids in the water, and is picked up at a different frequency. The magnitude of frequency change is directly proportional to water velocity.

A variation sends a beam to the water surface from an overhead transmitter and relates the return time to water depth, which is convertible to flow.

## Positive Displacement Meter

Positive displacement meters are service meters suitable for residential customers; the unit consists of a measuring chamber enclosing a disk or piston; with each pulse a magnetic contact is made to a register that totalizes flow.

## Turbine Meter

Turbine meters consist of a measuring chamber with a rotor that turns in response to the velocity of the water. Large customer flows (hotels, industries) are recorded with turbine, or the more efficient "turbo" meters.

## Compound Meter

Compound meters are installed when accurate reading at both high and low flows is required for customer billing; this device consists of turbine meter on the main line and positive displacement meter on the bypass.

## Weir

The weir is the least costly open channel flow meter, a flat plate over which the flow passes. For a rectangular weir,

$$Q = 3.33 \times L \times h^{1.5} \quad (91.13)$$

where  $L$  is the width of weir and  $h$  is the head on weir. For a 90-degree V-notch weir,

$$Q = 2.5 \times h^{2.5} \quad (91.14)$$

## Parshall Flume

The Parshall flume is widely used for wastewater and irrigation water flow measurement due to low head loss; this device has self-cleansing capacity and ability to operate accurately over significant flow range and consists of inlet, downward inclining throat, and diverging outlet. Depth measurement is taken from a stilling well at inlet. The following formula applies to throat widths 1-8 ft and a medium range of flows:

$$Q = 4W \times H_a^{1.52} \times W^{0.026} \quad (91.15)$$

where  $W$  is the width of throat and  $H_a$  is the depth in the stilling well upstream.

Parshall flume formulas are based on low flows; at higher flows, a hydraulic jump forms at the outlet, which may submerge the throat, restricting flow. Formulas will not yield a true flow value; a stilling well at throat bottom measures downstream depth  $H_b$ , and with percent submergence the correction graph (Fig. 91.7) can be referred to.

**Figure 91.7** Corrections for Parshall flume.

## 91.8 Centrifugal Pump

Centrifugal pumps are mechanical devices that convert other forms of energy to hydraulic energy; these pumps create the pressure needed for flow to occur. Pumping technology was limited to positive displacement and screw devices until the nineteenth century, when the centrifugal pump was developed. This device is a small, efficient unit employing a rapidly revolving impeller; high water velocity is developed, which is then converted to pressure upon exit. The pressure

developed, the horsepower required, and the resulting efficiency vary with the discharge. These values are diagrammed graphically for each pump on a pump characteristic curve (Fig. 91.8), which has been developed from the formula

$$\frac{\text{gpm} \times \text{TDH}}{3960} = \frac{\text{WHP}}{\text{Pump efficiency}} = \text{BHP} \quad (91.16)$$

where TDH is the total dynamic head (the work the pump must do in overcoming lift and losses to move the water), WHP is the water horsepower (the power needed to move the water), and BPH is the brake horsepower (the power which must be available to the pump).

**Figure 91.8** Pump characteristic curve.

Each pump is built to operate at its *design point*, the head and flow at which it achieves maximum efficiency. The point at which it does operate is dependent upon the characteristics of the system, the arrangement of the pipes and appurtenances through which the flow must pass. A centrifugal pump will perform according to its characteristic curve. Pump characteristics, however, may be changed by adjusting the pumping speed (change rpm or impeller size), and oak tree curves are designed to demonstrate characteristics using various sizes of impellers.

Pumps installed in series increase the pumping head, as in booster pumping (multiple pumps) or high-pressure or deep well pumps (multiple impellers). Pumps arranged in parallel increase the flow; the head remains that of one pump working.

For further information on incompressible fluids, refer to **Chapter 33**.

## Defining Terms

**Flow:** The quantity of water passing a point in a given unit of time (gpd, gpm, cfs).

**Force:** The total pressure registered on an entire surface area (lb).

**Head:** Pressure, registered as feet of water.

**Mechanical joint:** Bell and spigot type; has an outer follower that bolts to the flanged end.

**Momentum:** Mass multiplied by velocity; responsible for extent of hammer, thrust, surge.

**Nomograph:** A specialized chart with three or more components that may yield an answer with one or more of its dimensions unknown.

**Pressure:** Force exerted on a unit area (psf, psi).

**Suppressor:** Air chamber or open container with small orifice connection to pipeline; allows temporary exit of some water when pressures are high.

**Velocity:** Speed at which the water travels (ft/s).

## Vijay P. Singh

*Louisiana State University*

Hydrology can be defined as the science that deals with occurrence, movement, distribution, and storage of water in respect to both its quantity and quality over and below the land surface in space, time, and frequency domains. Water quantity encompasses the physical aspects, and water quality, the chemical and biological aspects. One might sum up hydrology as the study of water in all aspects at macro and higher scales.

The study of hydrology originated in the design of hydraulic works. This historical underpinning continues to dominate the scope and the range of hydrologic investigations. It is therefore no surprise that most often civil engineering is the home of hydrology. With the changing environmental landscape, however, there are signs of hydrology becoming a geophysical science in its own right.

## 92.1 Classification of Hydrology

---

It is instructive to peruse the various classifications of hydrology [Singh, 1993]. By definition, hydrology can be classified as physical hydrology, chemical hydrology, or biological hydrology; as water quantity hydrology or water quality hydrology; as surface-water hydrology or subsurface hydrology. Depending on the type of **watershed** for which the study of water is undertaken, it can be classified as agricultural hydrology, forest hydrology, urban hydrology, mountainous

hydrology, desert hydrology, wetlands hydrology, or coastal hydrology. Considering the form of water or where water occurs predominantly, this study can be classified as snow hydrology, ice and glacier hydrology, atmospheric hydrology, or lake hydrology. Depending on the particular emphasis on land phase or channel phase, it can be classified as watershed hydrology or river hydrology. Hydrology is also classified based on the tools employed for investigation of hydrologic systems. Parametric hydrology, theoretical hydrology, mathematical hydrology, statistical hydrology, probabilistic hydrology, stochastic hydrology, systems hydrology, and digital hydrology form this classification. The various classifications of hydrology are useful in that they point to its scope and the range of techniques employed in its study.

## 92.2 Hydrologic Cycle

---

Water originates in the atmosphere when water vapors are transformed into droplets forming precipitation that falls on the land surface. Part of this precipitation, which eventually returns to the atmosphere through evaporation, is intercepted during its fall by vegetative canopy, buildings, and so on. Another part, which may fall on water surfaces such as streams, lakes, ponds, and seas, may either run off, evaporate, or get stored and finally evaporate. The remainder fills in the depressions on the ground, meets the infiltrative demand of the soil, and runs off the ground to form stream flow. The infiltrated water percolates down and recharges the groundwater and may eventually become stream flow. The final destination of all streams is the ocean, so stream flows finally reach the ocean. Part of the oceanic water returns to the atmosphere through evaporation. Part of the infiltrated water as well as of the surface flow returns to the atmosphere through evapotranspiration. Thus the cyclic movement of water from the atmosphere through precipitation to the land, through stream flow to the ocean, and through evapotranspiration back to the atmosphere is designated the **hydrologic cycle**. This movement, of course, follows devious paths. The study of the hydrologic cycle can then be defined as hydrology. A sketch of the hydrologic cycle [[Ackermann \*et al.\*, 1955](#)], as shown in [Fig. 92.1](#), is meaningful in that it brings out the complexity as well as the challenge encountered in the study of water.

**Figure 92.1** A schematic of hydrologic cycle. (From Ackermann, W. C., Colman, E. A., and Ogrosky, H. O. 1955. From ocean to sky to land to ocean. In *U.S. Department of Agriculture Yearbook 1955*, pp. 41–51. USDA, Washington, DC.)

## 92.3 Laws of Science

---

The laws that govern the movement of water and the constituents it carries with it over and below the ground are the conservation of mass, momentum, and energy. The conservation of mass is expressed as a continuity equation, and that of momentum as an equation of motion. Depending on the type of flow, these equations are expressed in a variety of forms, as will be clear from the following discussion.

### Surface Flow

For simplicity, only the one-dimensional form of the governing equations using a control volume is given here. The continuity equation can be expressed as

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} = q(x, t) - i(x, t) - e(x, t) \quad (92.1)$$

the momentum equation as

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + g \frac{\partial h}{\partial x} = g(S_0 - S_f) - \frac{(q - i)(u - v)}{A} \quad (92.2)$$

and the energy equation as

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + g \frac{\partial h}{\partial x} = g(S_0 - S_f) + \frac{u - v(v/u)}{2A} q \quad (92.3)$$

where  $A$  is flow cross-sectional area,  $Q$  is discharge (volumetric rate =  $u \cdot A$ ),  $u$  is average flow velocity,  $h$  is depth of flow,  $S_0$  is bed slope,  $S_f$  is frictional slope,  $q$  is lateral inflow per unit length of flow,  $i$  is infiltration per unit length,  $e$  is evaporation rate and other abstractions per unit length,  $v$  is velocity of lateral inflow in the longitudinal direction,  $x$  is distance in the longitudinal direction, and  $t$  is time. Except for the term expressing the influence of lateral inflow or outflow, Eqs. (92.2) and (92.3) are equivalent.

Equation (92.1), in conjunction with either Eq. (92.2) or (92.3), can be employed to model **surface flows** on plains and/or in channels. Two popular approximations of Eq. (92.2) are the diffusion-wave and kinematic-wave approximations [[Lighthill and Whitham, 1955](#); [Dooge, 1973](#)], which can be expressed, respectively, as the following:

$$\frac{\partial h}{\partial x} = S_0 - S_f \quad (92.4)$$

$$S_0 = S_f \quad (92.5)$$

With use of a uniform flow formula such as Manning's or Chezy's,  $S_f$  can be expressed as

$$S_f = \beta \frac{u^2}{R^a} \quad (92.6)$$

where  $\beta = 1/C^2$  and  $a = 1$  for Chezy's equation;  $\beta = n_m^2$  and  $a = 4/3$  for Manning's equation;  $C$  is Chezy's roughness coefficient,  $n_m$  is Manning's roughness factor, and  $R$  is the hydraulic radius ( $=A/P$ ,  $P$ = wetted perimeter).

Substitution of Eq. (92.6) into Eq. (92.5) and the assumption that  $R$  and  $h$  are uniquely related leads to

$$u = \alpha h^m, \quad m > 0 \quad \text{or} \quad Q = \alpha h^n, \quad n = m + 1 \quad (92.7)$$

where  $m = 0.5$  and  $\alpha = C(S_0)^{0.5}$  for Chezy's equation, and  $m = 2/3$  and  $\alpha = (S_0)^{0.5}/n_m$  for Manning's equation.

The kinematic-wave approximation hypothesizes a unique relationship between the flux (average velocity), concentration (depth), and position. Thus, this approximation can also be expressed in forms different from Eq. (92.7), as shown by Beven [1979]. If control volume is extended to the scale of a watershed or a channel segment, then the flow variables are lumped or integrated in space and only their temporal variability is retained. Thus, integration of Eq. (92.1) in space leads to

$$\frac{dS}{dt} = Q - I(t) - f(t) - E(t) \quad (92.8)$$

where

$$\begin{aligned} S &= \int_{x_1}^{x_2} A \, dx, & Q &= Q(x_2, t), & I &= Q(x_1, t) + \int_{x_1}^{x_2} q \, dx, \\ f &= \int_{x_1}^{x_2} i \, dx, & E &= \int_{x_1}^{x_2} e \, dx \end{aligned}$$

Equation (92.8) is a volume balance or water budget equation with two unknowns,  $S$  and  $Q$ . Its solution requires another equation relating  $S$  to  $Q$ ,  $I$ , and/or other variables. A very general relation between  $S$  and  $I$  and  $Q$  is

$$S = \sum_{j=0}^M a(Q, I) \frac{d^j Q}{dt^j} + \sum_{i=0}^N b(Q, I) \frac{d^i I}{dt^i} \quad (92.9)$$

where  $a$  and  $b$  are coefficients, and  $M$  and  $N$  are some integers. A special case, involving one of the most frequently used relations in hydrology, is  $S = S(Q)$  :

$$S = KQ, \quad S = kQ^\beta \quad (92.10)$$

where  $K$  is the storage parameter (lag time for  $\beta = 1$ ), and  $k$  and  $\beta$  are parameters.

Since Eq. (92.8) is derived from Eq. (92.1), Eq. (92.10) can be derived from the momentum equation. As an example, consider Eq. (92.7) with  $n = 1$ . By multiplying both sides by  $\Delta x = x_2 - x_1$  and recalling that  $S = \Delta x \cdot h \cdot 1$  and  $Q$  is volumetric flow rate, Eq. (92.10) results immediately.

## Unsaturated Flow

In an unsaturated porous medium, part of the pore space is occupied by air, so the degree of saturation is to be taken into account in dealing with unsaturated flow. The moisture content  $\theta$  in the medium (volume of water per unit volume of porous medium) is a function of the capillary pressure  $\psi < 0$ , and likewise is the medium's hydraulic conductivity  $K(\psi)$ . The basic governing equations for **unsaturated flow** are the continuity equation and a flux law given by Darcy's equation in lieu of the momentum equation. This flux law can also be derived from energy conservation considerations. The three-dimensional continuity equation, under the assumption of incompressible water, can be written as

$$\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} + \frac{\partial q_z}{\partial z} = -\frac{\partial \theta}{\partial t} \quad (92.11)$$

and Darcy's equation as

$$q_s = -K_s(\psi) \frac{\partial h}{\partial s}, \quad s = x, y, z; \quad \vec{q} = \{q_x, q_y, q_z\} \quad (92.12)$$

where  $h$  is the hydraulic head and  $q_s$  is the flux in the  $s$  direction. Substituting Eq. (92.12) into Eq. (92.11) and recalling that  $h = \psi + z$ , one gets

$$\frac{\partial}{\partial x} \left( K_x(\psi) \frac{\partial \psi}{\partial x} \right) + \frac{\partial}{\partial y} \left( K_y(\psi) \frac{\partial \psi}{\partial y} \right) + \frac{\partial}{\partial z} \left( K_z(\psi) \frac{\partial \psi}{\partial z} + K_z(\psi) \right) = C(\psi) \frac{\partial \psi}{\partial t}$$

$$C(\psi) = \frac{\partial \theta}{\partial \psi} \quad (92.13)$$

where  $C(\psi)$  is the specific moisture capacity. This is the well-known Richards equation [Richards, 1931]. Based on simplifications of porous media properties (anisotropy and heterogeneity) and the nature of flow, a number of simpler versions can be derived. On the other hand, if the control volume is extended to a soil element, then spatially lumped equations can be derived. For example, Eq. (92.11) can be integrated over space and expressed in the form of a water balance equation as

$$\frac{dS(t)}{dt} = f_s(t) - f(t) \quad (92.14a)$$

where  $S(t)$  is the potential water storage space in the soil element,  $f_s(t)$  is the seepage rate from the element, and  $f(t)$  is the infiltration rate. If the initial storage space available in the element is  $S_0$ , then the amount of water storage at any time  $t$  is

$$W(t) = S_0 - S(t) = \int_0^t [f(t) - f_s(t)] dt \quad (92.14b)$$

which is an integral expression of continuity. Another relation in lieu of Eq. (92.12) can be expressed [Singh and Yu, 1990] as

$$f(t) = f_s(t) + \frac{a[S(t)]^m}{[S_0 - S(t)]^n} \quad (92.15)$$

where  $a$ ,  $m$ , and  $n$  are positive real constants.

## Saturated Flow

The governing equations for **saturated flow** are the continuity equation and the flux law specified by Darcy's equation. A three-dimensional form of continuity equation for incompressible flow is

$$\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} + \frac{\partial q_z}{\partial z} = -S_s \frac{\partial h}{\partial t} \quad (92.16)$$

where  $S_s$  is the specific storage for confined formations, or specific yield divided by the saturated thickness for unconfined formations. Darcy's equation can be written as

$$q_s = -K_s \frac{\partial h}{\partial s}, \quad s = x, y, z; \quad \vec{q} = \{q_x, q_y, q_z\} \quad (92.17)$$

where  $K_s$  = the saturated hydraulic conductivity in the  $s$  direction. Substitution of Eq. (92.17) into Eq. (92.16) gives the general flow equation, which specializes—depending on the simplifications of porous media properties and the nature of flow—into a number of equations, such as the Laplace equation, the diffusion equation, the Theis equation, the Poisson equation, the Boussinesq equation, and so on.

## Sediment Transport

The governing equations for transport of suspended sediment by convection and turbulent diffusion under gravity are the conservation of mass for sediment and the shallow-water equations of momentum and mass conservation for sediment-laden water. The latter two equations are Eqs. (92.1) and (92.2). The three-dimensional form of sediment mass conservation can be expressed as

$$\begin{aligned} \frac{\partial C}{\partial t} + u \frac{\partial C}{\partial x} + v \frac{\partial C}{\partial y} + w \frac{\partial C}{\partial z} = w_s \frac{\partial C}{\partial z} + \frac{\partial}{\partial x} \left( \varepsilon_x \frac{\partial C}{\partial x} \right) \\ + \frac{\partial}{\partial y} \left( \varepsilon_y \frac{\partial C}{\partial y} \right) + \frac{\partial}{\partial z} \left( \varepsilon_z \frac{\partial C}{\partial z} \right) \end{aligned} \quad (92.18)$$

where  $C$  is concentration of sediment by volume;  $u$ ,  $v$ , and  $w$  are velocity components in  $x$ ,  $y$ , and  $z$  directions;  $w_s$  is particle fall velocity; and  $\varepsilon_s$  is turbulent diffusion coefficient for sediment particle in the  $s$  direction ( $s = x, y, z$ ). A number of simplifying assumptions are often made regarding the flow, which gives rise to simplifying sediment transport models. For example, the flow is frequently assumed one-dimensional, and  $\varepsilon_s$  is considered constant or independent of the direction.

## Solute Transport

The governing equations for solute transport are the conservation of solute mass and flux laws and the shallow water equations of conservation of mass and momentum of flow containing solute. For expressing the solute mass conservation, advection, diffusion, and dispersion fluxes; adsorption and desorption; and loss and gain of solute have to be expressed. If the medium is unsaturated with moisture content  $\theta$ , then the solute-mass conservation can be expressed as

$$\frac{\partial}{\partial x} \left( \theta D_h \frac{\partial C}{\partial x} - qC \right) - \frac{\partial}{\partial t} (\theta C + \rho_s S) = \mu_w \theta C + \mu_s \rho_s S - \gamma_w \theta - \gamma_s \rho_s \quad (92.19)$$

where  $C$  is the solute concentration,  $q$  is Darcy's flux of water,  $\rho_s$  is the porous media bulk density,  $\mu_w$  is the rate constant for first-order decay in the liquid phase,  $\mu_s$  is the rate constant for first-order decay in the solid phase,  $\gamma_w$  is the rate constant for zero-order production in the liquid phase,  $\gamma_s$  is the rate constant for zero-order production in the solid phase,  $S$  is the adsorbed concentration, and  $D_h$  is the coefficient of hydrodynamic dispersion. Depending on the nature of solute and flow, a number of models can be derived from simplifications of Eq. (92.19).

## Microbial Transport

The fate of microorganisms in the subsurface environment depends on their survival and retention by soil particles. The governing equations for transport and retention of microorganisms are obtained from the conservation of microbial particles in porous media [Kommalapati *et al.*, 1991–92]. The first governing equation is for the deposited particles, which can be written as

$$\frac{\partial(\rho\sigma)}{\partial t} = K_c(\theta C) - k_d(\rho\sigma) - R_{dd} + R_{gd} \quad (92.20)$$

where  $R_{dd}$  and  $R_{gd}$  are decay and growth terms of the deposited microbes,  $\rho$  is density of microbial particles,  $\sigma$  is volume of deposited bacteria per unit volume of bulk soil,  $C$  is

concentration of suspended microbial particles per unit volume of flowing suspension, and  $\theta$  is effective porosity.

The second governing equation is the mass balance equation, including growth and decay terms:

$$\frac{\partial(\rho\sigma)}{\partial t} + \frac{\partial(\theta C)}{\partial t} = -\nabla[-\theta D \nabla C + \theta C(v_f + v_g + v_m)] + [\theta C + \rho\sigma](\mu - b) \quad (92.21)$$

where  $D$  is the coefficient of hydrodynamic dispersion,  $v_f$  is superficial longitudinal velocity of flow,  $v_g$  is settling velocity,  $v_m$  is migration velocity,  $\mu$  is specific growth term, and  $b$  is specific decay rate.

The third governing equation is derived from the mass conservation for the organic matter:

$$\frac{\partial(\rho_s S_F)}{\partial t} + \frac{\partial(\theta C_F)}{\partial t} = -\nabla(-D_e \theta \nabla C_F) + \theta v_f C_F - \frac{\mu}{Y}(\theta C + \rho\sigma) \quad (92.22)$$

where  $\rho_s$  is the bulk mass density of dry soil,  $S_F$  is the mass of adsorbed substrate per unit mass of soil particles,  $C_F$  is the mass of the substrate per unit volume,  $D_e$  is effective diffusivity coefficient, and  $Y$  is the true yield coefficient.

Depending upon the nature of flow, properties of porous media, and characteristics of microorganisms, a number of simplifications of Eqs. (92.20) through (92.22) have been made, which then form the basis of simpler models.

## Initial and Boundary Conditions

In hydrology, all three types of partial differential equations are involved. For example, Eqs. (92.1) and (92.2) are nonlinear hyperbolic; Eqs. (92.11) and (92.12) are nonlinear parabolic; and Eqs. (92.16), with unsteady state term dropped, and (92.17) are nonlinear elliptic. Initial and boundary conditions are needed to obtain a unique solution to a given problem. As an example, for surface flow the usual initial condition is one of dry surface or zero flow, the upstream boundary condition is one of zero discharge, and the downstream boundary condition is specified based on the type of flow or the existence of a control. For subcritical flow in a channel, it may be given by a known control; for supercritical flow another upstream boundary is specified. In a similar manner, conditions are to be specified for unsaturated flow, saturated flow, sediment transport, solute transport, or biological transport.

## 92.4 Approaches to Hydrologic Problems

Hydrologic systems are analyzed in one or more of three domains: (1) time, (2) space, and (3) frequency. They are also analyzed at different space-time scales. Most of the approaches developed in hydrology can be classified on the basis of domains and scales. Let us consider a hydrologic variable  $Y$  at any location  $(x, y, z)$  as a function of time. Then one can write

$$Y(t) = \overline{Y}(t) + \varepsilon(t) \quad (92.23)$$

where  $\bar{Y}(t)$  represents the mean value of  $Y$ , and  $\varepsilon$  the fluctuations around the mean. If  $Y$  is entirely deterministic, then  $\varepsilon$  vanishes and any approach for determination of  $Y$  is deterministic. If  $Y$  is entirely probabilistic, then  $Y$  is completely specified through modeling of  $\varepsilon$  and the approach is entirely probabilistic. If  $Y$  is part deterministic and part stochastic, the approach employed for determination of  $Y$  is mixed. Determination of  $\bar{Y}$  constitutes the subject matter of deterministic or mathematical hydrology, and that of  $\varepsilon$  the subject matter of statistical hydrology. All the deterministic approaches are either empirical, systems based, or physically based. Empirical approaches are based on data, systems approaches are based on the volume balance equation and a type of storage-discharge relation, and physically based approaches are based on the continuity equation together with an equation of motion or energy.

Methods for description of  $\varepsilon(t)$  are statistical, probabilistic, or stochastic. Statistical methods are mostly empirical and yield certain moment characteristics or descriptors such as mean, variance, skewness, and so on. Probabilistic approaches employ certain axioms, conceptually or physically based, and proceed to derive the probabilistic structure of  $\varepsilon$ . The stochastic approaches, on the other hand, can be likened to systems approaches and strive to describe the entire time series of  $\varepsilon$  without, however, deriving its probabilistic structure. These approaches constitute the subject matter of statistical hydrology. Frequently, the terms *statistical*, *probabilistic*, and *stochastic* are used interchangeably in hydrology. In this chapter the term *statistical* will be used to mean all three types.

## 92.5 Tools for Hydrologic Analyses

---

With continuing evolution of hydrology and its expanding role in environmental studies, a greater range of scientific, mathematical, and statistical tools are becoming increasingly important. In addition to physical, chemical, and biological training, hydrologic analyses require a good level of training in mathematics (at the level of partial differential equations and finite element method), statistics (at the level of stochastic processes, time series analysis, reliability analysis, spectral analysis, and multivariate analysis), and operations research (at the level of dynamic programming). Furthermore, to take full advantage of this knowledge, hydrologists of today have to be conversant with GIS, computer graphics, computer languages, and word processing. Methods of laboratory and field experimentation will receive increasing attention in the years to come. Hydrologic concepts and theories will have to be based more and more on what actually transpires in the field.

## 92.6 Components of Hydrology Cycle¾Deterministic Hydrology

---

### Precipitation

Precipitation forms input to hydrologic systems. It greatly varies in space and time and its space-time structure is highly random, especially at small time scales. The spatial and temporal variability of precipitation is sampled by a network of gages. These must be optimally located. An optimum number of rain gages  $N$  corresponding to an assigned percentage error  $\varepsilon$  in estimation of

mean areal rainfall can be obtained as

$$N = \left( \frac{C_v}{\varepsilon} \right)^2, \quad C_v = \frac{100S_p}{\bar{P}} \quad (92.24)$$

where  $C_v$  is the coefficient of variation of the rainfall values of the gages,  $S_p$  is the standard deviation of rainfall values, and  $\bar{P}$  is the mean of rainfall values.

Precipitation measurements are often inconsistent and incomplete. Methods for checking inconsistency are either graphical or statistical [Buishand, 1982,1984]. One of the popular methods for correcting it is the double mass curve [Singh, 1989]. Statistical methods include the von Neumann ratio test, cumulative deviations, likelihood ratio test, Bayesian tests, and run test. A multitude of methods exist for filling in the missing values, including the normal ratio method, arithmetic average, isohyetal method, the inverse distance method (IDM), ratio method, linear programming, and so on [Kruizinga and Yperlaan, 1978; Tung, 1983]. The IDM is quite popular and is based on the assumption that the dependence between any two gages is directly proportional to the inverse of some power (between 1.5 and 2.0) of the distance between them. Thus, the missing precipitation value at a gage  $x$  for a given time interval can be computed as

$$P(x) = \sum_{i=1}^m w_i P_i, \quad w_i = \frac{1/(D_i^a)}{\sum_{i=1}^m 1/(D_i^a)} \quad (92.25a)$$

where  $P_i$  is the precipitation at the  $i$  th gage,  $D_i$  is the distance between the gages  $x$  and  $i$ ,  $m$  is the number of gages used in filling (usually between three and five), and  $w_i$  is the weight assigned to the  $i$  th gage.

For hydrologic modeling, mean areal precipitation  $\bar{P}$  is often needed and is obtained in a variety of ways [Singh and Birsoy, 1975; Singh and Chowdhury, 1986], including unweighted mean, grouped area-aspect weighted mean, Thiessen polygons, individual area-altitude weighted mean, triangular area weighted mean, Myers method, isohyetal method, trend surface analysis, reciprocal distance-squared method, two-axis method, double Fourier series, modified polygon method, finite element method, analysis of variance, and kriging. These methods can be expressed as

$$\bar{P} = \sum_{i=1}^N a_i P_i \quad (92.25b)$$

where  $P_i$  is the precipitation value at the  $i$  th gage,  $N$  is the number of gages, and  $a_i$  is the weight assigned to the  $i$  th gage. The various methods differ in computation of  $a_i$  values. For example,  $a_i = 1/N$  for the arithmetic average, and  $a_i = A_i/A$  for the Thiessen polygon method, where  $A_i$  is the area of the polygon surrounding the  $i$  th gage and  $A$  is the watershed area. For monthly and yearly values all of these methods yield comparable results, but for short time intervals (e.g., hourly), isohyetal-type methods may be preferable.

An estimate of the mean areal rainfall is prone to random and systematic errors. Random errors

are caused by storm characteristics, rain gage density, and the representativeness of gages, whereas systematic errors are due to improper siting, poor exposure, and change in observer and in gage. Statistical methods for estimating the error in  $\bar{P}$  have been reported by Zawadzki [1973] and Bras and Rodriguez-Iturbe [1976].

## Evaporation and Transpiration

Evaporation is an energy exchange process through which water is transformed to vapor, and transpiration is the process by which plants transpire water. These are the only processes by which water is returned to the atmosphere to sustain the hydrologic cycle. Evaporation from a water body differs from that from land only if the latter has limited water that may be insufficient to satisfy the evaporative demand. The evaporation occurring from water bodies is referred to as *potential evaporation* (PE). If the soil has limited water and evaporative demand is not fully satisfied, then the evaporation occurs at a rate less than the potential and is called *actual evaporation* (AE).

Evaporation from a water body depends upon atmospheric conditions such as temperature, pressure, humidity, radiation, sunshine, wind velocity, and so on. As a result, a number of methods are available for estimating evaporation, some based on temperature, some on radiation, some on humidity, and some on combinations of the controlling factors [Jensen *et al.*, 1990]. Perhaps the best known is the Penman-Monteith method [Penman, 1948; Monteith, 1981]. This method combines the mass-transfer and energy balance approaches, and can be expressed as

$$E = \frac{\Delta}{\Delta + \gamma}(R_n + G) + \frac{\gamma}{\Delta + \gamma}E_a \quad (92.26)$$

where  $\Delta$  is the slope of the saturation vapor pressure curve for water,  $\gamma$  is the psychrometric constant,  $R_n$  is the net radiation,  $G$  is the sensible heat flux, and  $E_a$  is the evaporation due to water vapor saturation deficit at some height. Monteith [1981] incorporated aerodynamic and canopy resistance by modifying  $\gamma$ . Allen [1985] presents an account of several variants of the Penman method.

In addition to limiting soil moisture, evaporation from croplands is also affected by crop characteristics. In this case, evaporation from the soil and transpiration are combined to form *evapotranspiration* (ET). This phenomenon is also commonly referred to as *consumptive use*. One of the popular methods for its determination is the Jensen-Haise method [Jensen and Haise, 1963], expressed as

$$ET = C_T(T - T_x)R_s \quad (92.27)$$

where  $C_T$  is the temperature constant = 0.014 and  $T_x$  is the intercept axis = 26.5 for  $T$  in  $^{\circ}\text{F}$ ; and  $C_T = 0.025$  and  $T_x = -3$  for  $T$  in  $^{\circ}\text{C}$ .

The Blaney-Criddle method [Blaney and Criddle, 1962] is also quite popular for computing ET:

$$ET = KF = \sum kf, \quad f = \frac{TP}{100} \quad (92.28)$$

where  $ET$  is the consumptive use in inches of water during the growing season,  $K$  is the seasonal consumptive use coefficient for a crop,  $F$  is the sum of monthly consumptive use factors,  $T$  is the mean monthly air temperature in  $^{\circ}F$ ,  $P$  is the mean monthly percentage of daytime hours, and  $k$  is the monthly consumptive use coefficient.

Extraction of water by plants is limited by the availability of soil moisture. Holmes and Robertson [1959] showed that the ratio of AE to PE varies with the drying of soil and that the nature of this variation depends upon the type of soil and vegetation as well as drying rate. Thus, PE is modulated to account for soil moisture stress for determining AE [Singh and Dickinson, 1975].

## Infiltration and Soil Moisture

The process by which water enters into the soil at its surface is called *infiltration*. The subsequent downward movement of water is referred to as *percolation*. If water availability is not the limitation, then water will infiltrate the soil at the maximum rate, called *infiltration capacity*,  $f_p$ . Under water ponding, the soil's infiltration capacity declines exponentially in time. If availability of water is limited, then the infiltration rate,  $f$ , is less than the capacity rate. A number of factors affecting infiltration include soil characteristics, land use, vegetative cover, and rainfall characteristics.

A number of models for computing  $f_p$  are available. The physically based models are based on Eqs. (92.11) and (92.12), the conceptual models on Eqs. (92.14a) and (92.15), and empirical models on data. Singh and Yu [1990] showed that a number of empirical models could be derived using the systems-theoretic framework based on Eqs. (92.14a) and (92.15) and that these are actually conceptual models. Examples of some well-known conceptual models are the Philip two-term model [Philip, 1969],

$$F = At + st^{0.5} \quad (92.29)$$

the Green-Ampt model [Green and Ampt, 1911],

$$Kt = F - \eta S \ln \left( \frac{\eta S + F}{\eta S} \right) \quad (92.30)$$

and the Horton model [Horton, 1940],

$$F = f_c t + \frac{1}{k} (f_0 - f_c) [1 - \exp(-kt)] \quad (92.31)$$

where  $F$  is cumulative infiltration,  $t$  is time,  $A$  is the coefficient  $\simeq$  saturated hydraulic conductivity,  $s$  is sorptivity,  $\eta$  is wettable porosity,  $S$  is the capillary section at the setting front,  $K$  is hydraulic conductivity,  $f_0$  is the initial infiltration rate,  $f_c$  is the steady infiltration rate, and  $k$  is a constant depending upon the soil type and initial condition. By coupling these models with a rainfall event, the actual infiltration can be determined for that event.

The downward movement of water permits determination of soil moisture. This moisture is evapotranspired, so the status of soil moisture is predicted with the use of an appropriate evapotranspiration model.

## Surface Runoff

Surface runoff originates on the land surface and includes both overland flow and channel flow. Two fundamental problems in surface runoff are its time distribution for a specified rainfall event and the amount of surface runoff (also called *yield*) generated from it. A great deal of attention has historically been directed at these two problems, principally because of their ubiquitous application in the design of hydraulic works.

### Surface Runoff Hydrograph

The physically based models of the hydrograph are based on Eqs. (92.1) and (92.2) or (92.4) and (92.5). The most popular models for overland flow are based on the kinematic-wave approximation and those for channel flow on diffusion-wave approximation [Singh, 1990]. For realistic field conditions, equations are solved numerically [Liggett and Woolhiser, 1967].

The conceptual models most commonly employed in hydraulic design are based on Eqs. (92.8) and (92.9). The fundamental assumptions made in these models are that rainfall and infiltration are combined, forming excess rainfall, and that the watershed may be represented fictitiously through a network of reservoirs and/or channels, or through a geomorphologic network of average channels and cumulative overland areas [Singh, 1988]. If the watershed is assumed linear, then it is sufficient to compute the *instantaneous unit hydrograph* (IUH) for a delta-function excess rainfall, which, for a watershed represented by a linear reservoir [Dooge, 1959], is

$$h(t) = \frac{1}{k} \exp(-t/k) \quad (92.32)$$

where  $k$  is the reservoir lag time. For any excess rainfall the surface runoff hydrograph is then given by the convolution integral:

$$Q(t) = \int_0^t I(\tau)h(t-\tau)d\tau \quad (92.33)$$

If the watershed is represented by a series of  $n$  equal reservoirs each with lag time  $k$ , as done by Nash [1957], then

$$h(t) = \frac{1}{K\Gamma(n)} \left(\frac{t}{k}\right)^n \exp(-t/k) \quad (92.34)$$

where  $\Gamma(n)$  is the gamma function, with  $n$  as its argument. Convolution of this IUH with an excess rainfall yields the runoff hydrograph.

## Surface Runoff Volume

Determination of runoff volume for a given event is rather complicated, for the determination of the exact amount of infiltration and other abstractions in a watershed has been elusive. One of the popular methods for estimating storm runoff from agricultural areas is the SCS–curve number (SCS-CN) method [Soil Conservation Service, 1971]. This method is based on two main hypotheses: (1) The ratio of the actual amount of runoff to the potential amount of runoff is equal to the ratio of the actual amount of infiltration to the potential infiltration. (2) An initial amount of abstraction must be satisfied before commencement of any runoff, and that consists of interception, surface storage, and infiltration. The SCS-CN method can be written as

$$\frac{V_p - V_r - V_Q}{V_R} = \frac{V_Q}{V_p - V_r} \quad (92.35a)$$

where  $V_R$  is maximum possible retention,  $V_r$  is initial abstraction,  $V_p$  is amount of rainfall, and  $V_Q$  is amount of runoff. Note that  $V_r = aV_R$ ,  $a \simeq 0.1$  to  $0.2$ . The term  $V_R$  depends upon the characteristics of soil cover complex and antecedent soil moisture conditions. SCS expresses  $V_R$  as

$$V_r = \frac{1000}{C_N} - 10 \quad (92.35b)$$

where  $C_N$  is the curve number on a scale of 10 to 100. For computation of daily, weekly, monthly, or yearly runoff, water balance models are employed. Such models are also employed for computation of storm runoff. Reviews of such models have been presented by Sorooshian [1983] and Renard *et al.* [1982], among others.

## Sediment Transport and Yield

Sediment has been characterized as the greatest carrier of pollutant. Sediment yield generated by a storm or on a daily, monthly, or yearly basis has been modeled in a number of ways. By far the best known yield model for small watersheds is the *universal soil loss equation* (USLE) [Wischmeier and Smith, 1978], which can be written as

$$A = RKLSCP \quad (92.36)$$

where  $A$  is the soil loss per unit area, in the units of  $K$  and for the period of  $R$ ;  $R$  is the rainfall-runoff factor;  $K$  is the erodibility factor;  $L$  is the slope-length factor;  $S$  is the slope steepness factor;  $C$  is the cover and management factor; and  $P$  is the support practice factor. The values of these factors have been extensively tabulated for a wide range of soil-vegetation-land use conditions.

The conceptual models of sediment discharge are derived based on the unit hydrograph concept [Singh *et al.*, 1982; Williams, 1978; Sharma and Dickinson, 1980]. Consequently, a unit sediment graph for a watershed is defined as the graph of sediment discharge for a given duration that accumulates to 1 ton. The graph is generated by an effective sediment erosion intensity distributed

uniformly in time and in space of the watershed. Singh [1989] has presented a comprehensive discussion of conceptual sediment yield models.

There is a large volume of literature on sediment transport [Vanoni, 1975]. For comprehensive sediment transport models, the entire transport continuum, comprising detachment, deposition, degradation, suspension, and bed-load transport, has to be taken into account. Many of these processes can be modeled using the kinematic-wave theory.

## Solute Transport

The sources of water pollution can be distinguished as environmental, domestic, industrial, and agricultural. Depending upon the nature of the solute, transport process in a hydrologic environment may entail advection, diffusion, dispersion, adsorption, desorption, decay of contaminants, chemical reactions, solubilization, precipitation, volatilization, particulate transport, and miscibility. The mechanisms for transport are advection, dispersion, diffusion, solute-solid interaction, chemical reactions, and decay phenomena. The process by which solute is transported by the bulk motion of flowing water is called *advection*. When a solute moves, it tends to spread out from its advection path. This spreading, called *hydrodynamic dispersion*, comprises mechanical dispersion and molecular diffusion. Mechanical dispersion is caused entirely by mixing during the motion of the fluid. In molecular diffusion, molecular constituents move under the influence of their thermal kinetic energy in the direction of their concentration gradient. Many solutes react with soil through the process of adsorption. This reaction results in partitioning of the solute into the mobile solution phase and the immobile soil surface phase. The reverse of adsorption is the process of dislodgement of chemicals from soil, called *desorption*.

The fundamental law governing the solute transport is the law of conservation of solute mass, which for one-dimensional flow through unsaturated porous media is given by Eq. (92.19). Based on the consideration of sources and sinks, four groups of models can be identified: (1) models with no production and no decay terms ( $\gamma = \mu = 0$ ), (2) models with zero production only ( $\gamma \neq 0$ ,  $\mu = 0$ ), (3) models with first-order decay only ( $\mu \neq 0$ ,  $\gamma = 0$ ), and (4) models with zero-order production and first-order decay. If transport mechanisms constitute the basis of model classification, then they can be distinguished as kinematic-wave models and advection-dispersion models.

## Microbial Transport

Contaminated soils pose one of the most serious threats to surface and groundwater quality. In situ bioremediation is being touted as a viable technology to remedy this problem. Fundamental to development of this technology is the modeling of microbial transport. When microbes are injected into the subsurface environment to augment degradation, one of the problems faced is the limited capacity to transport and disperse bacteria by the soil through the zone of soil contamination [Jackson *et al.*, 1994]. The retention of bacteria by the soil matrix restricts transport of bacteria and is controlled by straining and adsorption. The models for bacterial transport are derived from Eqs. (92.20) through (92.22). Kommalapati *et al.* (1991–92) numerically solved the first two equations by assuming the absence of substrate for biological growth. In a similar manner,

simplifications of these equations lead to a variety of simple models.

## Models of Hydrologic Cycle

The models of hydrologic cycle are also the stream flow simulation models or the watershed hydrology models. These models are either event based or continuous-time. A large number of simulation models of both types are available. Singh [1989] has provided a short review of these models.

## 92.7 Statistical Hydrology

---

Statistical analyses in hydrology have been developed along three lines, as mentioned previously. The following sections present short discussions of each.

### Empirical Analyses

These analyses may involve determination of moments, regression and correlation, or entropy for given hydrologic data. If  $x_i, i = 1, 2, \dots, N$  represents a set of observations, then the mean  $\bar{x}$ , the variance  $S_x^2$ , and the skewness  $G$  are given, respectively, as

$$\begin{aligned}\bar{x} &= \frac{1}{N} \sum_{i=1}^N x_i; \\ S_1^2 &= \frac{1}{N} \sum_{i=1}^N (x_i - \bar{x})^2; \quad (92.37) \\ G &= \frac{1}{(n-1)(n-2)} \sum_{i=1}^N (x_i - \bar{x})^3\end{aligned}$$

The correlation coefficient  $r$  between two data sets of data  $X = \{x_1, x_2, \dots, x_N\}$  and  $Y = \{y_1, y_2, y_3, \dots, y_N\}$  is

$$r = \frac{\text{cov}(x, y)}{[\text{var}(x) \text{var}(y)]^{1/2}} = \frac{\sum_{i=1}^N (x_i - \bar{x})(y_i - \bar{y})}{N S_x S_y} = \frac{\sum_{i=1}^N x_i y_i - N \bar{x} \bar{y}}{N S_x S_y} \quad (92.38)$$

where  $\text{cov}(x, y)$  is the covariance of  $x$  and  $y$ ,  $\text{var}(\bullet)$  is the variance of  $(\bullet)$ ,  $S_x$  is the standard deviation of  $x$ , and  $S_y$  is the standard deviation of  $y$ . The coefficient of determination is the square of  $r$  and gives the amount of variability explained by the relationship between  $Y$  and  $X$ .

The regression analysis permits establishment of a relationship between the dependent variable  $Y$  and the set of independent variables  $X_i, i = 1, 2, \dots, M$  as

$$Y = f(X_i, i = 2, \dots, M; a_i, i = 0, 1, 2, \dots, M) \quad (92.39)$$

where  $a_i$  values are parameters. The parameters appearing in Eq. (92.39) are estimated using the least squares method.

Another empirical analysis frequently employed in hydrology involves finding a frequency distribution that best fits the given set of data. This can be done in three ways: (1) graphically, (2) testing the fit of an assumed distribution, and (3) applying the principle of maximum entropy subject to some information about the hydrologic system the data represent [Singh and Fiorentino, 1992]. A number of distributions have been used in hydrology and entropy has been used to derive a number of these distributions. Other examples of empirical analyses are pattern recognition-based analyses for in-filling of missing records, stream-flow forecasting, and so on [Unny, 1982; Panu, 1992].

## Phenomenological Analyses

These analyses make certain postulates about the behavior of a random variable and employ them to derive the probability distribution of the random variable. Examples of such analyses are the extreme-value analysis based on the random number of random variables [Todorovic, 1982], the point process theory of rainfall [Waymire *et al.*, 1984], the storage theory of reservoirs [Phatarford, 1976], and so on. As an example, probabilistic models of floods employ such assumptions as independence, stationarity, Markov property, and so on that concern the stochastic structure of the family of the random variables involved. A random number of random variable (RNRV) model considers flood exceedances above a threshold as a sequence of independent random variables and the number of such exceedances within the selected time interval, say a year, also as a random variable. The choice of probability distributions or stochastic processes for these random variables leads to a number of RNRV-based flood models [Todorovic, 1982].

## Stochastic Analyses

Stochastic analyses involve constructing the entire time series of a variable without explicitly knowing the probabilistic structure of the variable. Techniques based on time series analysis, spectral analysis, and so on belong to this class. As an example, consider a random variable  $X$  that is observed in a sequential manner as  $X_1, X_2, \dots$ , where the subscript may represent intervals of time, distance, and so forth. When the interval is time, this sequence is a time series and is stochastic. The set of random variables  $X_1, X_2, \dots$ , associated with its underlying probability distribution is a stochastic process. A time series model has a certain mathematical form and a set of parameters. A comprehensive discussion of time series models in hydrology is given by Salas *et al.* [1980].

## 92.8 Hydrologic Design

---

The type of project determines the need for a particular type of hydrologic information. Hydrologic design of many water resources projects is based on either a peak discharge or a complete discharge hydrograph. The selection of a design flood for water resources projects such as dams and spillways involves selecting safety criteria and estimating the flood that meets these criteria.

Depending upon the size of a water resources project, three types of design floods are recognized: (1) probable maximum flood (PMF), (2) standard project flood (SPF), and (3) frequency-based flood (FBF). Design of large dams is often based on the concepts of probable maximum precipitation (PMP) and probable maximum flood (PMF). These are either determined deterministically or statistically. Urban drainage is designed using design hydrographs and an acceptable level of risk. Reservoirs are designed using either the storage theory or flow duration curves. Methods of estimating a design flood can be distinguished, depending upon the data requirements, as rainfall-runoff methods, frequency-based methods, and risk-based methods.

## Defining Terms

**Hydrologic cycle:** Denotes the endless movement of water between atmospheric, earth, and oceanic systems through the processes of precipitation, evaporation, infiltration, and stream flow.

**Saturated flow:** Includes the flow of water occurring in the saturated geologic formations.

**Surface flow:** Includes flow of water occurring over the land.

**Unsaturated flow:** Includes the flow of water occurring in the vadose zone.

**Watershed:** Denotes the drainage area draining into an outlet; there is no flow across this area's boundaries. The magnitude of this area varies with the position of the outlet.

## E. V. Richardson

*Ayres Associates Fort Collins, Colorado*

Sedimentation in water resources engineering requires knowledge of and the ability to determine the yield of sediment from the land surface, the transport of sediment by streams, erosion and erosion control, and reservoir sedimentation. This project requires an understanding of **fluvial geomorphology**, sediment properties, hydraulics of open channel flow, river mechanics, and **bed forms** in alluvial channels.

## 93.1 Fluvial Geomorphology

---

Fluvial geomorphology is the science dealing with the profiles and planforms of streams and rivers. Rivers are dynamic—always changing their shape, position, and other morphological characteristics—with long- and short-term changes in water or sediment discharge, climate, tectonic and humanity's activities. A local change in a river or stream, such as construction of a dam or bridge, causes modifications of a river both up- and downstream. In a dam, changes in water and sediment discharge can cause degradation downstream, and backwater can cause aggradation upstream. The fluvial geomorphology of a stream determines its mode of sediment transport and its response to changes in climate, tectonic activity, man's activity, and changes in sediment and water discharge.

Geomorphic factors affecting stream morphology include stream size, flow habit (ephemeral, perennial but flashy, or perennial), bed and bank material, valley setting, flood plains, natural levies, apparent incision, channel boundaries, vegetation, stream planform, variability of width, and development of bars [Vanoni, 1975; Schumm, 1977; Richardson *et al.*, 1990; and Simons and Senturk, 1992]. Stream planform is broadly classified as **meandering, straight, braided, or anabranching**. These broad classifications have been subclassified by geomorphologists and engineers, but for sedimentation studies these broad classifications normally will be

sufficient.

Lane, studying the relationship between **slope**,  $S$ , **discharge**,  $Q$ , and channel planform, observed that, when  $SQ^{1/4}$  [Richardson *et al.*, 1990]. Also, when  $SQ^{1/4} > 0.01$ , a stream had a braided planform. A stream with a value between the two could have either a meandering or braided planform. A meandering stream with slope increased such that the value of  $SQ^{1/4}$  is larger than 0.0017 might become a braided stream. Conversely, a braided stream that has its discharge or slope decreased such that the value of  $SQ^{1/4}$  is smaller than 0.01 might change to a meandering planform.

Lane also proposed the following qualitative relationship to predict the response of a stream or river to changes in water discharge,  $Q$ , slope,  $S$ , sediment discharge,  $Q_s$ , and **median diameter** of the bed material,  $D_{50}$  [Schumm, 1972]:

$$QS \sim Q_s D_{50} \quad (93.1)$$

This relationship shows that, with a decrease in  $Q$  and no changes in the qualities on the right, there is an increase in the slope. The increase in slope results from deposition of  $Q_s$ . Changes in other qualities would induce a response to keep a balance between the left and right sides of the relationship. Richardson *et al.* [1990], Simons and Senturk [1992], and Lane [Schumm, 1972] give examples of the uses of this relationship and also expand on the effect of additional variables on the response of streams to change. Leopold and Maddock, Mackin, and others [Schumm, 1972, 1977] give additional insight into the response of streams to change and the importance of fluvial geomorphology in sedimentation.

## 93.2 Sediment Properties

---

Sediment properties of value in sedimentation are the physical size, fall velocity and density of the particles, and bulk properties of the bed and bank material and sediment deposits. Sediments are composed of clay (0.000 2 to 0.004 mm), silt (0.004 to 0.062 mm), sand (0.062 to 0.2 mm), gravel (2.0 to 64 mm), cobble (64 to 250 mm), or boulder (250 to 4000 mm) material. Bulk properties are described by the size frequency distributions, specific weight, and porosity. Size distributions are determined by sieving, visual accumulation tube analysis, pebble count, and pipette methods. Size distributions are usually expressed as a percentage finer than a given size in the distribution. Also of major importance is the viscosity of suspensions with large concentrations of silts and clays. Sediment properties and methods to determine them are discussed in detail by Brown [1950], Vanoni [1975], Richardson *et al.* [1990], and Simons and Senturk [1992].

## 93.3 Beginning of Motion

---

Knowledge of the point at which fluid forces are large enough to move sediment particles is important in sediment transport, erosion, and design of riprap. Shields [Brown, 1950; Vanoni, 1975; and Simons and Senturk, 1992] experimentally determined a relationship at beginning of motion between the ratio of the **critical shear stress**  $\tau_c$  to move a particle and its submerged

weight expressed as  $(S_s - 1)\gamma D$  and the **shear velocity**, particle size Reynolds number  $[(gRS)^{0.5} D/\nu]$ , where  $S_s$  is the specific gravity of the particle,  $\gamma$  is the unit weight of water,  $g$  is the acceleration of gravity,  $R$  is the hydraulic radius,  $D$  is the particle size, and  $\nu$  is the kinematic viscosity. Lane, Fortier and Scobey, Keown, and others [Brown, 1950; Vanoni, 1975; Richardson *et al.*, 1990; Simons and Senturk, 1992] give values for the critical shear or critical velocity for the beginning of motion of silts, clays, sand, and coarser particles. Equations for determining **shear stress** on a boundary are given in the above references. [Neil Richardson *et al.*, 1993] gives the following equation for the critical velocity at the beginning of motion of a particle:

$$V_c = 1.58[(S_s - 1)gD]^{1/2} (y/D)^{1/6} \quad (93.2)$$

where  $D$  = particle size (ft or m),  $g$  = acceleration of gravity (ft/s<sup>2</sup> or m/s<sup>2</sup>),  $V_c$  = critical velocity above which bed material of size  $D$  and smaller will be transported (ft/s or m/s),  $S_s$  = specific gravity of bed material particles, and  $y$  = depth of flow (ft or m). When  $S_s$  equals 2.65—a typical value for sand—Eq. (93.2) in metric units reduces to

$$V_c = 6.36y^{1/6} D^{1/3} \quad (93.3)$$

## 93.4 Sediment Yield

---

Determining the amount of erosion (*sediment yield*) from the land has great significance in water resources engineering. Erosion is classified into overland processes and stream processes. Overland processes include sheet wash, rilling, and gullying. Stream processes include bed and bank erosion and will be described later.

The *universal soil loss equation* (USLE), developed by the U.S. Department of Agriculture, is the most widely used regression equation for predicting sediment yield from overland flow [Vanoni, 1975; Simons and Senturk, 1992]. The five major factors used to determine the average annual soil loss  $A$ , in U.S. tons per acre, are the rainfall factor  $R$ , in inches per hour; soil erodibility factor  $k$ , in tons per acre per unit of rainfall factor  $R$ ; topography factors  $S$  for slope (land gradient) and  $L$  for length of slope; cropping and management factor  $C$ ; and erosion control practices factor  $P$ .

## 93.5 Bed Forms

---

Flow in sand and medium gravel alluvial channels ( $D_{50}$  from 0.062 to 16 mm) is divided into lower and upper flow regime, separated by a transition zone on the basis of the bed form, resistance to flow, and **bed material discharge**. In the lower flow regime the bed forms in natural channels are dunes, with large resistance to flow (Manning  $n$  ranges from 0.02 to 0.04) and low bed material discharge (concentrations ranging from 200 to 2000 parts per million by weight). In the upper flow regime the bed forms are plane beds or antidunes, with low resistance to flow

(Manning  $n$  ranging from 0.012 to 0.020) and large bed material discharge (concentrations of 1000 ppm and larger). In the transition between the two regimes the bed form, resistance to flow, and bed material discharge ranges between characteristics of the two. The bed form in an alluvial stream depends on the discharge, slope, depth of flow, size of bed material, and the viscosity of the fluid [Vanoni, 1975; Richardson *et al.*, 1990; and Simons and Senturk, 1992].

Alluvial streams with steep slopes may flow in the upper flow regime all the time, whereas streams with lower slopes change from lower to upper flow regimes depending upon the discharge, bed material size, and fluid viscosity. This tendency results in streams that at low flow are in the lower flow regime and at high flow are in the upper flow regimes. These streams can have a dune bed form in the summer and washed-out dunes, plane beds, or antidunes in the fall and winter. An example is the Missouri River along the border between Nebraska and Iowa. In the summer, when the water temperature is high (70 to 80°F), the bed form is in the lower flow regime and the Manning  $n$  is 0.020; in the fall, water temperatures are much lower (35 to 65°F) and the bed form is in the transition and Manning  $n$  is 0.015 with, consequently, a lower depth and higher velocity for the same discharge (U.S. Corps of Engineers, 1969). These changes in flow regime with discharge and temperature produces discontinuous or shifting rating curves for many sand channel streams and affects the determination of discharge, depths of flow, velocity, and bed material discharge in these streams.

## 93.6 Sediment Transport

---

The quantity of sediment transported by a stream consists of the **bed material discharge** and the **fine material discharge (washload discharge)** from the watershed and banks. The bed material discharge is determined by the flow variables and fluid and sediment properties and is, with some degree of accuracy, subject to calculation. The fine sediment discharge depends on availability of fine sediment, is not transported at the capacity of the stream to transport it, is not functionally related to measurable hydraulic variables, and must be measured.

Bed material and fine material are transported in suspension by the turbulence of the stream (**suspended sediment discharge**) or by rolling along in contact with the bed (**contact sediment discharge**). Laursen [Richardson *et al.*, 1990, 1993] determined that, when the ratio of the shear velocity  $[(gRS)^{0.5}]$  to the fall velocity ( $\omega$ ) of the bed material is less than 0.5, the bed material discharge is mostly contact bed material discharge; ratios between 0.5 and 2.0 suggest some suspended bed material discharge, and those larger than 2.0 suggest mostly suspended bed material discharge. When the bed material discharge is mostly in contact with the bed, the Meyer-Peter-Muller equation is normally used to determine bed material discharge. Suspended bed material discharge is measured or calculated by integrating the velocity and sediment concentration at a point through the vertical and across the stream. Suspended fine sediment discharge is measured by integrating the velocity and sediment concentration at a point through the vertical and across the stream using depth integrating samplers. To calculate suspended bed material discharge, an equation for the distribution of sediment particles in the vertical (developed by Rouse) is combined with a velocity distribution equation and integrated through the depth. Various investigators then combined the suspended bed material discharge with the contact bed material discharge to develop an equation to determine the total bed material discharge. To determine the

total sediment discharge of a stream or river, the fine sediment discharge, which has to be measured, is added to the measured or calculated bed material discharge.

The Meyer-Peter-Muller, Einstein, modified Einstein (developed by Colby and Hembree), and other equations for calculating total bed material discharge are given by Brown [1950], Vanoni [1975], Richardson *et al.* [1990], and Simons and Senturk [1992].

Colby [1964] developed a very useful graphical method of determining total bed material discharge. The method is given in Figs. 93.1 and 93.2 and Eqs. (93.4) and (93.5):

$$q_T = [1 + (K_1 K_2 - 1) K_3] q_n \quad (93.4)$$

$$Q_s = W q_T \quad (93.5)$$

where  $q_T$  is total bed material discharge per unit width (U.S. tons/day/ft), the  $K_s$  are correction coefficients determined from Fig. 93.2,  $q_n$  is the discharge of bed material determined from Fig. 93.1, and  $Q_s$  (U.S. tons/day) is the total bed material discharge for a channel of width  $W$  (ft).

**Figure 93.1** Relation of discharge of sands to mean velocity for six median sizes of bed sands, four depths of flow, and a water temperature of 60°F. (Source: Colby, B. R. 1964. *Discharge of Sands and Mean-Velocity in Sand-Bed Streams*. U.S. Geological Survey Professional Paper 462-A. U.S. Geological Survey, Washington DC.)

**Figure 93.1**

**Figure 93.2** Colby's correction curves for temperature and fine sediment (Source: Colby, B. R. 1964. *Discharge of Sands and Mean-Velocity in Sand-Bed Streams*. U.S. Geological Survey Professional Paper 462-A. U.S. Geological Survey, Washington, DC.)

The uncorrected total bed material discharge ( $q_n$ ) is determined from Fig. 93.1 for a given velocity, median diameter of the bed material, and two depths that bracket the desired depth by interpolating on a logarithmic graph of depth versus  $q_n$  to obtain the bed material discharge per unit width. The corrected bed material discharge per unit width ( $q_T$ ) is determined using Eq. (93.4) and Fig. 93.2. The total bed material discharge is then obtained using Eq. (93.5).

The modified Einstein method determines the **total bed material discharge** and **total sediment discharge** from measurements of the suspended sediment discharge to determine the **unmeasured sediment discharge** and, thus, is probably the most accurate of the methods used to calculate the total bed material discharge and the total sediment discharge of a stream. The unmeasured sediment discharge is composed of the contact bed material discharge and the suspended sediment discharge in the unmeasured zone. Suspended sediment samplers, except in special cases, only measure within a set distance to the bed (0.2 to 0.4 ft, depending on the sampler). Suspended sediment samplers that are used in very turbulent streams or in specially constructed turbulence flumes (all the bed material is in suspension, no contact discharge) or that traverse the total depth as at the nape of a weir measure the total sediment discharge of a stream. In fact, this method was used to obtain data for the development of the modified Einstein method and other equations. Suspended sediment samplers and measurement methods are described by Vanoni [1975] and Simons and Senturk [1992]. Mathematical computer models have been developed to determine total bed material discharge using currently available equations. Models are described by

Richardson, et al. [1990] and Simons and Senturk [1992].

## 93.7 Reservoir Sedimentation

---

The rate of depletion of reservoir storage from storage of sediment depends on (1) the volume of the reservoir in relation to inflow, (2) sediment inflow, (3) reservoir trap efficiencies, and (4) the specific weight (density) of the sediment deposits. The distribution of the sediment in the reservoir can sometimes be important. Sedimentation damages a reservoir over time if it decreases storage volume to such an extent that it no longer can serve its design function.

Reservoirs with large storage volume in relation to average annual inflow of water have a lower rate of storage loss due to sedimentation than reservoirs that do not—even with the same trap efficiency. Lake Mead on the Colorado River and Lake Nasser on the Nile River have storage volumes that are about double their average annual inflow. Their trap efficiencies are almost 100%. Their rate of sediment depletion of storage is so low that their useful life expectancy is measured in thousands of years. The reservoir behind Tarbella Dam on the Indus River has a storage volume that is less than 20% of the average annual flow. Its trap efficiency is also about 100%. Its rate of storage depletion is so large that its useful life as a storage reservoir is less than 100 years. All three reservoirs have approximately the same annual sediment inflow. Of interest is the fact that the reservoir behind Old Aswan Dam on the Nile (downstream of Lake Nasser), with a storage-to-inflow ratio of less than 3%, has an infinite useful life. The reservoir stored water for over 50 years before Lake Nasser was created by the High Aswan Dam. Its trap efficiency is close to zero because (1) it has under-sluices across the total dam width, and (2) most of the annual flood passes through the reservoir, with only the tail of the flood stored.

The sediment inflow into a reservoir can be estimated by (1) use of the recorded annual measured total sediment discharge of the stream, (2) computation by flow duration–sediment rating curve method, and (3) estimating the sediment yield from the watershed.

The use of recorded annual measured total sediment discharge of a stream is limited to those sites that have a historical record based on frequent sampling to establish a reliable estimate of the sediment inflow into the reservoir. Normally, the record of sediment inflow is less than the stream flow record and is only suspended sediment discharge. However, with studies, the suspended sediment record can be adjusted to obtain the total sediment discharge using methods described in the previous section.

The flow duration–sediment rating curve method, which extends the available total sediment discharge record to the historical stream flow record, is the most desirable. In this method a sediment rating curve is made by relating the daily sediment discharge (normally expressed in tons per day) to the daily discharge. There will be a large scatter in the data, some of which may be seasonal, but with study a reliable set of curves can be developed. A flow duration curve is also prepared for the entire stream flow record. From these two sets of relationships the average annual sediment discharge is determined [Vanoni, 1975; Simons and Senturk, 1992]. The sediment rating curve may be developed using measured suspended sediment discharge, measured total sediment discharge (suspended sediment plus unmeasured sediment discharge), or a measured suspended sediment discharge corrected for the unmeasured sediment discharge.

The sediment yield from a watershed is estimated using the universal soil loss equation given earlier. This value is then used with the appropriate trap efficiency to determine sedimentation rates in a reservoir. This method is often used for small reservoirs.

Trap efficiency is the measure of the percentage of the sediment inflow retained (trapped) in the reservoir. It depends on the velocity of flow through the reservoir as well as sediment size. The velocity of flow depends on the size of the reservoir, type of dam, and operating procedures. Reservoirs that are formed from large embankments (soil, concrete, or rock), with large storage volumes and over-year storage, and outlets that normally discharge less flow than the incoming floods have large trap efficiencies (close to 100%). These reservoirs may have some sediment removed by density currents or large velocities when the reservoir is low, but these amounts are ignored in consideration of the other approximations and uncertainties in the determination of the sediment inflow. Small reservoirs with large velocities or reservoirs with under-sluices that can pass large inflows will have low trap efficiencies. The Old Aswan Dam described earlier is an example of the latter. Operation of the dam to have a low pool with high velocities part of each year will decrease trap efficiency.

To determine trap efficiency, Churchill—from a study of TVA reservoirs—developed a relationship between the percentage of incoming silt passing through the reservoir and the ratio of period of retention divided by mean velocity; Brune developed a relationship between percentage of sediment trapped and a ratio of reservoir capacity divided by the mean annual inflow [Vanoni, 1975; Simons and Senturk, 1992]. In using these relations, engineering judgment must be used to determine trap efficiency for a particular reservoir.

The specific weight of the sediment deposited in a reservoir is needed to convert to volume the estimate of sediment deposited in the reservoir, which is normally given in terms of weight. The specific weight of the sediment deposits in the reservoir increases with time as they consolidate. Coarse sediments (sand and gravels) will consolidate faster than the finer silts and clays and will reach their ultimate weight faster. Also, sediments consolidate faster if they are not always submerged. Vanoni [1975] and Simons and Senturk [1992] present methods for estimating the specific weight developed by Lane and Koelzer, which takes into account the type of sediment and degree of submergence.

The distribution of sediment in reservoirs depends on the size composition of the sediment flowing into a reservoir and the management of the outflow. Coarse sediments are deposited in the upper reaches of the reservoir and the finer sediments farther down. If the water storage in the reservoir is managed so as to have a low water level part of the year, then the coarser materials are moved farther down into the reservoir. Coarse sediment deposits at the upper end of the reservoir can increase the backwater effects upstream. Vanoni [1975] and Simons and Senturk [1992] discuss the location of sediment deposits and present methods to evaluate the location.

Sediment deposits in reservoirs are measured using sonic sounders and surveying techniques to monitor the loss of storage with time. Vanoni [1975] describes methods for conducting these surveys.

## Defining Terms

**Anabranch:** A stream whose flow is divided at normal or lower discharges by large, relatively permanent islands. The channels are more permanent and more widely and distinctly separated than those of a braided stream.

**Bed form:** A relief feature on the bed of a stream, such as dunes, plane bed, or antidunes. Also called *bed configuration*.

**Bed material:** Material found on the bed of a stream. May be transported in contact with the bed or in suspension.

**Bed material discharge:** The part of the total sediment discharge of a stream that is composed of grain sizes found in the bed and is equal to the transport capability of the flow.

**Braided stream:** A stream whose flow is divided at normal and low flow into several channels by bars, sandbars, or islands. The bars and islands change with time, sometimes with each runoff event. A braided stream has the aspect of a single large channel, with several subordinate channels at normal and low flows.

**Contact sediment discharge:** Sediment that is transported in a stream by rolling, sliding, or skipping along in contact with the bed. Also called *bed load* or *contact load*.

**Critical shear stress:** The minimum amount of shear (force) exerted by the flow on a particle or group of particles that is required to initiate particle motion.

**Discharge:** Time rate of the movement of a quantity of water or sediment passing a given cross section of a stream or river.

**Fine sediment discharge (washload discharge):** That part of the total sediment discharge of a stream that is not found in appreciable quantities in the stream bed. Normally, the fine sediment discharge in a sand bed stream is composed of particles finer than sand (0.062 mm). In coarse gravel, cobble, or boulder bed stream silts, clays and sand could be fine sediment or washload discharge.

**Flow duration curve:** A graph indicating the percentage of time a given discharge is exceeded.

**Fluvial:** Related to stream or rivers.

**Geomorphology:** The branch of physiography and geology that deals with the general configuration (form) of the earth's surface and the changes that take place as the result of the forces of nature.

**Hydraulic radius:** The cross-sectional area of a stream, divided by its wetted perimeter. Equals the depth of flow when the width is larger than ten times depth.

**Meandering stream:** A stream with sinuous S-shaped flow pattern.

**Median diameter:** The particle diameter at which 50% of a sample's particles are coarser and 50% are finer (D<sub>50</sub>).

**Sediment yield:** The total sediment outflow from a unit of land (field, watershed, or drainage area) at a point of reference and per unit of time.

**Shear stress, tractive force:** The force or drag on the channel boundaries that is caused by the flowing water. For uniform flow, shear stress is equal to the unit weight of water times the hydraulic radius times the slope. Usually expressed as force per unit area.

**Shear velocity:** The square root of the shear stress divided by the mass density of water, in units of

velocity.

**Slope:** Fall per unit length of the channel bottom, water surface, or energy grade line.

**Suspended sediment:** Sediment particles that are suspended in the flow by the turbulence of the stream.

**Suspended sediment discharge:** The quantity of suspended sediment passing through a stream cross section per unit of time.

**Total bed material discharge:** The sum of the suspended sediment bed material discharge and the contact sediment (bed-load) discharge.

**Total sediment discharge:** The sum of the suspended sediment discharge and the contact sediment (bed-load) discharge, the sum of the bed material discharge and the wash-load discharge, or the sum of the measured sediment discharge and the unmeasured sediment discharge.

**Unmeasured sediment discharge:** The sediment discharge that is not measured by suspended sediment samplers. It consists of the suspended sediment discharge in the unsampled zone and the contact sediment discharge. Suspended sediment samplers normally do not measure to the bed of a stream.

## Further Information

The *ASCE Journal of Hydraulic Engineering, Transactions* and the annual publication titled *Hydraulic Engineering* report advances in sedimentation. For subscription information contact: ASCE, 345 E. 47th St. New York, NY 10164-0749. Phone: (800)548-2723.

The U.S. Geological Survey publishes data on the sediment discharge of streams in the U.S., techniques for measuring sediment discharge, and recent advances in the science of sedimentation.

Catalogs of their publications are available from USGS Map Distribution, Box 25286, MS 306, Federal Center, Denver, CO 80225.

The U.S. Army Corps of Engineers publishes reports on their research in sedimentation. These reports focus on studies of a specific river problem as well as the general subject of sedimentation. The library at the Waterways Experiment Station, Vicksburg, MS 39180, maintains copies of most Corps publications.

American Geophysical Union (AGU) is an excellent source for additional information on sedimentation. They can be contacted at AGU, 2000 Florida Ave. NW, Washington, DC. 20009.

The Water Resources Bulletin of AWRA contains papers on sedimentation. Their address is AWRA, 5410 Grosvenor Lane, Suite 220, Bethesda, MD 20814-2192.

Agencies of the federal government such as ARS and SCS (U.S. Department of Agriculture) and FEMA and USBR (U.S. Department of the Interior) have extensive information on sedimentation of both specific and general nature. Access to their publications can be made through their local offices or offices in Washington, DC.

This video camcorder provides a good example of the interaction of a number of subsystems which, taken together as a system, are capable of performing the necessary tasks of recording and playing back video imagery. One important component is the autofocus subsystem, which automatically adjusts the focus in the center of the scene via a feedback system. Digital signal processing is used in another subsystem to improve picture clarity and to provide special effects such as fading. The tape drive uses a combination of electrical and mechanical subsystems to maintain a constant speed of the tape past the record and playback heads. These are examples of only a few of the subsystems which enable this amazing technological marvel to provide high-quality video pictures in a small, easy-to-use, lightweight package. A SYSTEM CAN BE DEFINED as a combination and interconnection of several components or subsystems to perform a desired task. Systems can be mechanical, electrical, thermal, acoustic, or a combination of these as well as other possibilities. For example, the automatic focusing feature of a video camera incorporates an optical sensor subsystem coupled electronically to an electromechanical control subsystem for changing the focus of the lens subsystem.

A linear system is one for which the principle of superposition holds, that is, the response to a linear combination of two separate inputs yields the same result as the linear combination of the outputs due to each input applied separately. It is rather fortunate that many systems are well modeled as linear systems, because this simplifies their analysis considerably. For the most part, this section deals with linear systems and their models. It consists of eight chapters that deal with various aspects of system analysis and synthesis.

**Chapter 94**, on transfer functions and the Laplace transform, provides the cornerstone for

system analysis. The Laplace transform provides a one-to-one correspondence between a signal, or time function, and a function of a complex frequency variable,  $s$ , called the Laplace transform of the signal, which in turn converts the differential equation describing a system to an algebraic expression. The ratio of the Laplace transform of the output to the Laplace transform of the input of a fixed linear system (i.e., one whose properties do not vary with time) is the transfer function of the system. Many properties of the system can be deduced from the transfer function, and it in fact allows the design or synthesis of systems to perform desired tasks. **Chapter 95**, on block diagrams, provides a pictorial representation of a fixed linear system in terms of its subsystems. Manipulation of subsystems via the block diagram of the system allows much flexibility and power in analysis and synthesis of systems. **Chapter 96**, on signal flow graphics, provides an alternative to the block diagram of a system; the signal flow graph is more compact but still incorporates the convenience of a block diagram. In **Chapter 97**, on linear state-space models, a representation for a system is provided that is equally applicable to nonlinear and linear systems, is especially suited for time domain analysis, and allows multiple-input, multiple-output systems to be represented as conveniently as single-input, single-output systems. Furthermore, the state equations for a linear time-varying system are no more complex than those of a fixed linear system, and their numerical solution via digital computer can proceed with equal facility. **Chapter 98**, on frequency response, provides a description of a fixed linear system based on its response to a steady state unit-amplitude sinusoid in terms of the output sinusoid's amplitude (amplitude response) and phase (phase response). These two functions of frequency provide much insight into the response of a system to other inputs and its stability (i.e., its response to a bounded input). **Chapter 99** describes the convolution integral, its properties, and its applications. Among other applications, the convolution integral provides a means for determining the output of a linear system in response to a wide range of input signals. In **Chapter 100**, a treatment of stability analysis for linear systems is given. Various types of stability are defined and relationships between them are given. The final chapter in this section provides an introduction to discrete-time systems. The introduction to the  $z$  transform given in this chapter provides the basis for transform analysis of such systems much as the Laplace transform provides an analysis tool for continuous-time systems.

This section provides a thorough overview of linear systems, their mathematical modeling, and appropriate tools for analyzing them as summarized by eight experts in the field. >

- 94.1 Transfer Functions
- 94.2 The Laplace Transformation
- 94.3 Transform Properties
- 94.4 Transformation and Solution of a System Equation

**C. Nelson Dorny**

*University of Pennsylvania*

We perceive a system primarily through its behavior. Therefore, our mental image of a system usually includes representative response **signals**. The *step response*, the behavior when we suddenly turn on the system, is such a system-characterizing signal. We should view the step response as a description of the system. The *impulse response* is another description of the system. For a system represented by linear differential equations, the unit-step response is the integral of the unit-impulse response.

Let us represent time differentiation ( $d/dt$ ) by the *time-derivative operator*,  $p$ . Then we can denote the time derivative of a signal  $y$  by  $py$ , its second derivative by  $p^2y$ , its integral with respect to time by  $(1/p)y$ , and so on. This *operator notation* simplifies the expressions for differential equations. We shall use the expression *system equations* to mean a set of differential equations that determines fully the behaviors of the dependent variables that appear in those equations. We can reduce a *linear* set of system equations to a single **input-output system equation** by eliminating all but one dependent variable from the set. The *transfer function* associated with that dependent variable is a mathematical expression that contains all the essential information embodied in the system differential equation.

The Laplace transformation converts signals (functions of time) to functions of a *complex-frequency variable*,  $s = \sigma + j\omega$ . There is a one-to-one correspondence between a signal and its Laplace transform. We can retrieve the time function by inverse transformation. Laplace transformation produces images that have some properties that are more convenient than those of the original signals. In particular, time differentiating a signal corresponds to multiplying its Laplace transform by the complex-frequency variable  $s$ . Hence, the transformation converts linear constant-coefficient differential equations to linear algebraic equations. Such simplifications of time-domain operations make Laplace transformation useful.

The Laplace transformation also converts the impulse response of a system variable to the transfer function for that variable. As a consequence, we can view the differential equation that

represents a linear system as an expression of the response of that system to an impulsive input.

## 94.1 Transfer Functions

The node displacements  $x_1$  and  $x_2$  and the compressive forces  $f_1$  and  $f_2$  within the branches of the lumped model of Fig. 94.1 are related to each other by the spring equation, the damper equation, and the balance of forces at node 2. The spring equation is  $f_2 = k(x_1 - x_2)$ . The equation for the damper is  $f_1 = b(\dot{x}_1 - \dot{x}_2)$ . The balance of forces requires that  $f_1 + f_2 = m\ddot{x}_2$ . These equations describe fully the behavior of the system if the spring and mass are unenergized. (If the mass were moving and/or the spring were compressed, we would have to express separately their initial energy states to describe fully the future relations among the variables.)

**Figure 94.1** The lumped model of a mechanical system.

Eliminate  $f_1$  and  $f_2$  from the equations to obtain the operational equation:

$$(mp^2 + bp + k)x_2 = (bp + k)x_1 \quad (94.1)$$

This differential equation describes fully the **zero-state** relation between  $x_1$  and  $x_2$ . Rearrange Eq. (94.1) to form the ratio

$$\frac{x_2}{x_1} = \frac{bp + k}{mp^2 + bp + k} \quad (94.2)$$

We call Eq. (94.2) the *transfer function* from  $x_1$  to  $x_2$ . The transfer function focuses attention on the mathematical operations that characterize the behavioral relationships rather than on the particular natures of the variables. [Note that the transfer function from  $v_1$  to  $v_2$ , where  $v_1 = px_1$  and  $v_2 = px_2$ , is the same as the transfer function given by Eq. (94.2).]

In general, suppose that  $y_1$  and  $y_2$  are two variables related (in operator notation) by the linear differential equation

$$y_2 = G(p)y_1 \quad (94.3)$$

We formally define the *transfer function* from  $y_1$  to  $y_2$  by

$$G(p) = \left. \frac{y_2}{y_1} \right|_{\text{ZS}} \quad (94.4)$$

where the notation ZS means **zero state**. If  $y_1$  is an independent variable, then  $G(p)$  is the *input-output transfer function* for the variable  $y_2$  and accounts fully for its behavior owing to the **input signal**  $y_1$ . We can determine from that transfer function the behavior of the system for any source waveform and any initial state.

## 94.2 The Laplace Transformation

---

The *one-sided Laplace transformation*,  $\mathcal{L}$ , is an integral operator that converts a signal  $f(t)$  to a complex-valued function  $F(s)$  in the following fashion:

$$\mathcal{L}[f(t)] \equiv F(s) \triangleq \int_{0^-}^{\infty} f(t)e^{-st} dt \quad (94.5)$$

We refer to the transformed function  $F(s)$  as the *Laplace transform* of the signal  $f(t)$ . Picture the lower limit  $0^-$  of the integral as a *specific* instant prior to but infinitesimally close to  $t = 0$ . It is customary to use a lowercase symbol ( $f$ ) to represent a signal waveform and an uppercase symbol ( $F$ ) to represent its Laplace transform. [Although we speak here of time signals, there is nothing in Eq. (94.5) that requires  $f(t)$  to be a function of time. The transformation can be applied to functions of any quantity  $t$ .]

We shall use the Laplace transformation to transform the signals of **time-invariant** linear systems. The behavior of such a system for  $t \geq 0$  depends only on the input signal for  $t \geq 0$  and on the prior **state** of the output variable (at  $t = 0^-$ ). Hence, it does not matter that the Laplace transformation ignores  $f(t)$  for  $t < 0^-$ .

The process of finding the time function  $f(t)$  that corresponds to a particular Laplace transform  $F(s)$  is called *inverse Laplace transformation*, and is denoted by  $\mathcal{L}^{-1}$ . We also call  $f(t)$  the

*inverse Laplace transform* of  $F(s)$ . Since the one-sided Laplace transformation ignores  $t < 0^-$ ,  $F(s)$  contains no information about  $f(t)$  for  $t < 0^-$ . Therefore, inverse Laplace transformation cannot reconstruct  $f(t)$  for  $t < 0^-$ . We shall treat all signals as if they are defined only for  $t \geq 0^-$ . Then there is a one-to-one relation between  $f(t)$  and  $F(s)$ .

To illustrate the Laplace transformation, we find the Laplace transform of the decaying exponential,  $f(t) = e^{-\alpha t}$ ,  $t \geq 0^-$ . The transform is

$$\begin{aligned} F(s) &= \int_{0^-}^{\infty} e^{-\alpha t} e^{-st} dt = \left. \frac{e^{-(s+\alpha)t}}{-(s+\alpha)} \right|_{0^-}^{\infty} \\ &= \left. \frac{e^{-(\sigma+\alpha)t} e^{-j\omega t}}{-(s+\alpha)} \right|_{0^-}^{\infty} = \frac{1}{s+\alpha} \quad \text{for } \operatorname{Re}[s] > -\alpha \end{aligned} \quad (94.6)$$

We must require  $\sigma > -\alpha$ , where  $\sigma$  is the real part of  $s$ , in order that the real-exponent factor converge to zero at the upper limit. (The magnitude of the complex-exponent factor remains 1 for all  $t$ .) Therefore, the Laplace transform of the decaying exponential is defined only for  $\operatorname{Re}[s] > -\alpha$ . This restriction on the domain of  $F$  in the complex  $s$  plane is comparable to the restriction  $t \geq 0^-$  on the domain of  $f$ .

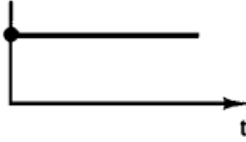

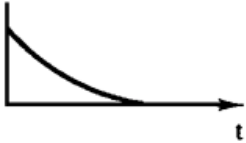

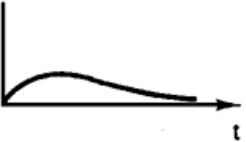

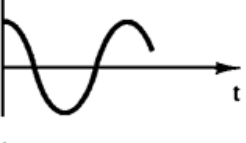

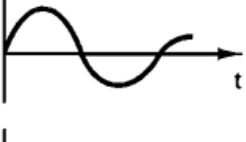

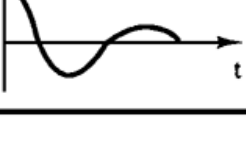

The significant features of the complex-frequency function  $1/(s+\alpha)$  are the existence of a single pole and the location of that pole,  $s = -\alpha$  rad/s. [The pole defines the left boundary of that region of the complex  $s$  plane over which the transform  $1/(s+\alpha)$  is defined.] The significant features of the corresponding time function are the fact of decay and the rate of decay, with the exponent  $-\alpha$  rad/s. There are clear parallels between the features of  $f(t)$  and  $F(s)$ . We should think of the whole complex-valued function  $F$  as representing the whole time waveform  $f$ .

As a second transformation example, let  $f(t) = \delta(t)$ , the unit impulse, essentially a unit-area pulse of very short duration. It acts at  $t = 0$ —barely within the lower limit of the Laplace integral. It has value zero at  $t = 0^-$ . (Because we use  $0^-$  as the lower limit of the defining integral, it does not matter whether the impulse straddles  $t = 0$  or begins to rise at  $t = 0$ .) The impulse is nonzero only for  $t \approx 0$ , where  $e^{-st} \approx 1$ . Therefore, the Laplace transform is

$$\Delta(s) = \int_{0^-}^{\infty} \delta(t) e^{-st} dt \approx \int_{0^-}^{\infty} \delta(t) (1) dt = 1 \quad (94.7)$$

It is not necessary to derive the Laplace transform for each signal that we use in the study of systems. [Table 94.1](#) gives the transforms for some signal waveforms that are common in dynamic systems.

**Table 94.1** Laplace Transform Pairs

	$f(t) = \mathcal{L}^{-1}[F(s)], t \geq 0^-$	$F(s) = \mathcal{L}[f(t)]$
1. Unit impulse $\delta(t)$		1
2. Unit step $u_s(t)$		$\frac{1}{s}$
3. $t^n, \quad n = 1, 2, \dots$		$\frac{n!}{s^{n+1}}$
4. $e^{-\alpha t}$		$\frac{1}{s + \alpha}$
5. $t^n e^{-\alpha t}, \quad n = 1, 2, \dots$		$\frac{n!}{(s + \alpha)^{n+1}}$
6. $\sin(\omega_0 t)$		$\frac{\omega_0}{s^2 + \omega_0^2}$
7. $\cos(\omega_0 t)$		$\frac{s}{s^2 + \omega_0^2}$
8. $e^{-\alpha t} \sin(\omega_d t)$		$\frac{\omega_d}{(s + \alpha)^2 + \omega_d^2}$
9. $e^{-\alpha t} \cos(\omega_d t)$		$\frac{s + \alpha}{(s + \alpha)^2 + \omega_d^2}$

## 94.3 Transform Properties

A number of useful properties of the Laplace transformation  $\mathcal{L}$  are summarized in [Table 94.2](#). According to the derivative property, the multiplier  $s$  acts precisely like the time-derivative operator, but in the domain of Laplace-transformed signals. When we Laplace transform the equation for an energy-storage element such as a mass or a spring, the derivative property automatically incorporates the prior energy state of the element—essentially the value of the variable at  $t = 0^-$ . When we Laplace transform the input-output system equation for a particular system variable, the derivative property automatically incorporates the whole prior system state. As a consequence, we can find the solution to the system equation without having to determine the initial conditions (at  $t = 0^+$ )—a considerable simplification of the solution process.

**Table 94.2** Properties of the Laplace Transformation,  $\mathcal{L}$

1. Magnification	$\mathcal{L}[af(t)] = aF(s)$
2. Addition	$\mathcal{L}[f_1(t) + f_2(t)] = F_1(s) + F_2(s)$
3. Derivative	$\mathcal{L}[\dot{f}(t)] = sF(s) - f(0^-)$
4. Derivatives	$\mathcal{L}[\ddot{f}(t)] = s^2F(s) - sf(0^-) - \dot{f}(0^-)$
5. Integral	$\mathcal{L}\left[\int_{0^-}^t f(t) dt\right] = \frac{F(s)}{s}$
6. Convolution	$\mathcal{L}\left[\int_0^t f_1(\lambda)f_2(t-\lambda) d\lambda\right] = F_1(s)F_2(s)$
7. Initial value	$f(0^+) = \lim_{t \rightarrow 0^+} f(t) = \lim_{s \rightarrow \infty} sF(s)$
8. Final value	$f(\infty) = \lim_{t \rightarrow \infty} f(t) = \lim_{s \rightarrow 0} sF(s) \quad \text{if finite}$
9. Definite integral	$\int_0^\infty f(t) dt = \lim_{s \rightarrow 0} F(s) \quad \text{if finite}$
10. Exponential decay	$\mathcal{L}[e^{-\alpha t} f(t)] = F(s + \alpha)$
11. Delay	$\mathcal{L}[f(t - t_0)u_s(t - t_0)] = e^{-t_0 s} F(s) \quad \text{for } t_0 \geq 0$
12. Time multiplication	$\mathcal{L}[tf(t)] = -\frac{dF(s)}{ds}$
13. Time division	$\mathcal{L}\left[\frac{f(t)}{t}\right] = \int_s^\infty F(s) ds$
14. Time scaling	$\mathcal{L}[f(at)] = \frac{F(s/a)}{a}$

Source: Dorny, C. N. 1993. *Understanding Dynamic Systems*, p. 413. Prentice Hall, Englewood Cliffs, NJ. With permission.

Since  $F(s)$  contains all information about  $f(t)$  for  $t \geq 0^-$ , it is possible to find some features of the signal  $f(t)$  from the transform  $F(s)$  without performing an inverse Laplace transformation.

Properties 7 through 9 of [Table 94.2](#) provide three of these features—namely, the initial value ( $t \rightarrow 0^+$ ), the final value ( $t \rightarrow \infty$ ), and the area under the waveform. The remaining properties in the table show the effect on the transform of various changes in the signal waveform.

The usual approach to finding inverse transforms is to use a table of transform pairs. That table might be stored in a software package such as CC, MATLAB, MAPLE, and so on. [Table 94.1](#) demonstrates that transforms of typical system signals are ratios of polynomials in  $s$ . A ratio of polynomials can be decomposed into a sum of *simple* polynomial fractions—a process referred to as *partial fraction expansion*. Hence, the inversion process can be accomplished by a computer program that incorporates a brief table of transforms.

## 94.4 Transformation and Solution of a System Equation

Suppose that an independent external source applies a specific velocity pattern  $v_1(t)$  to node 1 of [Fig. 94.1](#). To obtain the input-output system equation that relates the velocity  $v_2$  of node 2 to the input signal  $v_1$ , multiply Eq. (94.2) by  $p$  and substitute  $v_1$  for  $px_1$  and  $v_2$  for  $px_2$ . The result is

$$(mp^2 + bp + k)v_2 = (bp + k)v_1 \quad (94.8)$$

The two sides of Eq. (94.8) are identical functions of time. Therefore, the Laplace transforms of the two sides of Eq. (94.8) are equal. Since the Laplace transformation is linear (properties 1 and 2 of [Table 94.2](#)), and since the coefficients of the differential equation are constants, the Laplace transform can be applied separately to the individual terms of each side. The result is

$$\begin{aligned} m[s^2V_2(s) - sv_2(0^-) - \dot{v}_2(0^-)] + b[sV_2(s) - v_2(0^-)] + kV_2(s) \\ = b[sV_1(s) - v_1(0^-)] + kV_1(s) \end{aligned} \quad (94.9)$$

where the derivative properties of the Laplace transformation (properties 3 and 4 of [Table 94.2](#)) introduce the prior values  $v_1(0^-)$ ,  $v_2(0^-)$ , and  $\dot{v}_2(0^-)$  into the equation. According to Eq. (94.9), to fully determine the transform  $V_2(s)$  of the behavior  $v_2(t)$ , we must specify these prior values and also  $V_1(s)$ . It can be shown that specifying the three prior values is equivalent to specifying the energy states of the spring and mass.

Let us assume that the independent source applies the constant velocity  $v_1(t) = v_c$  beginning at  $t = 0$ . The corresponding transform, by item 3 of [Table 94.1](#) and property 1 of [Table 94.2](#), is  $V_1(s) = v_c/s$ . Substitute the transform  $V_1(s)$  into Eq. (94.9) and solve for

$$V_2(s) = \frac{(bs + k)v_c + ms\dot{v}_2(0^-) + bs[v_2(0^-) - v_1(0^-)] + ms^2v_2(0^-)}{s(ms^2 + bs + k)} \quad (94.10)$$

We could find the output signal waveform  $v_2(t)$  as a function of the model parameters  $m, k, b$ , the source-signal parameter  $v_c$ , and the prior state information  $v_1(0^-)$ ,  $v_2(0^-)$ , and  $\dot{v}_2(0^-)$ , but the

expression for the solution would be messy. Instead, we complete the solution process for specific numbers:  $m = 2$  kg,  $b = 4$  N · s/m,  $k = 10$  N/m,  $\dot{v}_2(0^-) = 0$  m/s<sup>2</sup>,  $v_1(0^-) = 0$  m/s,  $v_2(0^-) = -1$  m/s, and  $v_c = 1$  m/s. The partial-fraction expansion of the transform and the inverse transform, both obtained by a commercial computer program, are

$$V_2(s) = \frac{1}{s} - \frac{2s + 2}{(s + 1)^2 + 2^2} \quad (94.11)$$

$$v_2(t) = 1 - 2e^{-t} \cos(2t), \quad \text{for } t \geq 0 \quad (94.12)$$

We can take Laplace transforms of the system equations at any stage in their development. We can even write the equations directly in terms of transformed variables if we wish. The process of eliminating variables can be carried out as well in one notation as in another. For example, the operator  $G(p)$  in Eq. (94.3) represents a ratio of polynomials in the time-derivative operator  $p$ . Therefore, Laplace transforming the differential Eq. (94.3) introduces the prior values of various derivatives of  $y_1$  and  $y_2$ . If the prior values of all these derivatives are zero, then the Laplace-transformed equation is

$$Y_2(s) = G(s)Y_1(s) \quad (94.13)$$

where the operator  $p$  in Eq. (94.3) is replaced by the complex-frequency variable  $s$  in Eq. (94.13). It is appropriate, therefore, to define the transfer function directly in terms of Laplace-transformed signals:

$$G(s) = \left. \frac{Y_2(s)}{Y_1(s)} \right|_{\text{PV}=0} \quad (94.14)$$

where  $Y_1(s)$  and  $Y_2(s)$  are the Laplace transforms of the signals  $y_1(t)$  and  $y_2(t)$ , and the notation  $\text{PV} = 0$  means that the prior values (at  $t = 0^-$ ) of  $y_1(t)$  and  $y_2(t)$  and the various derivatives mentioned above in connection with Eq. (94.13) are set to zero. The *frequency domain* definition [Eq. (94.14)] is equivalent to the *time domain* definition [Eq. (94.4)].

Suppose that the input signal  $y_1(t)$  is the unit impulse  $\delta(t)$ . Then the response signal  $y_2(t)$  is the unit-impulse response of the system. Since the Laplace transform of the unit impulse is  $Y_1(s) = \Delta(s) = 1$  by entry 2 of [Table 94.1](#), Eq. (94.13) shows that the Laplace transform  $Y_2(s)$  of the unit-impulse response is identical to the zero-state transfer function (expressed in the transform domain).

The transfer function for a linear system has two interpretations. Both interpretations characterize the system. In the frequency domain, the transfer function  $G(s)$  is the multiplier that produces the response—by multiplying the source-signal transform, as in Eq. (94.13). In the time domain, we use a representative response signal—the impulse response—to characterize the system. The transfer function  $G(s)$  is the Laplace transform of that characteristic response.

## Defining Terms

**Input:** An independent variable.

**Input-output system equation:** A differential equation that describes the behavior of a single dependent variable.

**Output:** A dependent variable.

**Signal:** An observable variable; a quantity that reveals the behavior of a system.

**State:** The state of an  $n$ th-order linear system corresponds to the values of a dependent variable and its derivatives.

**Time invariant:** A system that can be represented by differential equations with constant coefficients.

**Zero state:** A condition in which no energy is stored or in which all variables have the value zero.

[95.1 Elements of the Block Diagram](#)[95.2 Block Diagram Reduction](#)[95.3 Summary](#)**Andrew P. Sage***George Mason University*

It is often very helpful to have a structural or pictorial representation that describes the flows of information and physical quantities in a system. In this chapter, we will examine two essentially equivalent ways of accomplishing this goal. First, we will examine the use of linear system block diagrams. This is a very traditional and conventional approach of the control systems engineer. We shall show that this method leads to the same transfer function determination formulas as does the signal flow graph method in the concluding portion of the chapter.

---

**95.1 Elements of the Block Diagram**

---

In previous chapters of this handbook, the Laplace transform of a system impulse response  $h(t)$  was defined as the system transfer function  $H(s)$ . It is often convenient to display this as a simple block diagram, as in [Fig. 95.1](#). Although it is proper to call either the time domain or frequency domain representations by the name **block diagram**, we will usually reserve the use of this term for the frequency domain representation. The block diagram may be a single-input, single-output block diagram that represents only the input-output behavior of the system. In this case we have a functional block diagram. On the other hand, the block diagram may be very detailed, such as to represent the entire physical structure of the systems. In either case the concepts developed here are applicable. Functional block diagram representations of input-output behavior are much more common than structural block diagrams in most control system design application studies. Structural representations that correspond to control system architectures are quite useful also. Generally, these have been converted to functional representations before control systems design efforts begin.

**Figure 95.1** Linear systems and block diagram representations.

**Linear systems** are often constructed by interconnecting subsystems. It will be of considerable value therefore to have a convenient method to cope with two (or more) coupled subsystems as indicated in Fig. 95.2. We must be very careful to describe precisely what we mean by the interconnection shown in this figure. The easiest way to accomplish this is to use a differential equation representation of the two subsystems. We assume that

$$\sum_{i=0}^{n_1} a_{1i} \frac{d^i x_1}{dt^i} = \sum_{i=0}^{m_1} b_{1i} \frac{d^i u_1}{dt^i} \quad (95.1)$$

describes the first system. The second system is assumed to be described by a similar relation, as given by

$$\sum_{i=0}^{n_2} a_{2i} \frac{d^i x_2}{dt^i} = \sum_{i=0}^{m_2} b_{2i} \frac{d^i u_2}{dt^i} \quad (95.2)$$

The systems are assumed to be interconnected such that the output from the first system serves as the input to the second system. This requires that

$$u_2 = x_1 \quad (95.3)$$

There are some physical requirements involving such factors as nonloading considerations that must be imposed to ensure that the output,  $x_1$ , of the first differential equation can be input to the

second differential equation,  $u_2$ , without altering the physical characteristics—and hence the differential equation—of the first system. Thus, there are a number of modeling assumptions involved, and loading considerations must be appreciated when attempting to cascade two systems together.

**Figure 95.2** Linear systems and block diagram representations for two cascaded system elements.

There are several ways in which we could describe this coupled system. We could use the impulse response characterization to write the output relations as

$$x_1(t) = \int_0^{\infty} h_1(\tau_1) u_1(t - \tau_1) d\tau_1 \quad (95.4)$$

$$x_2(t) = \int_0^{\infty} h_2(\tau_2) u_2(t - \tau_2) d\tau_2 \quad (95.5)$$

$$u_2(t) = x_1(t) \quad (95.6)$$

We can combine these three relations into a single relation that expresses the input-output dependency of the coupled system:

$$x_2(t) = \int_0^{\infty} \int_0^{\infty} h_2(\tau_2) h_1(\tau_1) u_1(t - \tau_1 - \tau_2) d\tau_1 d\tau_2 \quad (95.7)$$

Generally, this is a difficult integral to evaluate and shows very complex time domain coupling

between subsystems 1 and 2. Fortunately, the Laplace transform of this equation yields a very simple result, as we will now demonstrate. We use the fundamental definition of the Laplace transform,

$$X(s) = L[x(t)] = \int_0^{\infty} x(t)e^{-st} dt \quad (95.8)$$

and obtain, after a modest amount of relatively routine manipulation,

$$X_2(s) = H_1(s)H_2(s)U_1(s) \quad (95.9)$$

The transfer function of the interconnected system is just the ratio  $X_2(s)/U_1(s)$ . This ratio is simply the product of the two transfer functions, a very simple and desirable relationship:

$$H(s) = \frac{X_2(s)}{U_1(s)} = H_1(s)H_2(s) \quad (95.10)$$

A somewhat simpler proof of this product relationship can be obtained by determining the transfer function of the individual subsystems. We have, from Eqs. (95.4) through (95.6),

$$X_1(s) = \frac{\sum_{i=0}^{m_1} b_{1i} s^i}{\sum_{i=0}^{n_1} a_{1i} s^i} = \frac{Q_1(s)}{P_1(s)} = H_1(s) \quad (95.11)$$

$$X_2(s) = \frac{\sum_{i=0}^{m_2} b_{2i} s^i}{\sum_{i=0}^{n_2} a_{2i} s^i} = \frac{Q_2(s)}{P_2(s)} = H_2(s) \quad (95.12)$$

$$U_2(s) = X_1(s) \quad (95.13)$$

These are easily combined to yield Eq. (95.10).

We have just developed a very useful method to determine the transfer function of the two interconnected systems. It is also of interest to obtain the impulse response of an interconnected system. For the system considered here we can obtain impulse response from Eq. (95.10) by letting  $u_1(t)$  be an impulse occurring at  $t = 0$ . For  $u_1(t) = \delta(t)$ , we obtain from Eq. (95.10)

$$h(t) = \int_0^{\infty} h_2(\tau_2)h_1(t - \tau_2)d\tau_2 \quad (95.14)$$

and we see that the impulse response of the interconnected system is just the convolution of the impulse response of the individual systems. It will generally be simpler to obtain the transfer functions of systems such as these and manipulate these functions rather than convolve impulse responses.

Two other elements are needed in order to complete our description of the fundamental linear block diagram elements. These are the summation ("summer") and pick-off point, which are

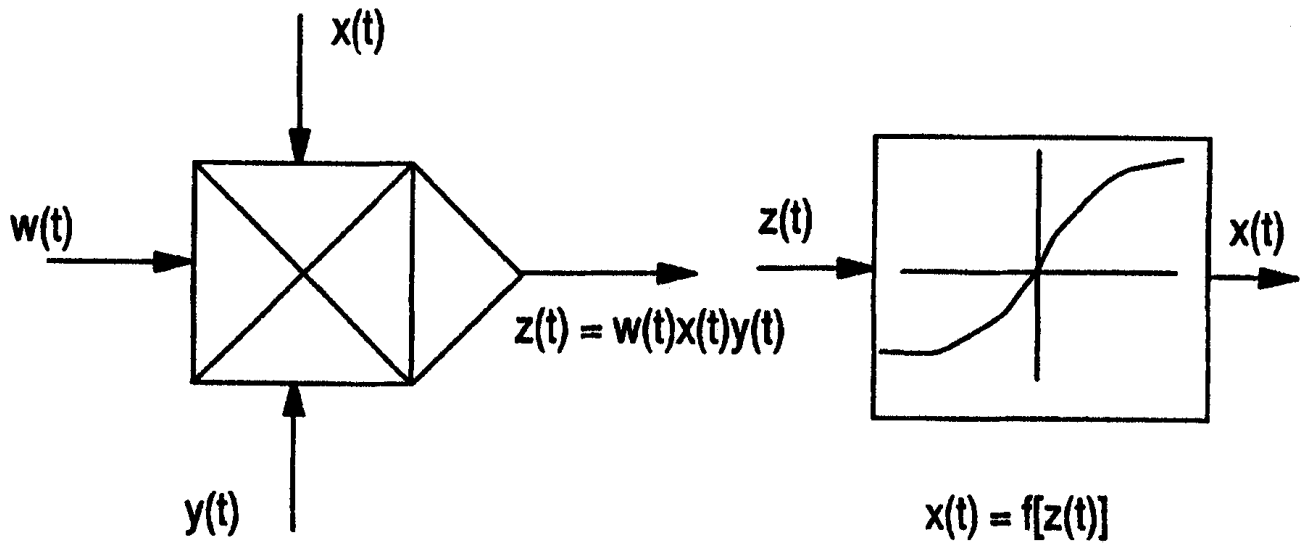

depicted in Fig. 95.3. We usually place signs alongside a summer to denote whether inputs to the summer are added or subtracted. If no signs are shown, all inputs are generally summed. As was the case with interconnection of subsystems, it is assumed that the physical model is such that no physical loading of the system occurs through use of these elements.

**Figure 95.3** Summation and pick-off symbols.

We could devise elements for multiplication and other nonlinear elements such as those shown in Fig. 95.4. The block diagram approach is primarily useful for **linear systems**, however, which is our primary concern here. Since this chapter is primarily concerned with linear systems, we shall not explore nonlinear elements in any detail here.

**Figure 95.4** Representation of nonlinear elements.

## 95.2 Block Diagram Reduction

A linear system block diagram is a representation of oriented lines and transfer function boxes, each of which is labeled with a variable and interconnect using summers and pick-off points. More often than not there will be one or more feedback loops in a typical linear system block diagram. One very simple diagram of this sort, representative of a linear-positioning servomechanism, is shown in Fig. 95.5. The presence of a closed loop whereby we can start at point  $A(s)$  and move through the system in the feed-forward position and return to point  $A(s)$  is noted. The term *closed loop system* is used to denote systems of this type in which there are feedback elements such that we may go through a complete path in the forward direction and return to the starting point. We may combine the forward transfer functions  $G_3(s)$  and  $G_4(s)$  and redraw the block diagram that represents the transfer function of this system. This step results in Fig. 95.6, which shows a single feedback loop. Often, this is called **major loop feedback**. Then we may combine the two elements in this reduced block diagram such that we obtain the single-block representation shown in Fig. 95.7. We use the elements in Fig. 95.6 and write the simple algebraic equations, or transfer function relations,

$$X(s) = G_2(s)A(s) \quad (95.15)$$

$$A(s) = U(s) - G_1(s)X(s) \quad (95.16)$$

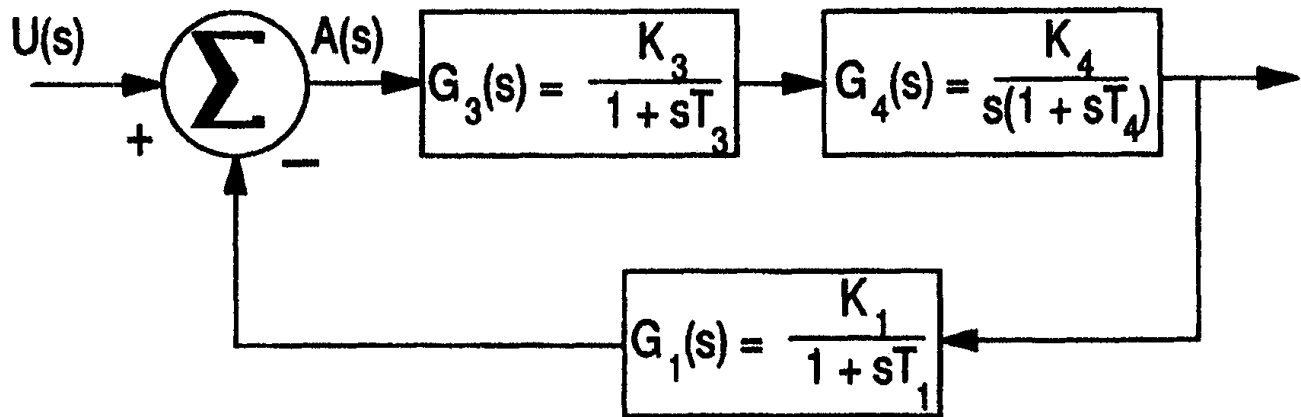

which we may solve for the desired input-output transfer relation as

$$\frac{X(s)}{U(s)} = H(s) = \frac{G_2(s)}{1 + G_1(s)G_2(s)} \quad (95.17)$$

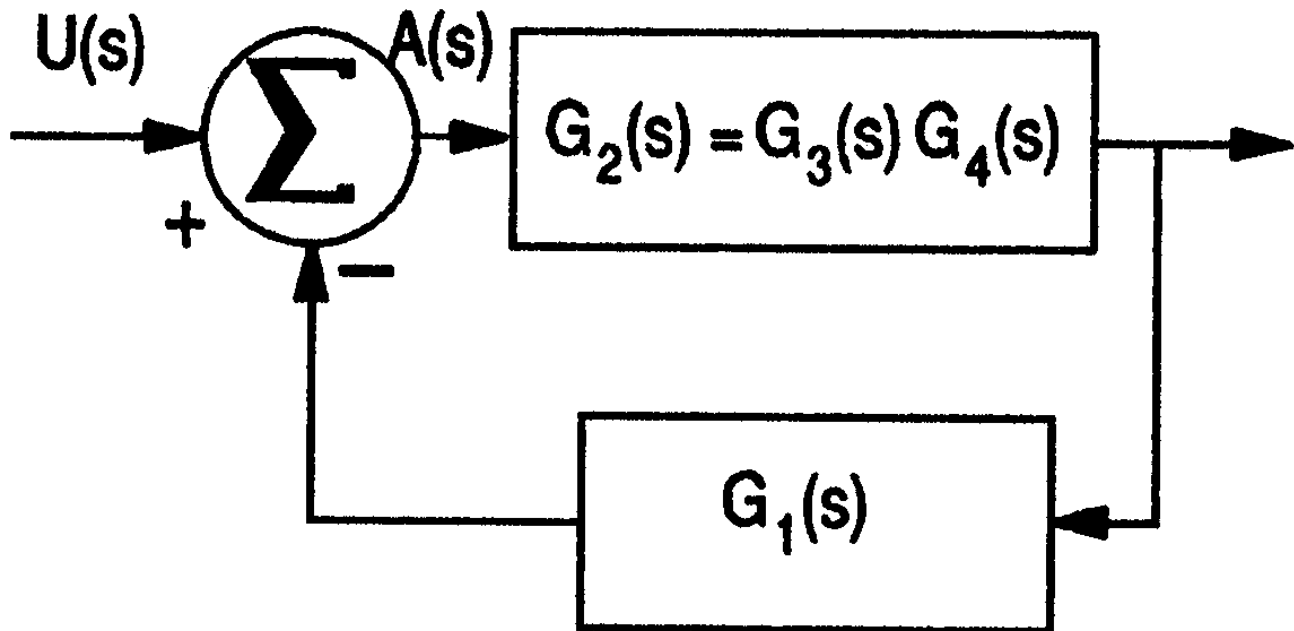

This simple relation is a very important one. We may restate it as follows: *The input-output*

transfer function for a single closed loop system is the forward transfer function divided by one plus the closed loop transfer function.

**Figure 95.5** Initial block diagram of simple positioning systems.

**Figure 95.6** Partially reduced block diagram.

**Figure 95.7** Single-block equivalent of initial feedback system.

Three other rules for block diagram manipulation are helpful: a rule for combining transfer functions in parallel, and two rules for moving summing junctions and takeoff points around transfer functions. Figures 95.8 through 95.12 illustrate these rules as well as the rules for cascading transfer functions and feedback loop reduction that we have already obtained.

**Figure 95.8** Combining parallel transfer functions.

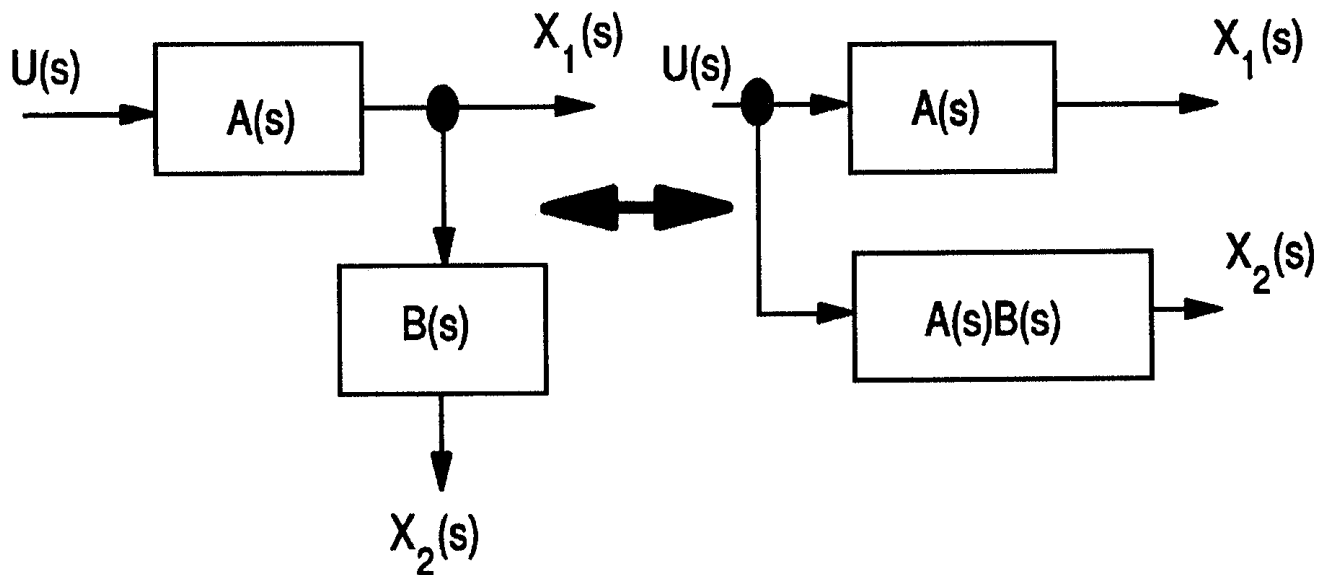

**Figure 95.9** Moving a summing junction.

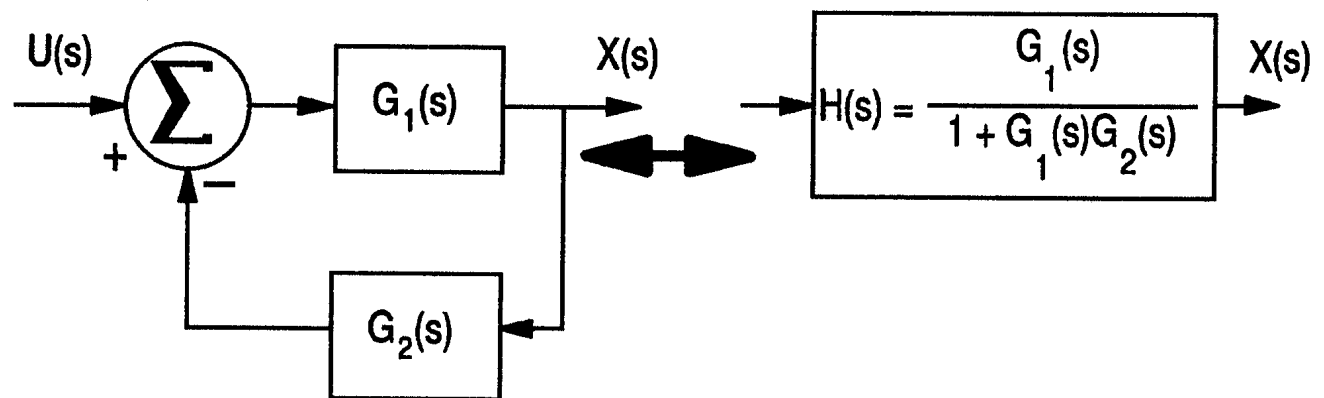

**Figure 95.10** Moving a takeoff point.

**Figure 95.11** Combining cascaded transfer functions.

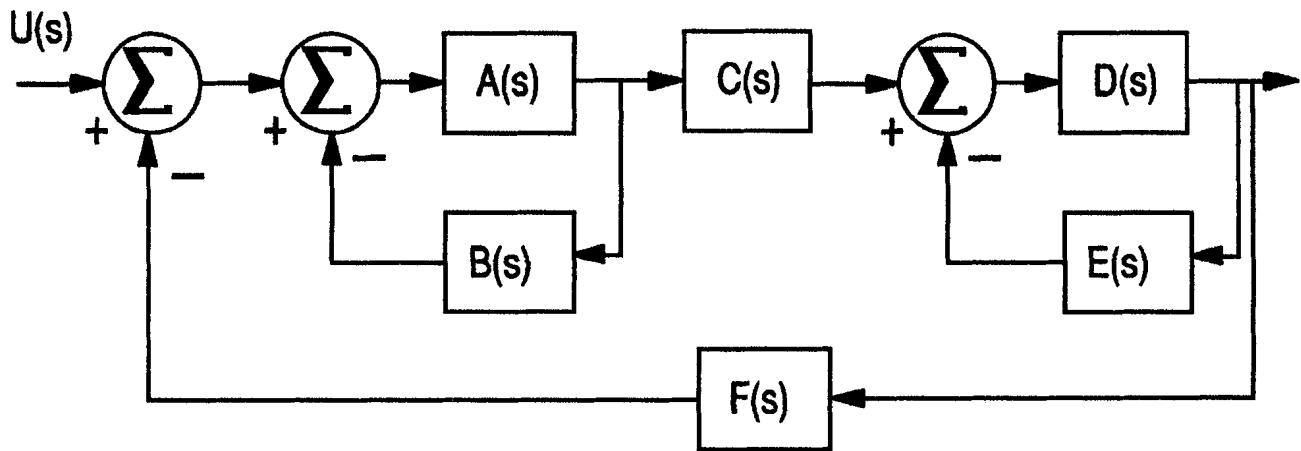

**Figure 95.12** Reduction of single-loop feedback system.

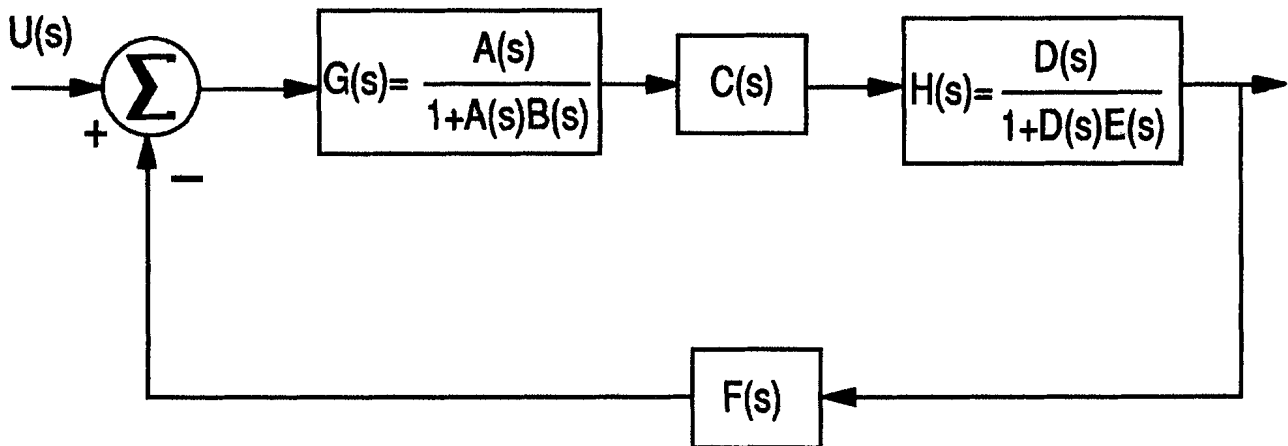

We could now proceed to establish general formulas for transfer functions of complex multiple-loop feedback systems. To motivate this, we first consider several examples that establish some preliminary ground rules and then present the more complex general rule. In each case we apply the rules established in Figs. 95.8 through 95.12.

**Example 95.1.** Consider the three-loop feedback system shown in Fig. 95.13. We want to obtain the input-output transfer function. Each of the single-loop feedback systems may be reduced to yield Fig. 95.14 by use of the rule for obtaining a single block from a feedback loop, as in Fig. 95.12. The cascade rule of Fig. 95.11 then allows us to represent the system as in Fig. 95.15. Use of the simple feedback rule of Fig. 95.12 allows us to obtain the final single-block transfer function of Fig. 95.16. Through this process we have reduced the complex three-loop system to an equivalent transfer function. This is the end of the example as far as block diagram reduction is concerned.

**Figure 95.13** Original feedback system.

**Figure 95.14** System after reduction of two feedback loops.

**Figure 95.15** Feedback control system after application of cascade transfer function rule.

**Figure 95.16** Final single-blockdiagram.

Before stating a general formula for multiple-loop feedback systems, it is first desirable to give some further interpretation of the overall system transfer function, which is

$$H(s) = \frac{ACD}{1 + AB + DE + ACDF + ABDE} \quad (95.18)$$

In this expression we have deleted the  $(s)$  arguments for convenience. Notice that the numerator of this expression is just the forward transfer function from  $U(s)$  to  $X(s)$ . The denominator contains one minus the sum of the closed loop transfer functions, whose sum is  $AB + DE + ACDF$ . Also in the denominator is the term  $ABDE$ , which is the product of two of the closed loop transfer functions. We naturally ask why there are no products with the third loop transfer function,  $ACDF$ . A little examination reveals that such a circumstance arises because this loop contains elements in common with other closed loops. Thus it seems that a plausible rule, which certainly

works for this example, is that the overall input-output transfer function is the forward transfer function divided by one plus the sum of the loop gains plus the product of loop gains taken two at a time with nontouching nodes or common paths or elements.

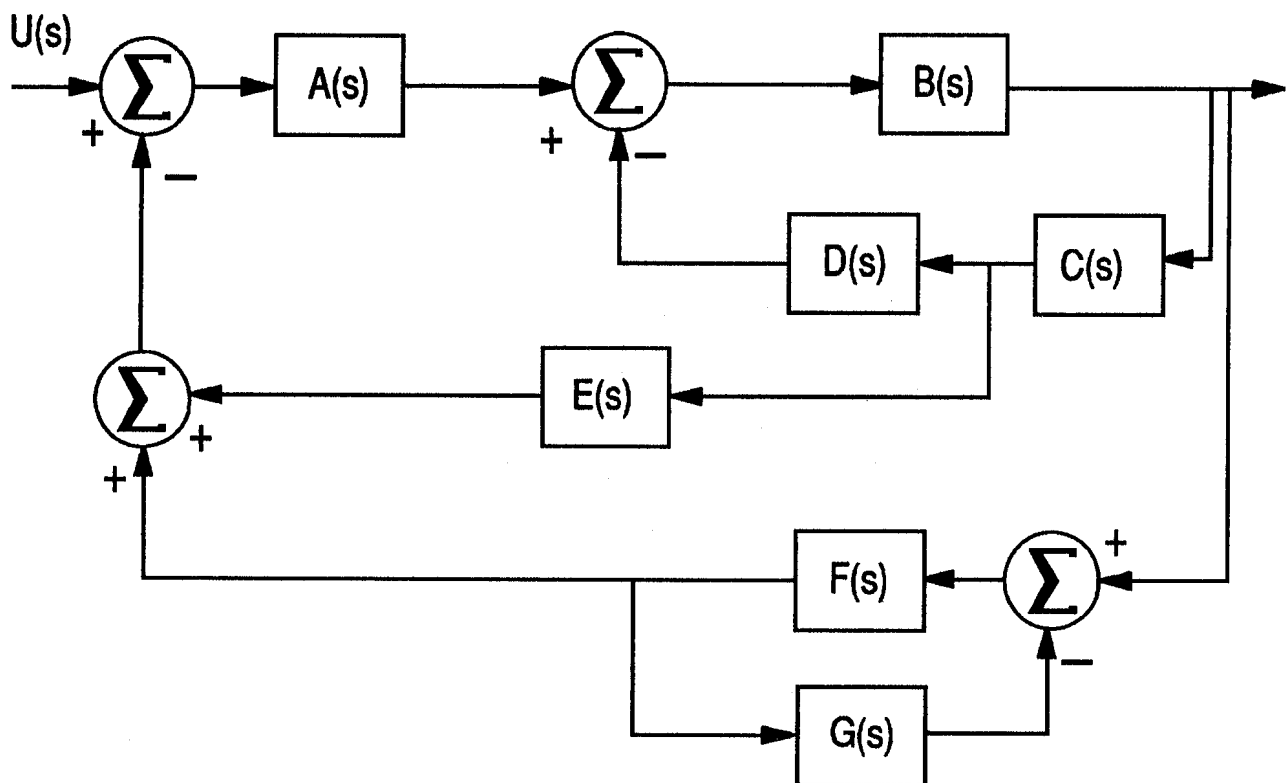

This observation turns out to be a correct rule for this system but not a complete rule, as we see in our next example, in which there is a minor loop feedback loop.

**Example 95.2.** We now consider block diagram reduction for the system shown in Fig. 95.17, in which there is a minor feedback loop. The system shown is reduced by applying our block diagram reduction rules. Solution is left as an exercise for the interested reader; it serves as a useful check on understanding material covered up to this point. The final transfer function is determined, in terms of the basic transfer functions of Fig. 95.17, as the expression

$$H(s) = \frac{X(s)}{U(s)} = \frac{AB(1 + FG)}{1 + BCD + ABCE + ABF + FG + BCDFG + ABCEFG} \quad (95.19)$$

Inspection of this result indicates that the numerator of this expression is different from that which would have been computed using the rule established in the previous example. Evaluation, through induction, reveals that the numerator here is multiplied by all terms in the denominator that do not have a path element in common with the forward transfer function contained in the numerator.

**Figure 95.17** System to be reduced by block diagram reduction.

This is still not quite the most general statement of the transfer function formula. Extension of these examples to cases in which three or more closed loops have no paths in common would show that the general input-output transfer function formula is

$$H(s) = \frac{X(s)}{U(s)} = \sum_k \frac{G_k(s)\Delta_k(s)}{\Delta(s)} \quad (95.20)$$

where

$G_k(s)$  is the  $k$ th forward transfer function through the system from  $u(t)$  to  $x(t)$ . No feedback loops can be contained in any  $G_k(s)$ .

$\Delta(s) = 1 -$  (sum of all individual closed loop transfer functions)  $+$  (sum of products of all closed loop transfer functions taken two at a time with no common paths or elements)  $-$  (sum of products of all closed loop transfer functions taken three at a time with no common paths or elements)  $+$   $\cdots$ .

$\Delta_k(s)$  = all terms in  $\Delta(s)$  that do not have elements or paths in common with an element or path in  $G_k(s)$ .

The summation is taken over all forward transfer function paths in the system.

The inputs and outputs,  $u(t)$  and  $z(t)$ , must be true inputs and outputs and not just nodes within a more complex feedback system.

**Example 95.3.** This example uses the general transfer function formula of Eq. (95.20) to evaluate the input-output transfer function of the system shown in Fig. 95.18. Direct application of Eq. (95.20) yields

$$\Delta = 1 + A + B + ABC + D + AB + AD + BD + ABCD + ABD$$

$$G_k = AB$$

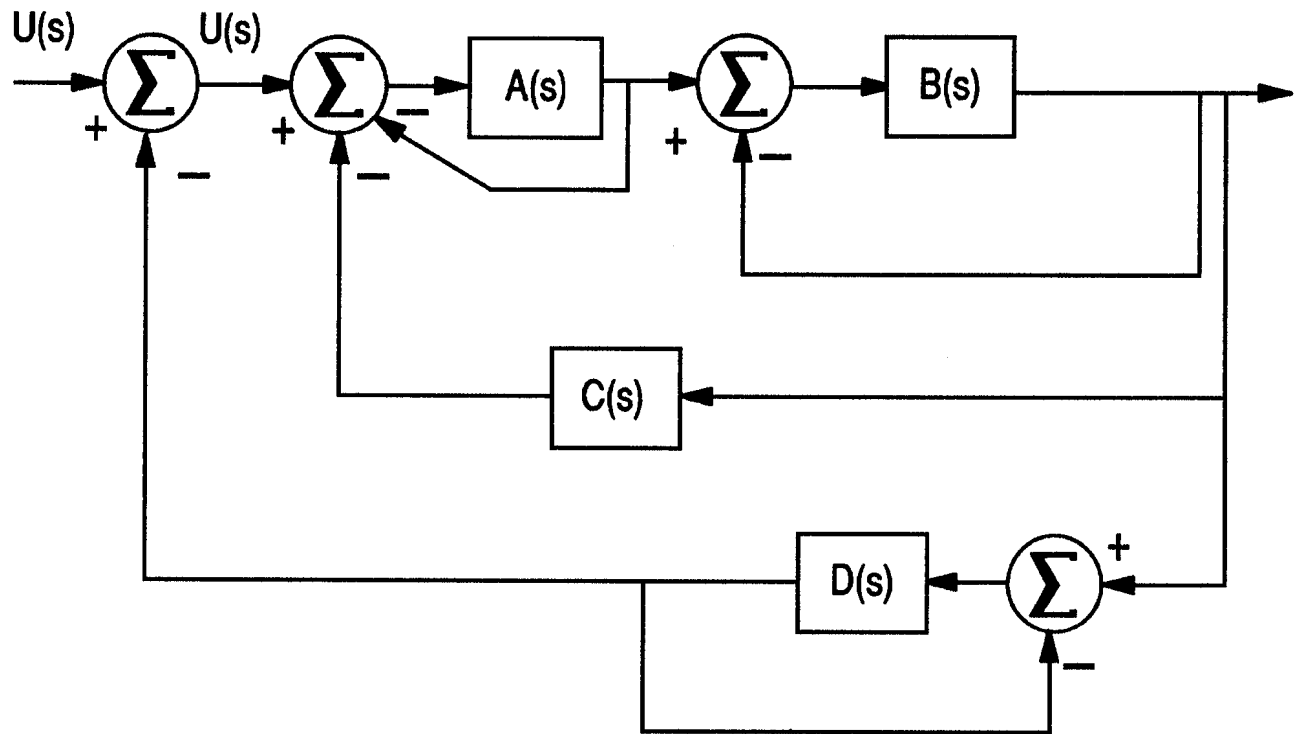

$$\Delta_k = 1 + D$$

and so we have

$$\begin{aligned} H(s) &= \frac{X(s)}{U(s)} = \frac{G_k \Delta_k}{\Delta} \\ &= \frac{AB(1 + D)}{1 + A + B + ABC + D + AB + AD + BD + ABCD + ABD} \end{aligned}$$

It would be of interest to obtain this transfer function from block diagram reduction as a check on our knowledge of the procedures involved.

**Figure 95.18** Block diagram with minor loop.

**Figure 95.19** A not-so-simple signal flow graph.

$$\frac{X(s)}{U(s)} = \frac{ABCD(1-KM)+AJKLD}{1-(AE+BF+CG+DH+KM+JKLFG)+AE(CG+DH+KM)+BF(DH+KM)+CG(KM)+DH(KM)-KM[AE(CG+DH)+BFDH]}$$

It turns out that we have obtained what was initially called the *general gain expression* for the gain, or transfer function, of a **signal flow graph**. The initial representation used for the signal flow graph is that illustrated in Fig. 95.19. Addition is accomplished at every node in a signal flow graph. To obtain subtraction, all we need to do is use a negative sign for the transfer function associated with appropriate path gains. Thus, we see that we have also developed an approach that may be used to evaluate the generalized gain, or transfer function, of a signal flow graph.

## 95.3 Summary

---

In this chapter of Section XVI, which has been devoted to a study of linear systems and models, we have studied block diagrams and block diagram reduction procedures. These are very useful for analysis and design of linear control systems and are among the many tools for analysis and design of linear systems.

### Defining Terms

**Block diagram:** A block diagram is generally a functional or input-output representation of a system. A block diagram may be a detailed structural representation of the architecture in a system, although this is generally not the case.

**Linear system:** A linear system is formally one that is described by a linear differential equation. Often, but not necessarily, the differential equation is time-invariant.

**Major loop feedback:** When there is a single feedback loop associated with a system, that loop is called a *major feedback loop*. When there are many feedback loops associated with a system, the outermost loop is generally called a *major loop*, and the feedback loops on the interior of the major loop are called *minor loops*.

**Signal flow graph:** A graph theoretic equivalent of a linear block diagram. It is composed of nodes and elements between nodes that represent gain and transfer function elements.

### Further Information

Because the material reviewed here is quite basic to any beginning study of linear control systems, there are many references appropriate for this chapter. Among the favorites of the author are the classic papers by Mason that describe the signal flow graph procedures, a work by the author, and a very classic work by Kuo that has seen many new editions. There are a plethora of good control systems texts that discuss block diagrams. You may consult the one most available to you or any of those cited in other chapters of this handbook that relate to linear systems and control for ancillary approaches to the study of block diagrams.

- 96.3 Signal Flow Graph Algebra
- 96.4 The Mason Gain Rule

**Allan D. Kraus**

*Naval Postgraduate School*

The signal flow graph is a viable alternative to the block diagram, and its use has many advocates. Because of this, signal flow analysis has, to some extent, replaced block diagram analysis as a means for reducing a complex system to a single transfer block or transfer function. Perhaps the outstanding feature of the signal flow graph is the use of node points or **nodes** to represent signals and the use of directed line segments (called **branches** or transmission **paths**) between the nodes.

## 96.1 The Signal Flow Graph

---

The signal flow graph applies only to linear systems, and an introduction to its use can derive from a consideration of the set of simultaneous, linear algebraic equations

$$\begin{aligned}
 8x_1 - 2x_2 - 4x_3 &= u_1 \\
 -2x_1 + 4x_2 - x_3 &= 0 \\
 -4x_1 - x_2 + 10x_3 &= u_2
 \end{aligned} \tag{96.1}$$

Here, the  $u$ 's are *excitations* or *forcing functions*. It should be noted that these equations represent an oversimplified case, and that it is common to see the coefficients as functions of the Laplace transform variable,  $s$ , to provide an  $s$ -domain representation of a system of linear ordinary differential equations. Equations (96.1) may be written in matrix form as

$$\begin{bmatrix} 8 & -2 & -4 \\ -2 & 4 & -1 \\ -4 & -1 & 10 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} u_1 \\ 0 \\ u_2 \end{bmatrix}$$

If  $u_1 = 24$  and  $u_2 = -12$ , the solution vector is

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 15/4 \\ 2 \\ 1/2 \end{bmatrix}$$

which is easily verified.

Equations (96.1) may be rearranged to a form that isolates each of the three dependent variables:

$$x_1 = \frac{1}{4}x_2 + \frac{1}{2}x_3 + \frac{1}{8}u_1 \quad (96.2a)$$

$$x_2 = \frac{1}{2}x_1 + \frac{1}{4}x_3 \quad (96.2b)$$

$$x_3 = \frac{2}{5}x_1 + \frac{1}{10}x_2 + \frac{1}{10}u_2 \quad (96.2c)$$

Observe that the objective here is to select a different dependent variable from each equation and to rewrite the equation in a manner such that the selected dependent variable is equal to a sum of terms involving the remaining variables. The signal flow graph representing these equations can then be constructed as indicated in Fig. 96.1. In this figure,  $x_1$ ,  $x_2$ , and  $x_3$  are considered as signals, and  $u_1$  and  $u_2$  are treated as inputs.

**Figure 96.1** Steps in the construction of the signal flow graph representing Eqs. (96.2). The final graph is indicated in (d).

The graph is constructed by first defining nodes to represent all signals and inputs, with no connections at arbitrary points. Here the preference is to place all inputs at the top and all dependent variables in sequence, from left to right, below the inputs. This is indicated in Fig. 96.1(a). Then each equation in the system is added; Figs. 96.1(b) through 96.1(d) show how Eqs. (96.2a), (96.2b), and (96.2c) are handled. The net result is Fig. 96.1(d).

In Fig. 96.2, the inputs are designated  $u_1$ ,  $u_2$ , and  $u_3$ , and these inputs are located at the nodes so marked. The output nodes—

The nodes marked  $x_1$ ,  $x_2$ ,  $x_3$ , and  $x_4$  are output nodes because each of them contains at least one incoming branch.

are  $x_1$ ,  $x_2$ ,  $x_3$ , and  $x_4$ , and there are two paths from  $u_1$  to  $x_4$ :  $ade f$  and  $ag f$ . There are five loops, three of which are  $dh$ ,  $gfkh$ , and  $fke$ .

**Figure 96.2** A signal flow graph.

## 96.2 Transmission Gain

The form of the signal flow graph as well as the principle of linearity suggests that any of the outputs can be represented as a superposition of the inputs. In general, if there are  $n$  outputs, each represented by  $x_i$ , and  $m$  inputs, each represented by  $u_j$ , then each output  $x_i$  is related to each input  $u_k$  by a transmission gain  $T_{ik}$ :

$$x_i = \sum_{k=1}^{i=k} T_{ik} u_k \quad i = 1, 2, 3, \dots, n \quad (96.3)$$

Thus, in Fig. 96.1(d), there will be two transmission gains for each output. For example, for  $x_2$ ,

$$x_2 = T_{21} u_1 + T_{22} u_2$$

In Fig. 96.2, there are three transmission gains for each output  $w$ ,  $x$ ,  $y$ , and  $z$ , one each for  $u_1$ ,  $u_2$ , and  $u_3$ . Transmission gains are determined in an effective manner through an application of signal flow graph algebra, which is considered in the next section, or through the use of the *Mason gain rule*.

## 96.3 Signal Flow Graph Algebra

1. Incoming signals to a node add. That is, the value of a variable at any node will be equal to the sum of all of the signals that enter the node. For example, in Fig. 96.3 (a), the value of variable  $x_1$  is

$$x_1 = au_1 + bu_2 - cu_3$$

and the value at node  $x_4$  is

$$x_4 = jx_2 + kx_3$$

**Figure 96.3** Steps in the simplification of a particular signal flow graph. (a) The graph. (b) Simplification with the parallel branches from  $x_1$  to  $x_2$  replaced by a single branch,  $l$ . (c) Simplification with the feedback loop from  $x_2$  to  $x_3$  replaced by a single branch,  $m$ . (d) Simplification with the parallel branches from  $x_2$  to  $x_4$  replaced by a single branch,  $n$ . (e) Simplification with the parallel branches between  $x_2$  and  $x_4$  replaced by a single branch,  $p$ .

2. The value of the variable at any node is transmitted by all branches that leave the node. Notice in Fig. 96.3(a) that the value of the signal at the "upstream" ends of the branches with gains  $d$ ,  $-e$ , and  $f$  is  $x_1$ .
3. Parallel branches may be combined by addition, provided that they connect the same two nodes and are flowing in the same direction. In Fig. 96.3(a), the branches with gains  $d$ ,  $-e$ , and  $f$  are in parallel and flow from  $x_1$  to  $x_2$ . They may be replaced by a single branch with gain

$$l = d - e + f$$

as indicated in Fig. 96.3(b).

4. A feedback loop with forward transfer  $G(s)$  and feedback transfer  $H(s)$  may be replaced by a single branch whose gain,  $T(s)$ , is given by

$$T(s) = \frac{G(s)}{1 \mp G(s)H(s)} \quad (96.4)$$

where the plus (+) sign is used for negative feedback. In Fig. 96.3(b), the feedback loop with  $G(s) = g$  and  $H(s) = -h$  reduces to the single branch with gain

$$m = \frac{g}{1 + gh}$$

as shown in Fig. 96.3(c).

5. Single branches in series may be replaced by a single branch whose gain is the product of the gains of the individual branches. This is similar to the procedure for the cascade of transfer blocks in the block diagram, and it is observed that the two branches in series in Fig. 96.3(c) can be replaced by a single branch with gain

$$n = mk = \frac{gk}{1 + gh}$$

as shown in Fig. 96.3(d).

6. Additional combinations are possible. Observe that the parallel combination in Fig. 96.3(d) can be converted to a single branch

$$p = j + n = j + \frac{gk}{1 + gh}$$

or

$$p = \frac{j(1 + gh) + gk}{1 + gh}$$

as indicated in Fig. 96.3(e).

The overall transfer between the three inputs  $u_1$ ,  $u_2$ , and  $u_3$  to the single output  $x_4$  may now be obtained. Because this is a linear system, superposition must be applicable. Thus, with the series or cascade combination of the branches with gains  $l$  and  $p$  to form a single branch  $q$ ,

$$q = lp = (d - e + f) \left[ \frac{j(1 + gh) + gk}{1 + gh} \right]$$

one obtains  $x_4$  in terms of the inputs,  $u_1$ ,  $u_2$ , and  $u_3$ :

$$x_4 = \left[ \frac{(d - e + f)[j(1 + gh) + gk]}{1 + gh} \right] [au_1 + bu_2 - cu_3]$$

While simplification of a signal flow graph is always in order, a technique that does not rely on such simplification is available. This will be discussed in the next section.

## 96.4 The Mason Gain Rule

The transmission gains in a signal flow graph may be evaluated through the use of the Mason gain rule:

$$T_{ik} = \frac{x_i}{u_k} = \sum_j \frac{P_j \Delta_j}{\Delta} \quad (96.5)$$

where

$P_j$  is the  $j$ th path gain between the input  $u_k$  and the output  $x_i$

$\Delta$  is the graph determinant

$\Delta_j$  is the cofactor for the  $j$ th path

The graph determinant,  $\Delta$ , is determined from products involving the  $l$  loops in the graph:

$$\Delta = 1 - \sum L_i L_j + \sum L_i L_j L_k - \sum L_i L_j L_k L_m \cdots$$

where  $L_i L_j$  represents the products of all *nontouching* loops taken two at a time (doublets),  $L_i L_j L_k$  represents the products of all nontouching loops taken three at a time (triplets), and  $L_i L_j L_k L_m$  represents the products of all nontouching loops taken four at a time (quadruplets). Be aware that in signal flow graphs of even moderate complexity, it is possible to have quintuplets involving five loops, sextuplets involving six loops, and even more.

After the gain of the  $j$ th path has been determined, the cofactor,  $\Delta_j$ , of the  $j$ th path is formed by taking the graph determinant,  $\Delta$ , and striking out all terms associated with the loops that are touched by the  $j$ th path.

**Example.** Consider the system of Eqs. (96.1) and verify that  $x_3 = 1/2$  using a signal flow graph.

**Solution.** The signal flow graph of Fig. 96.1(d) is reproduced in Fig. 96.4 along with its five loops. Observe that all loops touch (loops that touch a single node are considered touching), so that the graph determinant is

$$\Delta = 1 - (L_1 + L_2 + L_3 + L_4 + L_5)$$

With the loop gains

$$L_1 = (1/2)(1/4) = 1/8 = 0.125$$

$$L_2 = (1/10)(1/4) = 1/40 = 0.025$$

$$L_3 = (2/5)(1/4)(1/4) = 1/40 = 0.025$$

$$L_4 = (2/5)(1/2) = 1/5 = 0.200$$

$$L_5 = (1/2)(1/10)(1/2) = 1/40 = 0.025$$

the graph determinant is computed as

$$\Delta = 1 - (0.125 + 0.025 + 0.025 + 0.200 + 0.025) = 1 - 0.400 = 0.600$$

or

$$\Delta = 3/5$$

There are two paths between  $u_1$  and  $x_3$ . All loops touch both paths. Thus,  $\Delta_1 = \Delta_2 = 1$ , and

**Figure 96.4** The signal flow graph of Fig. 96.1(d) along with its five loops.

with

$$P_1 = (1/8)(1/2)(1/10) = 1/160$$

and

$$P_2 = (1/8)(2/5) = 1/20$$

the transmission gain will be in accordance with the Mason gain rule,

$$T_{31} = \frac{P_1 \Delta_1 + P_2 \Delta_2}{\Delta}$$

or

$$T_{31} = \frac{1/160 + 1/20}{3/5} = \frac{3}{32}$$

There is one path between  $u_2$  and  $x_3$ ,

$$P_1 = 1/10$$

but  $L_1$  does not touch this path. The cofactor of this path is therefore

$$\Delta_1 = 1 - L_1 = 1 - 1/8 = 7/8$$

and by the Mason gain rule,

$$T_{32} = \frac{P_1 \Delta_1}{\Delta}$$

or

$$T_{32} = \frac{(1/10)(7/8)}{3/5} = \frac{7}{48}$$

The value of  $x_3$  is determined from an application of Eq. (96.5). With  $u_1 = 24$  and  $u_2 = -12$ ,

$$\begin{aligned}
 x_3 &= T_{31} u_1 + T_{32} u_2 \\
 &= \frac{3}{32} 24 + \frac{7}{48} (-12) \\
 &= \frac{72}{32} - \frac{84}{48} \\
 &= \frac{1}{2}
 \end{aligned}$$

## Defining Terms

The following terminology pertains generally to all signal flow graphs and specifically to the graph in Fig. 96.1(d).

**Branch:** A directed line segment, having an associated gain, that connects two nodes in a graph. A signal  $x_1$  traveling along a branch between nodes  $x_1$  and  $x_2$  is multiplied by the gain of the branch. If the gain of the branch is unmarked, it is customary to assume that the gain is unity. Note well that signals travel along the branch only in the direction of the arrow; a branch that directs a signal from  $x_1$  to  $x_2$  indicates the dependency of  $x_2$  on  $x_1$ , and not the reverse. Just as in block diagram analysis, *unidirectionality* must hold.

**Loop:** A continuous sequence of branches, traversed in the indicated branch directions, from one node around a closed path back to the same node, in which no other node is encountered more than once.

**Nodes:** Points on the graph where the signals appear. At any node, quantities associated with incoming branches are added (summed), while outgoing branches have no effect on the signal that the node represents. In Fig. 96.1(d),  $x_1$ ,  $x_2$ ,  $x_3$ ,  $u_1$ , and  $u_2$  are all signals.

- *Input node:* A node at which there are only outgoing branches. In Fig. 96.1(d),  $u_1$  and  $u_2$  are input nodes.
- *Output node:* A node for which there is at least one incoming branch. This means that when all of the input nodes are identified, the rest of the nodes in the graph may be considered output nodes.

**Path:** A continuous sequence of branches, traversed as indicated by the branch directions, along which no node is encountered more than once.

## 97.1 State-Space Models

---

The general **state-space** model that we will consider for a continuous-time dynamical system consists of a system of  $n_x$  first-order differential equations of the form

$$\begin{aligned} \frac{dx_1}{dt} &= f_1(x_1, \dots, x_{n_x}, u_1, \dots, u_{n_u}) \\ &\vdots \\ \frac{dx_{n_x}}{dt} &= f_{n_x}(x_1, \dots, x_{n_x}, u_1, \dots, u_{n_u}) \end{aligned} \quad (97.1)$$

where  $t$  denotes time;  $\mathbf{x}(t) = [x_1 \dots x_{n_x}]^T$  is an  $n_x$ -dimensional **state vector**;  $\mathbf{u} = [u_1 \dots u_{n_u}]^T$  is an  $n_u$ -dimensional control or **input vector**; and  $[\cdot]^T$  denotes the transpose. Loosely speaking, the dimension of the state vector equals the number of initial conditions required to determine the motion, given the input—say  $\mathbf{u}(t)$  or  $\mathbf{u}(\mathbf{x}, t)$ —and the model of Eq. (97.1). As an example, the motion of a point mass  $m$  satisfying Newton's equations may be described by

$$m \frac{d^2 \mathbf{y}}{dt^2} = \mathbf{F}$$

where  $\mathbf{y} = [y_1 \ y_2 \ y_3]^T$  is the position vector and  $\mathbf{F} = [F_1 \ F_2 \ F_3]^T$  is the applied force. This second-order system can be converted to first-order state-space form by, for example, taking the state vector as  $\mathbf{x} = [y_1 \ y_2 \ y_3 \ dy_1/dt \ dy_2/dt \ dy_3/dt]^T$  and the input vector as  $\mathbf{u} = (1/m)\mathbf{F}$ , yielding

$$\dot{x}_1 = x_4$$

$$\dot{x}_2 = x_5$$

$$\dot{x}_3 = x_6$$

$$\dot{x}_4 = u_1$$

$$\dot{x}_5 = u_2$$

$$\dot{x}_6 = u_3$$

where  $(\dot{\phantom{x}}) = d(\phantom{x})/dt$ . This state-space formulation makes it clear that the required initial conditions include not only the initial position  $\mathbf{y}(t)$  but also the initial velocity  $\dot{\mathbf{y}}(0)$ . Writing dynamic system models as first-order differential equations also allows numerical analysts, for example, to focus on one type of numerical integration procedure, rather than having one scheme for first-order systems, another for second-order systems, and various other schemes for  $n$ th-order systems, since all systems of higher-order differential equations can be converted to equivalent systems of first-order differential equations, as illustrated in the preceding equations.

It should be noted that Eq. (97.1) does not explicitly cover systems governed by partial differential equations, such as the vibration of a drumhead, in which the motion of the object is distributed over space as well as time. Nor does Eq. (97.1) cover time-delay systems, in which the motion depends not only on the current state  $\mathbf{x}(t)$  and current input  $\mathbf{u}(t)$ , but also on a history of past conditions, such as the state  $\mathbf{x}(t - \tau)$  at some time  $\tau$  seconds in the past. Both of these situations could be (and typically are) converted to state-space models of the form in Eq. (97.1), by discretizing the spatial region for partial differential equations or discretizing the time-delay interval for time delay systems. In the limit as the discretization intervals become small the dimension of the state vector would become infinite.

In addition to the state and input vectors, there are typically various output or measurement quantities of interest, which are related to the state and input vectors by algebraic **output equations** of the general form

$$\begin{aligned} y_1 &= g_1(x_1, \dots, x_{n_x}, u_1, \dots, u_{n_u}) \\ &\vdots \\ y_{n_y} &= g_{n_y}(x_1, \dots, x_{n_x}, u_1, \dots, u_{n_u}) \end{aligned} \quad (97.2)$$

where  $\mathbf{y} = [y_1 \dots y_{n_y}]^T$  is an  $n_y$ -dimensional **output vector**. For our point-mass example, taking the position vector as the output would correspond to the output equations

$$y_1 = x_1$$

$$y_2 = x_2$$

$$y_3 = x_3$$

In vector form the state equations (97.1) and the output equations (97.2) can be written as

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}) \quad (97.3)$$

$$\mathbf{y} = \mathbf{g}(\mathbf{x}, \mathbf{u}) \quad (97.4)$$

where  $(\dot{\phantom{x}}) = d(\phantom{x})/dt$ ,  $\mathbf{f} = [f_1 \dots f_{n_x}]^T$ , and  $\mathbf{g} = [g_1 \dots g_{n_y}]^T$ . Systems in which time  $t$  appears explicitly in the right-hand sides of Eq. (97.3) or (97.4) can be handled, for example, either by including such terms in the input vector  $\mathbf{u}$  or by treating  $t$  as a state variable, say  $x_{n_x} = t$  with the differential equation  $\dot{t} = 1$ .

## 97.2 Linearization

---

For a system of the form

$$\dot{\mathbf{X}} = \mathbf{f}(\mathbf{X}, \mathbf{U}) \quad (97.5)$$

with output equations

$$\mathbf{Y} = \mathbf{g}(\mathbf{X}, \mathbf{U}) \quad (97.6)$$

let  $\mathbf{U}(t) = \bar{\mathbf{U}}(t)$  be a reference input. For a given initial state  $\bar{\mathbf{X}}(0)$  let  $\bar{\mathbf{X}}(t)$  be the corresponding solution to Eq. (97.5) generated by  $\bar{\mathbf{U}}(t)$  and let  $\bar{\mathbf{Y}}(t)$  be the resulting output, given by Eq. (97.6). Let  $\mathbf{x}(t)$ ,  $\mathbf{y}(t)$ , and  $\mathbf{u}(t)$  denote small deviations from the reference state, output, and input, respectively. Substituting  $\mathbf{X}(t) = \bar{\mathbf{X}}(t) + \mathbf{x}(t)$ ,  $\mathbf{Y}(t) = \bar{\mathbf{Y}}(t) + \mathbf{y}(t)$ , and  $\mathbf{U}(t) = \bar{\mathbf{U}}(t) + \mathbf{u}(t)$  into Eqs. (97.5) and (97.6), expanding the results using Taylor's theorem, and retaining only the first-order (linear) terms yields the time-varying **linear state equations**,

$$\dot{\mathbf{x}} = \mathbf{A}(t)\mathbf{x} + \mathbf{B}(t)\mathbf{u} \quad (97.7)$$

and the **linear output equations**

$$\mathbf{y} = \mathbf{C}(t)\mathbf{x} + \mathbf{D}(t)\mathbf{u} \quad (97.8)$$

where  $\mathbf{A}(t) = [a_{ij}(t)] = [\partial f_i / \partial X_j]$ ,  $i = \text{row}$ ,  $j = \text{column}$  is an  $n_x \times n_x$  matrix;  
 $\mathbf{B}(t) = [\partial f_i / \partial U_j]$  is an  $n_x \times n_u$  matrix;  $\mathbf{C}(t) = [\partial g_i / \partial X_j]$  is an  $n_y \times n_x$  matrix;  
 $\mathbf{D}(t) = [\partial g_i / \partial U_j]$  is an  $n_y \times n_u$  matrix; and all matrices are evaluated along the reference

conditions  $\bar{X}(t), \bar{U}(t)$ .

The most common occurrence of linear systems arises when the reference input is a constant  $\bar{U}(t) = \bar{U}$  and the reference state is an equilibrium (i.e., constant) state  $\bar{X}(t) = \bar{X}$ . Then the reference output  $\bar{Y}(t) = \bar{Y}$  is also constant. In this case the matrices in the linear model are also constant. This yields a constant-coefficient **multiple-input, multiple-output (MIMO)** linear state-space model, with linear state equations

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}u \quad (97.9)$$

and the linear output equations

$$y = \mathbf{C}\mathbf{x} + Du \quad (97.10)$$

Henceforth we will be concerned only with constant-coefficient linear state-space models of the form given in Eqs. (97.9) and (97.10).

For the special case of a single input  $u$  and a single output  $y$  ( $n_u = n_y = 1$ ) we have a **single-input, single-output (SISO)** state-space system,

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}u \quad (97.11)$$

$$y = \mathbf{C}\mathbf{x} + Du \quad (97.12)$$

where  $u$  and  $y$  are scalar variables,  $D$  is a scalar constant,  $\mathbf{B} = [b_1 \dots b_{n_x}]^T$ , and  $\mathbf{C} = [c_1 \dots c_{n_x}]$ .

## 97.3 Linear System Representations

---

The representation of a linear state-space system is generally not unique. For example, a change in the coordinate system for  $\mathbf{x}$  will change the matrices in the state-space representation. In addition, there are certain state-space representations and other types of representations that may be more convenient for various types of analyses.

### State-Space Systems

There are several special representations for a state-space system that occur frequently in control systems analysis:

#### Decoupled Form

The simplest representation of a state-space system occurs when the state equations are decoupled, that is, when the  $\mathbf{A}$  matrix is in the diagonalized form,

$$\mathbf{A} = \text{diag} [\lambda_1, \dots, \lambda_{n_x}] = \begin{bmatrix} \lambda_1 & & 0 \\ & \ddots & \\ 0 & & \lambda_{n_x} \end{bmatrix} \quad (97.13)$$

so that the evolution of each state variable depends only on itself and the inputs, but not on the other state variables.

### Block Diagonal Form

For a particular state-space system it may not be possible to completely diagonalize the  $\mathbf{A}$  matrix so that each state variable is decoupled from the others. In this case a generalization of the diagonal structure occurs where the  $\mathbf{A}$  matrix is in block diagonal form,

$$\mathbf{A} = \text{diag} [\mathbf{A}_1, \dots, \mathbf{A}_n] \quad (97.14)$$

in which the  $\mathbf{A}_i$  are square matrices on the diagonal of  $\mathbf{A}$ .

### Companion Form

For a special class of SISO state-space systems, a representation exists that can lead to a description of the system in terms of a single higher-order differential equation. A single-input, single-output state-space system is said to be in companion form if the  $\mathbf{A}$  matrix is a companion matrix,

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ & & & \ddots & \\ 0 & 0 & 0 & \cdots & 1 \\ -a_1 & -a_2 & -a_3 & \cdots & -a_{n_x} \end{bmatrix} \quad (97.15)$$

and the scalar control input enters only in the  $\dot{x}_{n_x}$  equation, with the column matrix  $\mathbf{B}$  of the form  $\mathbf{B} = [0 \ 0 \ \dots \ 1]^T$ . As we will see, a companion form representation has a particularly simple relationship to a representation involving a single  $n_x$ - order differential equation.

## Input-Output Systems

Equations (97.11) and (97.12) are the general representation of a constant-coefficient SISO system. Another common representation for a special class of SISO systems is referred to as an **input-output (IO)** representation. Using the notation  $y^{(n)} = d^n y / dt^n$  we call an SISO system an IO system if the system can be represented by a single  $n_x$ - order differential equation of the form

$$y^{(n_x)} + p_{n_x-1} y^{(n_x-1)} + \cdots + p_1 \dot{y} + p_0 y = q_0 u + q_1 \dot{u} + \cdots + q_{n_x} u^{(n_x)} \quad (97.16)$$

Note that the left-hand side of Eq. (97.16) is expressed in terms of the output  $y(t)$  and the right-hand side is expressed in terms of the input  $u(t)$ . In order for the output to depend on the input, at least one of the right-hand coefficients must be nonzero.

There is a close relationship between the state-space representation of an SISO system in companion form and the IO representation of the same system, provided that certain conditions are

satisfied. For example, if the output is just the first state component—that is, the  $\mathbf{C}$  matrix is of the form  $\mathbf{C} = [1 \ 0 \dots 0]$  and  $D = 0$ , with  $\mathbf{B} = [0 \dots 0 \ 1]^T$  — then from Eqs. (97.11) and (97.15) the last state equation can be written as

$$\dot{x}_{n_x} + a_{n_x} x_{n_x} + \dots + a_2 x_2 + a_1 x_1 = u \quad (97.17)$$

Since  $x_1 = y$ , it follows from the other state equations of (97.11) and (97.15),  $\dot{x}_i = x_{i+1}$  for  $i = 1, \dots, n_x - 1$ , that

$$\begin{aligned} x_2 &= \dot{x}_1 = \dot{y} \\ x_3 &= \dot{x}_2 = \ddot{y} \\ &\vdots \\ x_{n_x} &= \dot{x}_{n_x-1} = y^{(n_x-1)} \end{aligned}$$

Thus Eq. (97.17) becomes

$$y^{(n_x)} + a_{n_x} y^{(n_x-1)} + \dots + a_2 \dot{y} + a_1 y = u$$

which is in the IO format.

If the output is not just the first state component, then it may not be possible to convert an SISO system in companion form to an equivalent IO representation. In the next section we will discuss a general requirement that, when satisfied, will guarantee that a state-space SISO system (whether in companion form or not) can be converted to an equivalent IO representation.

## 97.4 Transforming System Representations

---

For the remainder of this chapter we will be concerned with transforming between various types of representations of constant-coefficient linear systems. It turns out that two fundamental concepts, controllability and observability, govern whether or not certain equivalent representations can be achieved.

### Controllability and Observability

**Controllability** is concerned with whether a control input  $u(t)$  exists that will transfer the state  $\mathbf{x}(t)$  from a given initial point  $\mathbf{x}(0)$  to a specified final state  $\mathbf{x}(t_f)$  in some finite time interval  $0 \leq t \leq t_f$ . A linear constant-coefficient system of the form in Eq. (97.9) is completely controllable (from any initial state to any final state) if and only if the Kalman controllability criterion,  $\text{rank } [\mathbf{P}] = n_x$ , is satisfied, where the  $n_x \times n_x n_u$  matrix,

$$\mathbf{P} = [\mathbf{B}, \mathbf{AB}, \mathbf{A}^2\mathbf{B}, \dots, \mathbf{A}^{n_x-1}\mathbf{B}] \quad (97.18)$$

is called the *controllability matrix*. Here,  $\text{rank } [\mathbf{P}]$  is the maximum number of linearly independent rows (or columns) in  $\mathbf{P}$  and is equal to the size of the largest nonzero square determinant obtained by deleting various rows and/or columns of  $\mathbf{P}$ . For a single-input system,  $\mathbf{P}$  is square and the controllability criterion requires  $|\mathbf{P}| \neq 0$ , where  $|\mathbf{P}|$  denotes the determinant of  $\mathbf{P}$ .

**Observability** is concerned with the problem of determining the state based on the measured outputs. In particular, a linear state-space system is observable if it is possible to uniquely determine the initial state  $\mathbf{x}(0)$  given the output and input histories  $y(t)$  and  $u(t)$  over a finite time interval  $0 \leq t \leq t_f$ . A linear constant-coefficient system of the form in Eqs. (97.9) and (97.10) is completely observable (over any nonzero time interval) if and only if the Kalman observability criterion,  $\text{rank } [\mathbf{Q}] = n_x$ , is satisfied, where the  $n_x n_y \times n_x$  matrix,

$$\mathbf{Q} = \begin{bmatrix} \mathbf{C} \\ \mathbf{CA} \\ \mathbf{CA}^2 \\ \vdots \\ \mathbf{CA}^{n_x-1} \end{bmatrix} \quad (97.19)$$

is called the *observability matrix*. For a single-output system,  $\mathbf{Q}$  is square and the observability criterion requires  $|\mathbf{Q}| \neq 0$ .

## State-Space Transformations

As indicated previously, the state-space representation of a linear system is not unique. Let  $\mathbf{M}$  be any constant nonsingular  $n_x \times n_x$  matrix with inverse  $\mathbf{M}^{-1}$ . Then the coordinate transformation  $\mathbf{z} = \mathbf{M}^{-1}\mathbf{x}$  transforms the system given in Eqs. (97.9) and (97.10) into

$$\dot{\mathbf{z}} = \hat{\mathbf{A}}\mathbf{z} + \hat{\mathbf{B}}\mathbf{u} \quad (97.20)$$

$$\mathbf{y} = \hat{\mathbf{C}}\mathbf{z} + \mathbf{D}\mathbf{u} \quad (97.21)$$

where

$$\hat{\mathbf{A}} = \mathbf{M}^{-1}\mathbf{A}\mathbf{M}, \quad \hat{\mathbf{B}} = \mathbf{M}^{-1}\mathbf{B}, \quad \hat{\mathbf{C}} = \mathbf{C}\mathbf{M} \quad (97.22)$$

### Diagonalization

For  $i = 1, \dots, n_x$  let  $\lambda_i$  denote the scalar **eigenvalues** of  $\mathbf{A}$ , with corresponding **eigenvectors**  $\xi_i \neq 0$ . That is,

$$\mathbf{A}\xi_i = \lambda_i\xi_i \quad (97.23)$$

where the eigenvalues satisfy the  $n_x$ -order polynomial characteristic equation

$$0 = |\lambda \mathbf{I} - \mathbf{A}| = \mathcal{P}(\lambda) = \lambda^{n_x} + p_{n_x-1} \lambda^{n_x-1} + \cdots + p_1 \lambda + p_0 \quad (97.24)$$

Suppose that the  $n_x$  eigenvectors are linearly independent. A sufficient condition for this, from linear algebra, is that the eigenvalues be distinct ( $\lambda_i \neq \lambda_j$  for  $i \neq j$ ). Then the eigenvector matrix (also called the *modal matrix*),

$$\mathbf{M} = [\xi_1 \cdots \xi_{n_x}] \quad (97.25)$$

whose columns are the eigenvectors of  $\mathbf{A}$ , has an inverse. Using the eigenvector matrix and the coordinate transformation  $\mathbf{z} = \mathbf{M}^{-1}\mathbf{x}$  applied to the system given in Eqs. (97.9) and (97.10) yields the transformed system of Eqs. (97.20) and (97.21), in which  $\hat{\mathbf{A}} = \mathbf{M}^{-1}\mathbf{A}\mathbf{M}$  is a diagonal matrix, with eigenvalues on the main diagonal in the same order as the eigenvector columns of  $\mathbf{M}$ . That is, the state equations become decoupled in the new state variables.

In component form the decoupled state equations are

$$\dot{z}_i = \lambda_i z_i + \hat{\mathbf{b}}_i^T \mathbf{u}, \quad i = 1, \dots, n_x \quad (97.26)$$

and the output equations can be written as

$$\mathbf{y} = z_1 \hat{\mathbf{c}}_1 + \cdots + z_{n_x} \hat{\mathbf{c}}_{n_x} + \mathbf{D}\mathbf{u} \quad (97.27)$$

where  $\hat{\mathbf{b}}_i^T$  is the  $i$ th row of  $\hat{\mathbf{B}} = \mathbf{M}^{-1}\mathbf{B}$  and  $\hat{\mathbf{c}}_i$  is the  $i$ th column of  $\hat{\mathbf{C}} = \mathbf{C}\mathbf{M}$ .

In terms of the decoupled system equations, we have direct alternate tests for controllability and observability. The system of Eqs. (97.9) and (97.10) is controllable if and only if  $\hat{\mathbf{B}}$  contains no zero row, so that  $\mathbf{u}$  affects each eigenstate  $z_i$ . Similarly, the system of Eqs. (97.9) and (97.10) is observable if and only if  $\hat{\mathbf{C}}$  contains no zero column, so that  $\mathbf{y}$  reflects each eigenstate  $z_i$ .

### Block Diagonalization

If the  $n_x$  eigenvectors of  $\mathbf{A}$  are not linearly independent, then it is not possible to transform  $\mathbf{A}$  to a diagonal matrix. That is, we cannot find a coordinate system in which each state variable is decoupled from the other state variables. However, we can always find a coordinate transformation matrix  $\mathbf{M}$  so that  $\mathbf{z} = \mathbf{M}^{-1}\mathbf{x}$  transforms  $\mathbf{A}$  to an  $n_x \times n_x$  block diagonal *Jordan matrix*,

$$\mathbf{J} = \text{diag} [\mathbf{J}_1, \mathbf{J}_2, \dots, \mathbf{J}_n] \quad (97.28)$$

where  $n$  is the number of linearly independent eigenvectors and each Jordan block  $\mathbf{J}_i$ , associated with an eigenvalue  $\lambda_i$  of  $\mathbf{A}$ , is either a  $1 \times 1$  matrix  $[\lambda_i]$  for distinct eigenvalues or, for repeated eigenvalues, a square submatrix in upper triangular form with  $\lambda_i$  on the diagonal, ones above and adjacent to the diagonal, and zeroes elsewhere:

$$\mathbf{J}_i = \begin{bmatrix} \lambda_i & 1 & & \\ & \lambda_i & 1 & 0 \\ & & \lambda_i & \ddots \\ 0 & & & \ddots & 1 \\ & & & & \lambda_i \end{bmatrix} \quad (97.29)$$

The resulting transformed system, of the form

$$\dot{\mathbf{z}}_i = \mathbf{J}_i \mathbf{z}_i + \mathbf{B}_i \mathbf{u} \quad (97.30)$$

will be composed of block-decoupled subsystems, whose state variables are decoupled from those of the other subsystems.

The development of the matrix  $\mathbf{M}$ , so that  $\mathbf{z} = \mathbf{M}^{-1} \mathbf{x}$  transforms  $\mathbf{A}$  to Jordan block diagonal form, is essentially the same as in the case of complete diagonalization. The difference is that in order for the matrix  $\mathbf{M}$  to have an inverse, any linearly dependent eigenvectors of  $\mathbf{A}$  are replaced by "generalized eigenvectors" to form an  $\mathbf{M}$  matrix with  $n_x$  linearly independent columns. For a repeated eigenvalue  $\lambda$  with eigenvector  $\xi$ , a *generalized eigenvector*  $\hat{\xi}$  is a nonzero solution to the equation

$$[\lambda_i \mathbf{I} - \mathbf{A}] \hat{\xi} = -\xi \quad (97.31)$$

This equation can be used repeatedly, if necessary, with the right-hand side being either an eigenvector or a previously generated generalized eigenvector.

Let  $\lambda_1, \dots, \lambda_{n_x}$  and  $\xi_1, \dots, \xi_{n_x}$  be the eigenvalues and the associated linearly independent eigenvectors or generalized eigenvectors. Order them such that each generalized eigenvector  $\xi_i$  is generated from  $\xi_{i-1}$  by

$$[\lambda_i \mathbf{I} - \mathbf{A}] \xi_i = -\xi_{i-1} \quad (97.32)$$

whereas each eigenvector  $\xi_i$  satisfies

$$[\lambda_i \mathbf{I} - \mathbf{A}] \xi_i = 0 \quad (97.33)$$

Then the transformation  $\mathbf{z} = \mathbf{M}^{-1} \mathbf{x}$ , with  $\mathbf{M} = [\xi_1 \dots \xi_{n_x}]$ , converts  $\mathbf{A}$  to a Jordan block diagonal form  $\mathbf{J} = \mathbf{M}^{-1} \mathbf{A} \mathbf{M}$ , since  $\mathbf{M} \mathbf{J} = \mathbf{A} \mathbf{M}$ . For more details on block diagonalization see [Brogan \[1982, p. 143\]](#).

Instead of block diagonalization one can employ a matrix perturbation technique and only consider the case where the eigenvalues of  $\mathbf{A}$  are distinct, so that the eigenvectors are linearly independent and complete diagonalization is possible. This technique is based on the fact that distinct eigenvalues can always be achieved by making a small perturbation  $\varepsilon$  in the elements of  $\mathbf{A}$  that cause repeated eigenvalues [[Luenberger, 1979, p. 149](#)]. After any ensuing analysis has been

performed—for example, for the solution  $\mathbf{x}(t, \varepsilon)$  — the results can be examined in the limit as  $\varepsilon \rightarrow 0$ .

### Companion Form Systems

An SISO state-space system such as in Eqs. (97.11) and (97.12) can be transformed to a unique companion form if, and only if, the system is controllable. By way of construction, we note from Eqs. (97.11) and (97.15) that in companion form the state variables  $z_i$  all follow from  $z_1$  in a cascade:  $z_{i+1} = \dot{z}_i, i = 1, \dots, n_x - 1$ . Thus we can construct the transformation matrix by finding an  $n_x$ -dimensional vector  $\rho$  such that, by choosing  $z_1 = \rho^T \mathbf{x}$ , repeated differentiation yields a system in companion form. In particular, we choose

$$\begin{aligned}
 z_1 &= \rho^T \mathbf{x} \\
 z_2 &= \dot{z}_1 = \rho^T \mathbf{A} \mathbf{x} && \text{with } \rho^T \mathbf{B} = 0 \\
 z_3 &= \dot{z}_2 = \rho^T \mathbf{A}^2 \mathbf{x} && \text{with } \rho^T \mathbf{A} \mathbf{B} = 0 \\
 &\vdots && \\
 z_{n_x} &= \dot{z}_{n_x-1} = \rho^T \mathbf{A}^{n_x-1} \mathbf{x} && \text{with } \rho^T \mathbf{A}^{n_x-2} \mathbf{B} = 0 \\
 \dot{z}_{n_x} &= \rho^T \mathbf{A}^{n_x} \mathbf{x} + u && \text{with } \rho^T \mathbf{A}^{n_x-1} \mathbf{B} = 1
 \end{aligned} \tag{97.34}$$

From the left-hand sides of Eq. (97.34) and  $\mathbf{z} = \mathbf{M}^{-1} \mathbf{x}$ , we have

$$\mathbf{M}^{-1} = \begin{bmatrix} \rho^T \\ \rho^T \mathbf{A} \\ \rho^T \mathbf{A}^2 \\ \vdots \\ \rho^T \mathbf{A}^{n_x-1} \end{bmatrix} \tag{97.35}$$

From the right-hand sides of Eq. (97.34),  $\rho$  is the solution to

$$\rho^T [\mathbf{B}, \mathbf{A} \mathbf{B}, \mathbf{A}^2 \mathbf{B}, \dots, \mathbf{A}^{n_x-1} \mathbf{B}] = [0 \ 0 \dots 1]$$

For SISO systems, the controllability matrix  $\mathbf{P}$  is square and the controllability condition ensures the existence of  $\mathbf{P}^{-1}$ . Thus

$$\rho^T = [0 \ 0 \dots 1] \mathbf{P}^{-1} \tag{97.36}$$

Hence  $\rho^T$  is the last row of  $\mathbf{P}^{-1}$  and we construct  $\mathbf{M}^{-1}$  as shown in Eq. (97.35). The matrix  $\mathbf{M}^{-1}$  has an inverse, since the right-hand sides of Eq. (97.34) imply that the rows in Eq. (97.35) are linearly independent [Luenberger, 1979, p. 292].

## Input-Output Systems

We can transform a state-space SISO system to a unique equivalent  $n_x$ -\*order IO form if, and only if, the system is observable. To perform the transformation we differentiate the output  $y(t)$   $n_x$  times. Using the state equation (97.11) to substitute for  $\dot{\mathbf{x}}$  at each step yields the following system of equations:

$$\begin{aligned}
 y &= \mathbf{C}\mathbf{x} + D u \\
 \dot{y} &= \mathbf{C}\mathbf{A}\mathbf{x} + D\dot{u} + \mathbf{C}\mathbf{B} u \\
 \ddot{y} &= \mathbf{C}\mathbf{A}^2\mathbf{x} + D\ddot{u} + \mathbf{C}\{\mathbf{B}\dot{u} + \mathbf{A}\mathbf{B} u\} \\
 y^{(3)} &= \mathbf{C}\mathbf{A}^3\mathbf{x} + D u^{(3)} + \mathbf{C}\{\mathbf{B}\ddot{u} + \mathbf{A}\mathbf{B} \dot{u} + \mathbf{A}^2\mathbf{B} u\} \\
 &\vdots \\
 y^{(n_x-1)} &= \mathbf{C}\mathbf{A}^{n_x-1}\mathbf{x} + D u^{(n_x-1)} + \mathbf{C}\{\mathbf{B} u^{(n_x-2)} + \mathbf{A}\mathbf{B} u^{(n_x-3)} + \dots + \mathbf{A}^{n_x-2}\mathbf{B} u\} \\
 y^{(n_x)} &= \mathbf{C}\mathbf{A}^{n_x}\mathbf{x} + D u^{(n_x)} + \mathbf{C}\{\mathbf{B} u^{(n_x-1)} + \mathbf{A}\mathbf{B} u^{(n_x-2)} + \dots + \mathbf{A}^{n_x-1}\mathbf{B} u\}
 \end{aligned} \tag{97.37}$$

The first  $n_x$  of these equations can be solved for  $\mathbf{x}$  in terms of  $y, u$ , and their derivatives. For SISO systems the observability matrix  $\mathbf{Q}$  is square and the observability condition ensures the existence of an inverse. Thus  $\mathbf{x}$  will be a unique function of  $y, u$ , and their derivatives. Substituting this result into the  $y^{(n_x)}$  equation in (97.37) and collecting terms yields an IO system of the form in Eq. (97.16).

## State Equations from the Transfer Matrix

For a multiple-input, multiple-output state-space system of the form in Eqs. (97.9) and (97.10), taking the Laplace transform of both equations and setting the initial condition terms to zero yields

$$\mathbf{Y}(s) = \mathbf{G}(s)\mathbf{U}(s) \tag{97.38}$$

where  $\mathbf{Y}(s) = \mathcal{L}[\mathbf{y}(t)]$  and  $\mathbf{U}(s) = \mathcal{L}[\mathbf{u}(t)]$  are the Laplace transforms of  $\mathbf{y}(t)$  and  $\mathbf{u}(t)$ , respectively, and

$$\mathbf{G}(s) = \mathbf{C}[s\mathbf{I} - \mathbf{A}]^{-1}\mathbf{B} + \mathbf{D} \tag{97.39}$$

is the  $n_y \times n_u$  transfer matrix. Suppose that the transfer matrix is known, perhaps from experimental results, and is given by

$$\mathbf{G}(s) = \frac{1}{\mathcal{P}(s)} \begin{bmatrix} \mathcal{Q}_{11}(s) & \cdots & \mathcal{Q}_{1n_u}(s) \\ \vdots & \ddots & \vdots \\ \mathcal{Q}_{n_y 1}(s) & \cdots & \mathcal{Q}_{n_y n_u}(s) \end{bmatrix} \quad (97.40)$$

where each  $\mathcal{Q}_{ij}(s)$  is a polynomial of order less than or equal to the order  $n_x$  of the characteristic polynomial  $\mathcal{P}(s) = |s\mathbf{I} - \mathbf{A}|$ . We wish to construct a state-space model from the transfer matrix model.

We will first obtain a decoupled model in which the  $\mathbf{A}$  matrix is diagonal. Then a suitable coordinate transformation is applied to yield a state-space representation having specified properties, such as a desired set of eigenvectors or an  $\mathbf{A}$  matrix that is in companion form.

We compute the eigenvalues from the  $n_x$ -order characteristic equation  $\mathcal{P}(\lambda) = 0$ . Assuming that these eigenvalues are distinct, we define the diagonalized state matrix as  $\hat{\mathbf{A}} = \text{diag} [\lambda_1, \dots, \lambda_{n_x}]$ . The next step is to determine an  $n_x \times n_u$  matrix  $\hat{\mathbf{B}}$ , an  $n_y \times n_x$  matrix  $\hat{\mathbf{C}}$ , and an  $n_y \times n_u$  matrix  $\mathbf{D}$  such that the following conditions hold:

1. The transfer matrix corresponds to a state-space system, that is,

$$\mathbf{G}(s) = \hat{\mathbf{C}} \left[ s\mathbf{I} - \hat{\mathbf{A}} \right]^{-1} \hat{\mathbf{B}} + \mathbf{D}.$$

2.  $\hat{\mathbf{B}}$  has no zero rows (controllability is satisfied).
3.  $\hat{\mathbf{C}}$  has no zero columns (observability is satisfied).

Usually, the system of equations that result from equating like powers of  $s$  in condition 1 involves fewer equations than unknowns in  $\hat{\mathbf{B}}$ ,  $\hat{\mathbf{C}}$ , and  $\mathbf{D}$ , so there is some degree of freedom in choosing the elements of  $\hat{\mathbf{B}}$ ,  $\hat{\mathbf{C}}$ , and  $\mathbf{D}$ . The resulting decoupled state-space system is

$$\begin{aligned} \dot{\mathbf{z}} &= \hat{\mathbf{A}}\mathbf{z} + \hat{\mathbf{B}}\mathbf{u} \\ \mathbf{y} &= \hat{\mathbf{C}}\mathbf{z} + \mathbf{D}\mathbf{u} \end{aligned} \quad (97.41)$$

From the diagonalized representation, which may have complex-valued matrices, we can change to a final set of state variables  $\mathbf{x} = \mathbf{M}\mathbf{z}$  by choosing a set of desired linearly independent eigenvectors as the columns of the transformation matrix  $\mathbf{M} = [\xi_1 \dots \xi_{n_x}]$ . This transformation yields

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \\ \mathbf{y} &= \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u} \end{aligned} \quad (97.42)$$

where  $\mathbf{A} = \mathbf{M}\hat{\mathbf{A}}\mathbf{M}^{-1}$ ,  $\mathbf{B} = \mathbf{M}\hat{\mathbf{B}}$ , and  $\mathbf{C} = \hat{\mathbf{C}}\mathbf{M}^{-1}$ . The matrix  $\mathbf{A}$  will have eigenvalues  $\lambda_i$  and the chosen eigenvectors. For real-valued final matrices, complex conjugate eigenvectors should be chosen for any corresponding conjugate eigenvalues.

As an example, consider the IO system,

$$\ddot{y} + 3\dot{y} + 2y = u_1 + 3u_2 + \dot{u}_2$$

that has the transfer matrix representation

$$Y(s) = \begin{bmatrix} \frac{1}{s^2 + 3s + 2} & \frac{s + 3}{s^2 + 3s + 2} \end{bmatrix} \begin{bmatrix} U_1(s) \\ U_2(s) \end{bmatrix} = \mathbf{G}(s)\mathbf{U}(s)$$

The characteristic equation  $\lambda^2 + 3\lambda + 2 = 0$  yields the eigenvalues  $\lambda_1 = -1, \lambda_2 = -2$ . Thus the diagonalized state equations will have the  $\hat{\mathbf{A}}$  matrix given by

$$\hat{\mathbf{A}} = \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix}$$

The condition  $\mathbf{G}(s) = \hat{\mathbf{C}} [s\mathbf{I} - \hat{\mathbf{A}}]^{-1} \hat{\mathbf{B}} + \mathbf{D}$  yields

$$\frac{\begin{bmatrix} 1 & s + 3 \end{bmatrix}}{s^2 + 3s + 2} = \begin{bmatrix} \hat{c}_1 & \hat{c}_2 \end{bmatrix} \begin{bmatrix} \frac{1}{s + 1} & 0 \\ 0 & \frac{1}{s + 2} \end{bmatrix} \begin{bmatrix} \hat{b}_{11} & \hat{b}_{12} \\ \hat{b}_{21} & \hat{b}_{22} \end{bmatrix} + \begin{bmatrix} d_1 & d_2 \end{bmatrix}$$

Thus the elements of  $\hat{\mathbf{B}}, \hat{\mathbf{C}},$  and  $\mathbf{D}$  must satisfy

$$\begin{aligned} 1 &= d_1 s^2 + (\hat{c}_1 \hat{b}_{11} + \hat{c}_2 \hat{b}_{21} + 3d_1) s + (2\hat{c}_1 \hat{b}_{11} + \hat{c}_2 \hat{b}_{21} + 2d_1) \\ s + 3 &= d_2 s^2 + (\hat{c}_1 \hat{b}_{12} + \hat{c}_2 \hat{b}_{22} + 3d_2) s + (2\hat{c}_1 \hat{b}_{12} + \hat{c}_2 \hat{b}_{22} + 2d_2) \end{aligned}$$

Equating like powers of  $s$  and solving the resulting equations yields

$$d_1 = d_2 = 0, \quad \hat{c}_1 \hat{b}_{11} = 1, \quad \hat{c}_2 \hat{b}_{21} = -1, \quad \hat{c}_1 \hat{b}_{12} = 2, \quad \hat{c}_2 \hat{b}_{22} = -1$$

The observability condition in 3 requires that  $\hat{c}_1 \neq 0$  and  $\hat{c}_2 \neq 0$ . Therefore, these results can be solved for the  $\hat{b}_{ij}$  in terms of  $\hat{c}_1$  and  $\hat{c}_2$ . The resulting  $\hat{b}_{ij}$  are all nonzero, so the controllability condition in 2 is also satisfied. For this example, we choose  $\hat{c}_1 = \hat{c}_2 = 1$ , yielding the decoupled system of Eq. (97.41) with

$$\hat{\mathbf{A}} = \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix}, \quad \hat{\mathbf{B}} = \begin{bmatrix} 1 & 2 \\ -1 & -1 \end{bmatrix}, \quad \hat{\mathbf{C}} = \begin{bmatrix} 1 & 1 \end{bmatrix}, \quad \mathbf{D} = \begin{bmatrix} 0 & 0 \end{bmatrix}$$

Since the eigenvalues were all real, the diagonalized state-space model is real, so further transformation is not required. However, to complete the example, suppose we want to change from this diagonal form to a state-space system having a specified set of eigenvectors, such as  $\xi_1 = [1 \quad -1]^T$  and  $\xi_2 = [1 \quad -2]^T$ . As a final step, we employ a coordinate transformation  $\mathbf{x} = \mathbf{M}\mathbf{z}$ , where  $\mathbf{M} = [\xi_1 \quad \xi_2]$ . This yields a state-space system as in Eq. (97.42), with

$$\mathbf{A} = \begin{bmatrix} 0 & 1 \\ -2 & -3 \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \mathbf{C} = [1 \quad 0], \quad \mathbf{D} = [0 \quad 0]$$

Note that our choice of eigenvectors happened to produce an  $\mathbf{A}$  matrix in companion form, with the same eigenvalues as  $\hat{\mathbf{A}}$ , but with different eigenvectors. If our objective had been to directly produce an  $\mathbf{A}$  matrix in companion form, we could have chosen  $\xi_1 = [1 \quad \alpha]^T$  and  $\xi_2 = [1 \quad \beta]^T$  as variables, computed  $\mathbf{A} = \mathbf{M}\hat{\mathbf{A}}\mathbf{M}^{-1} = [a_{ij}]$ , and then solved for the parameters  $\alpha$  and  $\beta$  to satisfy the two companion matrix conditions  $a_{11} = 0$  and  $a_{12} = 1$ .

## Defining Terms

**Cause and effect:** In this context for the IO formulation, a condition that requires that the order of any derivative in the input be less than or equal to the highest order of derivative in the output.

**Controllability:** The ability to drive a system from an arbitrary initial state to an arbitrary final state in finite time.

**Eigenvalue:** Any scalar  $\lambda$  satisfying the equation  $\det[\lambda\mathbf{I} - \mathbf{A}] = 0$ , where  $\mathbf{A}$  is an  $n_x \times n_x$  matrix and  $\mathbf{I}$  is the identity matrix; alternately, a scalar  $\lambda$  satisfying the equation  $\mathbf{A}\xi = \lambda\xi$ , where  $\xi$  is an  $n_x$ -dimensional eigenvector.

**Eigenvector:** Any nonzero  $n_x$ -dimensional vector  $\xi$  satisfying the equation  $\mathbf{A}\xi = \lambda\xi$ , where  $\mathbf{A}$  is an  $n_x \times n_x$  dimensional matrix and  $\lambda$  is an eigenvalue.

**Input-output (IO) model:** A representation of a dynamic system in terms of a single  $n_x$ -order differential equation relating the output  $y(t)$  to the input  $u(t)$ .

**Input vector:** An  $n_u$ -dimensional column vector consisting of the variable quantities, other than state variables, that affect the evolution of the state of a dynamic system.

**Linear output equations:** A set of algebraic equations defining the output variables in terms of linear combinations of the state and input variables.

**Linear state equations:** A set of first-order differential equations that model the behavior of a physical system in terms of a linear combination of the state and input variables.

**Multiple-input, multiple-output (MIMO) model:** A state-space model with an input vector,  $\mathbf{u}$ , of dimension  $n_u$  greater than one and output vector,  $\mathbf{y}$ , of dimension  $n_y$  greater than one.

**Observability:** The ability to determine a system's initial state given the output and input histories over a finite time interval.

**Output equations:** A set of algebraic equations defining the output variables as functions of the state variables and the input variables.

**Output vector:** An  $n_y$ -dimensional column vector whose elements model the measurements of a physical system.

**Single-input, single-output (SISO) model:** A state-space model with a single scalar input,  $u$ , and single scalar output,  $y$ .

**State equations:** A set of first-order differential equations that model the behavior of a physical system.

**State space:** A geometric space with dimension  $n_x$  equal to the number of state variables. Any possible state of a dynamic model can be represented as a point in state space.

**State variables:** The smallest set of time-differentiated variables whose initial conditions, along with the inputs and the model, allow complete prediction of the behavior of a dynamic system. It is possible to define more than one set of state variables for any particular model. However, the number of state variables is a unique quantity for a system.

**State vector:** An  $n_x$ -dimensional column vector consisting of the state variables of a model.

### 98.1 Frequency Response Plotting

Linear Plots • Bode Diagrams

### 98.2 A Comparison of Methods

**Paul Neudorfer**

*Seattle University*

**Pierre Gehlen**

*Seattle University*

**Frequency response** in stable, linear systems is defined as "the frequency-dependent relation in both gain and phase difference between steady-state sinusoidal inputs and the resultant steady-state sinusoidal outputs" [IEEE, 1988]. The frequency response characteristics of a system can be found analytically from its transfer function. They are also commonly generated from laboratory or field tests. A single-input/single-output linear time-invariant system is shown in Fig. 98.1.

**Figure 98.1** A single-input/single-output linear system.

For systems with no time delay, the transfer function  $H(s)$  is in the form of a ratio of polynomials in the complex frequency  $s$ ,

$$H(s) = K \frac{N(s)}{D(s)}$$

where  $K$  is a frequency-independent constant. For a system in the sinusoidal steady state,  $s$  is replaced by the sinusoidal frequency  $j\omega$  ( $j = \sqrt{-1}$ ) and the system function becomes

$$H(j\omega) = K \frac{N(j\omega)}{D(j\omega)} = |H(j\omega)| e^{j \arg H(j\omega)}$$

$H(j\omega)$  is a complex quantity. Its magnitude,  $|H(j\omega)|$ , and its argument or angle,  $\arg H(j\omega)$ , relate, respectively, the amplitudes and phase angles of sinusoidal steady state input and output signals. Referring to [Fig. 98.1](#), if the input and output signals are

$$x(t) = X \cos(\omega t + \theta_x)$$

$$y(t) = Y \cos(\omega t + \theta_y)$$

then the output's amplitude  $Y$  and phase angle  $\theta_y$  are related to those of the input by the two equations

$$Y = |H(j\omega)| X$$

$$\theta_y = \arg H(j\omega) + \theta_x$$

The term *frequency response characteristic* usually implies a complete description of a system's sinusoidal steady state behavior as a function of frequency. Because  $H(j\omega)$  is complex, frequency response characteristics cannot be graphically displayed as a single curve plotted with respect to frequency. Instead, the magnitude and argument of  $H(j\omega)$  can be separately plotted as functions of frequency. It is often advantageous to plot frequency response curves on other than linearly scaled Cartesian coordinates. **Bode diagrams** (developed in the 1930s by H. W. Bode of Bell Labs) use a logarithmic scale for frequency and a decibel measure for magnitude. In **Nyquist plots** (from Harry Nyquist, also of Bell Labs),  $H(j\omega)$  is displayed in Argand diagram form on the complex plane— $\text{Re}[H(j\omega)]$  being on the horizontal axis and  $\text{Im}[H(j\omega)]$  on the vertical. Frequency is a parameter of such curves. It is sometimes numerically identified at selected points of the curve and sometimes omitted. The **Nichols chart** (developed by N. B. Nichols) graphs magnitude versus phase for the system function—frequency again being a parameter of the curve.

Frequency response techniques are most obviously applicable to topics such as communications and electrical filters, in which the frequency response behaviors of systems are central to an understanding of their operations. It is, however, in the area of control systems that frequency response techniques are most fully developed as analytical and design tools. The Nichols chart, for instance, is used exclusively in the analysis and design of classical feedback control systems. Although frequency response concepts are most often associated with electrical engineering, they are also commonly employed in other branches of engineering and the natural sciences. Two

nonelectrical examples are given in Figs. 98.2 and 98.3, which show, respectively, a frequency response test of a scale model of the suspension system of a truck and the modulation transfer function (MTF) of a photographic film. MTFs provide an accurate description of the quality of photographic systems and have largely replaced more subjective parameters, such as resolving power, sharpness, and acutance. Note that frequency response concepts are equally applicable to problems involving temporal (Fig. 98.2) and spatial (Fig. 98.3) frequencies.

## 98.1 Frequency Response Plotting

Frequency response plots are prepared by computing the magnitude and argument of  $H(j\omega)$ .

### Linear Plots

In linear plots  $|H(j\omega)|$  and  $\arg H(j\omega)$  are shown in separate diagrams as functions of frequency (either  $f$  or  $\omega$ ). Cartesian coordinates are used and all scales are linear.

**Example 98.1.** Consider the transfer function

$$H(s) = \frac{160\,000}{s^2 + 220s + 160\,000}$$

The complex frequency variable  $s$  is replaced by the sinusoidal frequency  $j\omega$  and the magnitude

and argument found.

$$H(j\omega) = \frac{160\,000}{(j\omega)^2 + 220(j\omega) + 160\,000}$$

$$|H(j\omega)| = \frac{160\,000}{\sqrt{(160\,000 - \omega^2)^2 + (220\omega)^2}}$$

$$\arg H(j\omega) = -\tan^{-1} \frac{220\omega}{160\,000 - \omega^2}$$

The plots of magnitude and argument are shown in Fig. 98.4. Linear plots are most useful when the frequency range of interest is small, as is commonly the case for mechanical systems. Such plots give a straightforward representation of system response.

**Figure 98.4** Rectangular frequency response curves of  $H(j\omega)$ . (Source: Dorf, R. C. (Ed.) 1993. *The Electrical Engineering Handbook*, Chap. 11. CRC, Boca Raton, FL.)

The peaking of the magnitude function near  $\omega = 400$  rad/s in Fig. 98.4 is a reflection of the phenomenon of **resonance**. Resonance may exist in lightly damped second or higher order systems. Examples of resonance are common in the natural and human-made worlds. Organ pipes, for example, are designed to resonate at desired pitches. Resonances can have undesirable effects such as when the steering mechanism of a vehicle with misaligned front wheels shimmies at certain operating speeds. Two well-known examples of the destructive effects of resonance are the Tacoma Narrows suspension bridge, which underwent catastrophic failure during a moderate windstorm, and the collapse of an elevated walkway in the lobby of a Kansas City hotel under the load of a crowd of dancers. All mechanical systems resonate at certain critical frequencies. The careful design engineer makes sure that vibrations that might affect the system's structural integrity are well outside the service range.

## Bode Diagrams

A Bode diagram consists of plots of the gain and phase of a transfer function, each with respect to logarithmically scaled frequency axes. In addition, the gain of the transfer function is scaled in **decibels** according to the definition

$$H_{\text{dB}} = 20 \log_{10} |H(j\omega)|$$

Bode diagrams have the advantage of clearly identifying system features even if they occur over wide ranges of frequency or dynamic response. Before constructing a Bode diagram, the transfer function is normalized so that each pole or zero term (except those at  $s = 0$ ) has a DC gain of one. For instance,

$$H(s) = K \frac{s + \omega_z}{s(s + \omega_p)} = \frac{K\omega_z}{\omega_p} \frac{s/\omega_z + 1}{s(s/\omega_p + 1)} = K' \frac{s\tau_z + 1}{s(s\tau_p + 1)}$$

It is common to draw Bode diagrams directly from  $H(s)$  without making the formal substitution  $s = j\omega$ .

When drawn by hand, Bode magnitude and phase curves are developed by adding the individual contributions of the factored terms of the transfer function's numerator and denominator. In general, these factored terms may include (1) a constant  $K$ , (2) a simple  $s$  term corresponding to either a zero or a pole at the origin, (3) a term such as  $(s\tau + 1)$  corresponding to a real valued (nonzero) pole or zero, and (4) a quadratic term with a possible standard form of  $[(s/\omega_n)^2 + 2\zeta(s/\omega_n) + 1]$  corresponding to a pair of complex conjugate poles or zeros and for which  $0 < \zeta < 1$ . With the exception of quadratic terms having small  $\zeta$  (**damping ratio**), the Bode magnitude and phase curves for all such expressions can be reasonably approximated by a series of straight-line segments. Detailed procedures for drawing Bode diagrams from these basic forms are described in many references. Examples are given in Fig. 98.5, which shows straight-line approximations for both a numerator-factored term  $(s/\omega_z + 1)$  and a denominator-factored term,  $1/(s/\omega_p + 1)$ . The approximations are shown as heavy straight lines. The exact curves are shown

as dashed lines and have actually been displaced somewhat so as not to be obscured by the approximations.

**Figure 98.5** Bode curves for (1) a pole at  $s = -\omega_p$  and (2) a zero at  $s = -\omega_z$ . (Source: Dorf, R. C. (Ed.). 1993. *The Electrical Engineering Handbook*, Chap. 11. CRC, Boca Raton, FL.)

Note in Fig. 98.5 that both decibel magnitude and phase are plotted semilogarithmically. The frequency axis is logarithmically scaled so that every tenfold, or **decade**, change in frequency occurs over an equal distance. The magnitude axis is given in decibels. Positive decibel magnitudes correspond to amplifications between input and output that are greater than one (output amplitude larger than input). Negative decibel gains correspond to attenuation between input and output (output amplitude smaller than input). The straight-line approximations differ most greatly from the exact curves at points where the approximation changes slope. In magnitude curves these are called **breakpoints**. At these points the approximate and exact curves differ by 3 dB for each real pole or zero.

Bode diagrams are easily constructed because, with the exception of lightly damped quadratic terms, each contribution can be reasonably approximated with straight lines. Also, the overall frequency response curve is found by adding the individual contributions. Two examples follow.

### Example 98.2

$$A(s) = \frac{10^4 s}{s^2 + 1100s + 10^5} = \frac{10^4 s}{(s + 100)(s + 1000)} = 10^{-1} \frac{s}{(s/100 + 1)(s/1000 + 1)}$$

In Fig. 98.6 the individual contributions of the four factored terms of  $H(s)$  are shown as long-dashed lines. The straight-line approximations for gain and phase are shown with solid lines.

The exact curves are presented with short-dashed lines.

### Example 98.3

$$G(s) = \frac{1000(s + 500)}{s^2 + 70s + 10\,000} = \frac{50(s/500 + 1)}{(s/100)^2 + 2(.35)(s/100) + 1}$$

Note that, for the quadratic term in the denominator, the damping ratio is .35, an indication of resonance. For small damping ratios the straight-line approximations of Bode magnitude and phase plots vary significantly from the exact curves. For improved accuracy the approximations would have to be adjusted near the frequency of  $\omega = 100$  rad/s. This is not a consideration when a computer is used to generate a Bode diagram. Figure 98.7 shows the exact gain and phase frequency response curves for  $G(s)$ .

**Figure 98.6** Bode diagram of  $A(s)$ . (Source: Dorf, R. C. (Ed.). 1993. *The Electrical Engineering Handbook*, Chap. 11. CRC, Boca Raton, FL.)

**Figure 98.7** Bode diagram of  $G(s)$ . (Source: Dorf, R. C. (Ed.). 1993. *The Electrical Engineering Handbook*, Chap. 11. CRC, Boca Raton, FL.)

## 98.2 A Comparison of Methods

This chapter concludes with the frequency response of a simple system function plotted in three different ways.

### Example 98.4

$$T(s) = \frac{10^7}{(s + 100)(s + 200)(s + 300)}$$

Figure 98.8 shows linear frequency response curves for  $H(s)$ . Corresponding Bode and Nyquist diagrams are shown, respectively, in Figs. 98.9 and 98.10.

**Figure 98.8** Linear frequency response plot of  $T(s)$ . (Source: Dorf, R. C. (Ed.). 1993. *The Electrical Engineering Handbook*, Chap. 11. CRC, Boca Raton, FL.)

**Figure 98.9** Bode diagram of  $T(s)$ . (Source: Dorf, R. C. (Ed.). 1993. *The Electrical Engineering Handbook*, Chap. 11. CRC, Boca Raton, FL.)

**Figure 98.10** Nyquist plot of  $T(s)$ . (Source: Dorf, R. C. (Ed.). 1993. *The Electrical Engineering Handbook*, Chap. 11. CRC, Boca Raton, FL.)

## Defining Terms

**Bode diagram:** A frequency response plot of 20-log gain and phase angle on a log-frequency base.

**Breakpoint:** A point of abrupt change in slope in the straight line approximation of a Bode magnitude curve.

**Damping ratio:** The ratio between a system's damping factor (measure of rate of decay of response) and the damping factor when the system is critically damped.

**Decade:** Power of ten. In context, a tenfold change in frequency.

**Decibel:** A measure of relative size. The decibel gain between voltages  $V_1$  and  $V_2$  is  $20 \log_{10}(V_1/V_2)$ .

**Frequency response:** The frequency-dependent relation in both gain and phase difference between steady state sinusoidal inputs and the resultant steady state sinusoidal outputs.

**Nichols chart:** A plot showing magnitude contours and phase contours of the closed-loop transfer function referred to ordinates of logarithmic loop gain and abscissas of loop phase angle.

**Nyquist plot:** A parametric frequency response plot with the real part of the transfer function on the abscissa and the imaginary part of the transfer function on the ordinate.

**Resonance:** The enhancement of the response of a physical system to a steady state sinusoidal input when the excitation frequency is near a natural frequency of the system.

### Rodger E. Ziemer

*University of Colorado, Colorado Springs*

The mathematical operation of **convolution** is defined in the first sections of this chapter, both for **continuous-time** and **discrete-time signals**. Properties of convolution are given and illustrated. Several applications are then enumerated and illustrated. Further discussions and illustrations of convolution are given in Ziemer *et al.* [1993] and Close and Frederick [1993]. A good reference on engineering mathematics—including many of the system analysis tools arising in linear systems where the convolution integral arises—is Kreyszig [1988].

## 99.1 Fundamentals

---

### Continuous-Time Convolution

Let  $x(t)$  and  $h(t)$  be two continuous-time signals defined for  $-\infty < t < \infty$ . Their **continuous-time convolution** is defined as the integral operation

$$y(t) = \int_{-\infty}^{\infty} x(\tau)h(t - \tau) d\tau \quad (99.1)$$

With the change of variables  $\lambda = t - \tau$ , Eq. (99.1) can be written in the equivalent form

$$y(t) = \int_{-\infty}^{\infty} x(t - \lambda)h(\lambda) d\lambda \quad (99.2)$$

Inspection of Eq. (99.1) reveals that the convolution operation is composed of four steps with respect to the variable of integration:

1. **Shifting** of  $h(\lambda)$ , represented by replacing  $\lambda$  by  $\lambda - t$
2. Reversal with respect to the independent variable, also known as **folding**, which gives the signal  $h(t - \lambda)$
3. Multiplication by the second signal to produce the integrand  $x(t)h(t - \lambda)$
4. Integration of the product with respect to  $\lambda$  for all values of the delay variable  $t$ , which is the independent variable of the new signal  $y(t)$

**Example 99.1.** Consider the convolution of the following two signals:

$$x(t) = \begin{cases} e^{-\alpha t}, & t \geq 0, \\ 0, & t < 0 \end{cases} \quad \alpha > 0 \quad (99.3)$$

$$h(t) = \begin{cases} e^{-\beta t}, & t \geq 0, \\ 0, & t < 0 \end{cases} \quad \alpha \neq \beta > 0 \quad (99.4)$$

The convolution of these two signals, using Eq. (99.1), is given by

$$y(t) = \int_0^t e^{-\alpha \lambda} e^{-\beta(t-\lambda)} d\lambda = e^{-\beta t} \int_0^t e^{-(\alpha-\beta)\lambda} d\lambda = \frac{e^{-\beta t} - e^{-\alpha t}}{\alpha - \beta}, \quad (99.5)$$

$t \geq 0$

where the lower limit on the integral is 0, by virtue of  $x(\tau) = 0$  for  $\tau < 0$ , and the upper limit is  $t$ , by virtue of  $h(t - \tau) = 0$  for  $t - \tau < 0$  or  $\tau > t$ . [Figures 99.1\(a–c\)](#) illustrate the factors in the integrand for various values of  $t$ , and [Fig. 99.1\(d\)](#) shows the result of the convolution for  $0 \leq t \leq 6$ .

**Figure 99.1** Steps in the convolution of two exponential signals and the final result ( $\alpha = 2$  and  $\beta = 1$ ). See Example 99.1 for mathematical details.

(a) Integrand factors for  $t = 0.5$ .

(b) Integrand factors for  $t = 1$ .

(c) Integrand factors for  $t = 2$ .

(d) Final result for the convolution.

Convolution is often used to find the output of a **linear time-invariant system** to an input signal. (The linearity property means that superposition holds; that is, an arbitrary linear combination of two inputs applied to a linear system results in the same linear combination of outputs due to the inputs applied separately. *Time invariant* means that if a given input results in a certain output, the output due to the input delayed is the original output delayed by the same amount as the input.) When used in this context, Eq. (99.1) or (99.2) involves the following functions or **signals**: the input signal  $x(t)$ , the output signal  $y(t)$ , and the **impulse response**,  $h(t)$ , which is the response of the system to a unit impulse function applied at time zero. The latter completely characterizes the system. A system is **causal** if its output does not anticipate the application of an input, which is manifested in the impulse response being zero for  $t < 0$ . The system is **stable** if every bounded input results in a bounded output, which is manifested by the impulse response being **absolutely integrable**.

## Discrete-Time Convolution

Given two discrete-time signals  $x(n)$  and  $h(n)$  defined for  $-\infty < n < \infty$ , their **discrete-time convolution** (sum) is

$$y(n) = \sum_{k=-\infty}^{\infty} x(k)h(n-k) \quad (99.6)$$

With the change of variables  $j = n - k$ , this can be written as

$$y(n) = \sum_{k=-\infty}^{\infty} x(n-j)h(j) \quad (99.7)$$

Discrete-time convolution involves the same operations as continuous-time convolution except that integration is replaced by summation.

**Example 99.2.** Consider the convolution of the following two discrete-time signals:

$$x(n) = \begin{cases} 1, & n = 0, 1, 2 \\ 0, & n < 0 \text{ and } n > 2 \end{cases} \quad (99.8)$$

$$h(n) = \begin{cases} 0, & n \leq 0 \text{ and } n > 3 \\ 1, & n = 1 \\ 2, & n = 2 \\ 3, & n = 3 \end{cases} \quad (99.9)$$

The discrete-time convolution can be carried out as shown in [Table 99.1](#). Note that the duration of  $x(n)$  is 3, that of  $h(n)$  is 3, and that of  $y(n)$  is  $3 + 3 - 1 = 5$ .

**Table 99.1** Discrete-Time Convolution

$x(n)$							
$h(-n)$	1	1	1	0	0	$n =$	$y(n)$
0 3 2 1	0					-1	0
0 3 2	1	0				0	1
0 3	2	1	0			1	3
0	3	2	1	0		2	6
	0	3	2	1	0	3	5
	0	0	3	2	1	4	3
	0	0	0	3	2	5	0
	0	0	0	0	3	6	0

## 99.2 Properties of the Convolution Operation

Several convenient **properties of convolution** can be proved. These are listed in [Table 99.2](#). Hints at proving these properties are given in the right-hand column.

**Table 99.2** Properties of the Convolution Integral

Number	Property	Comments on Proof
1	$x(t) * h(t) = h(t) * x(t)$ $\text{or } x(n) * h(n) = h(n) * x(n)$ <p style="text-align: center;">(commutative)</p>	Compare Eqs. (99.1) and (99.2) or Eqs. (99.6) and (99.7).
2	$x(t) * [\alpha h(t)] = \alpha [x(t) * h(t)]$ $\text{or } x(n) * [\alpha h(n)] = \alpha [x(n) * h(n)]$ <p style="text-align: center;"><math>\alpha</math> constant</p>	Convolution is an integral from which the constant $\alpha$ can be taken outside.
3	$x(t) * [y(t) * z(t)] = [x(t) * y(t)] * z(t)$ $\text{or } x(n) * [y(n) * z(n)] = [x(n) * y(n)] * z(n)$ <p style="text-align: center;">(associative)</p>	Write the two convolution operations as integrals and reverse the orders of integration.
4	$x(t) * [y(t) + z(t)] = x(t) * y(t) + x(t) * z(t)$ $\text{or } x(n) * [y(n) + z(n)] = x(n) * y(n) + x(n) * z(n)$ <p style="text-align: center;">(distributive)</p>	Separate the integral involving the convolution of $x(t)$ with the sum of the other two signals into the sum of two convolution integrals.
5	If the duration of $x(t)$ is $T_1$ and the duration of $y(t)$ is $T_2$ , then the duration of their convolution is $T_1 + T_2$ . For discrete-time sequences, the length of the convolution is $N_1 + N_2 - 1$ , where $x(n)$ has length $N_1$ and $y(n)$ has length $N_2$ .	Evident by sketching time-limited versions of the integrand or summand factors and considering the overlap.
6	$x(t) * \delta(t - \tau) = x(t - \tau),$ <p style="text-align: center;"><math>\tau</math> constant</p> $x(n) * \delta(n - n_0) = x(n - n_0),$ <p style="text-align: center;"><math>n_0</math> constant</p>	Use the sifting property of the delta function inside convolution integral, or the sifting property of the unit pulse function inside the convolution sum.
7	$\mathcal{F}[x(t) * h(t)] = \mathcal{F}[x(t)]\mathcal{F}[h(t)]$ $\mathcal{L}[x(t) * h(t)] = \mathcal{L}[x(t)]\mathcal{L}[h(t)]$ $\mathcal{Z}[x(n) * h(n)] = \mathcal{Z}[x(n)]\mathcal{Z}[h(n)]$ <p style="text-align: center;"><math>\mathcal{F}(\cdot)</math> = Fourier transform</p> <p style="text-align: center;"><math>\mathcal{L}(\cdot)</math> = Laplace transform</p> <p style="text-align: center;"><math>\mathcal{Z}(\cdot)</math> = <math>z</math> transform</p>	Write the Fourier or Laplace transform integrals and interchange the order of transforming and convolution. For the $z$ transform, interchange the order of the $z$ transform and convolution sums.
8	$x(t) * y(-t) = \int_{-\infty}^{\infty} x(\lambda)y(t + \lambda) d\lambda$ <p style="text-align: center;">= correlation of</p> <p style="text-align: center;"><math>x(t)</math> and <math>y(t)</math></p>	Write out the convolution integral with the argument of the second signal negated. A similar expression holds for discrete-time sequences.
9	$x(t) * e^{j\omega t} = H(j\omega)e^{j\omega t}$ <p style="text-align: center;">where <math>H(j\omega) = \int_{-\infty}^{\infty} h(t)e^{j\omega t} dt</math></p> $x(n) * e^{jn\omega T} = H(e^{j\omega T})e^{jn\omega T}$ <p style="text-align: center;">where <math>H(e^{j\omega T}) = \sum_{k=-\infty}^{\infty} h(k)e^{jk\omega T}</math></p>	Do a direct substitution into the convolution integral, factor out the term $\exp(j\omega t)$ , and use the given definition of $H(j\omega)$ . A similar derivation holds for discrete-time sequences.

## 99.3 Applications of the Convolution Integral

---

### Filtering

From property 7 of Table 99.2, it follows that

$$\begin{aligned}|Y(f)| &= |H(f)||X(f)| \\ \angle Y(f) &= \angle H(f) + \angle X(f)\end{aligned}\quad (99.10)$$

where  $f = \omega/2\pi$  is frequency in hertz. The first equation shows that the magnitude of the spectral content of  $x(t)$  is enhanced or attenuated by the magnitude of  $H(f)$ , which is known as the **amplitude response** of the system. Similarly, the phase components of the spectrum of  $x(t)$  are shifted by the argument of  $H(f)$ , which is known as the **phase response** of the system. Standard design techniques can be used to design filters to modify the amplitude and phase components of  $x(t)$  as desired. Similar statements can be applied to a discrete-time system where  $H(e^{j2\pi fT})$  plays a role similar to  $H(f)$ .

### Spectral Analysis

The approach for determining the presence of spectral components in a signal is similar to filtering, where now the amplitude response function of the filter is designed to pass the desired spectral components of the signal. In the case of random signals, spectral analysis is sometimes better carried out by estimating the autocorrelation function of the signal, Fourier transforming it, and looking for suspected spectral content [Bendat and Piersol, 1980].

### Correlation or Matched Filtering

An important problem in signal detection involves maximizing the peak signal-to-rms-noise ratio at the output of a filter at a certain time. The filter that does this is called the **matched filter** for the particular signal under consideration. Its impulse response is the time reverse of the signal to which it is matched, or, for a signal  $s(t)$ , the matched filter impulse response is

$$h_m(t) = s(t_0 - t) \quad (99.11)$$

where  $t_0$  is the time at which the output peak signal-to-rms-noise ratio is a maximum. The constant  $t_0$  is often chosen to make the impulse response of the matched filter causal. In this case **causality** can be taken to mean that the impulse response is zero for  $t < 0$ . If  $x(t) = 0$  outside of the interval  $[0, T]$ , Eq. (99.1) can be used to write the output of a matched filter to signal alone at its input as

$$y(t) = \int_0^T s(\tau)s(t_0 - t + \tau) d\tau \quad (99.12)$$

If  $t_0 = T$  and the output is taken at  $t = T$ , Eq. (99.12) becomes the energy in the

signal.

$$y(T) = \int_0^T s(\tau)s(\tau) d\tau = \int_0^T s^2(\tau) d\tau = E \quad (99.13)$$

The peak output signal squared-to-mean-square noise ratio can be shown to be

$$\text{SNR}_{\text{out}} = \frac{2E}{N_0} \quad (99.14)$$

where  $N_0$  is the single-sided power spectral density of the white input noise.

## 99.4 Two-Dimensional Convolution

---

Convolution of two-dimensional signals, such as images, is important for several reasons, including pattern recognition and image compression. This topic will be considered briefly here in terms of discrete-spatial-variable signals. Consider two-dimensional signals defined as  $x(m, n)$  and  $h(m, n)$ . Their **two-dimensional convolution** is defined as

$$y(m, n) = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} x(j, k)h(m - j, n - k) \quad (99.15)$$

A double change of summation variables permits this to also be written as

$$y(m, n) = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} x(m - j, n - k)h(j, k) \quad (99.16)$$

Properties similar to those shown for the one-dimensional case can also be given.

**Example 99.3.** The shift property given in [Table 99.2](#) (generalized to two dimensions) and superposition will be used to convolve the two-dimensional signals given in the table that follows (assumed zero outside of its definition array), with

$$h(m, n) = \delta(m - 1, n - 1) + \delta(m - 2, n - 1) \quad (99.17)$$

For  $x(m, n)$ ,

2	2	1	0	0
2	1	0	0	0
1	0	0	0	0
0	0	0	0	0
0	0	0	0	0

The two-dimensional convolution of these two signals is given by

$$y(m, n) = x(m - 1, n - 1) + x(m - 2, n - 1) \quad (99.18)$$

The result of the two-dimensional convolution is given in the table that follows, for  $y(m, n)$  :

0	0	0	0	0
0	2	4	3	1
0	2	3	1	0
0	1	1	0	0
0	0	0	0	0

## 99.5 Time-Varying System Analysis

---

The form of the convolution integral given in Eq. (99.1), when applied to finding the output of a system to a given input, assumes that the system is time-invariant—that is, its properties do not change with time. In this context  $x(t)$  is viewed as the input to the system,  $y(t)$  its output, and  $h(t)$  the response of the system to a delta function applied at time zero. The generalization of Eq. (99.1) to time-varying (i.e., *not* time-invariant) systems is

$$y(t) = \int_{-\infty}^{\infty} x(\tau)h(t, \tau) d\tau \quad (99.19)$$

where now  $h(t, \tau)$  is the response of the system at time  $t$  to a delta function applied at time  $\tau$ .

### Defining Terms

**Amplitude response:** The amount of attenuation or amplification given to a steady state sinusoidal input by a filter or time-invariant linear system. This is the magnitude of the Fourier transform of the impulse response of the system at the frequency of the sinusoidal input.

**Causal:** A property of a system stating that the system does not respond to a given input before that input is applied. Also, for a linear time-invariant system, **causality** implies that its impulse response is zero for  $t < 0$ .

**Continuous-time signal (system):** A signal for which the independent variable—quite often time—takes on a continuum of values. When applied to a system, continuous time refers to

the fact that the system processes continuous-time signals.

**Convolution:** The process of taking two signals, reversing one in time and shifting it, then multiplying the signals point by point and integrating the product (**continuous-time convolution**). The result of the convolution is then a signal whose independent variable is the shift used in the operation. When done for all shifts, the resulting convolution then produces the output signal for all values of its independent variable, quite often time. When convolving discrete-time signals, the integration of continuous-time convolution is replaced by summation and referred to as the **convolution sum** or **discrete-time convolution**.

**Discrete-time signal (system):** A signal for which the independent variable takes on a discrete set of values. When applied to a system, discrete time refers to the fact that the system processes discrete-time signals.

**Folding:** The process of reversing one of the signals in the convolution integral or sum.

**Impulse response:** The response of an LTI system to a unit impulse function applied at time zero. For a system that is linear but not time invariant, the impulse response,  $h(t, \tau)$ , is the response of the system at time  $t$  to a unit impulse function applied at time  $\tau$ .

**Linear time-invariant (LTI) system:** A system for which superposition holds and for which the output is invariant to time shifts of the input.

**Matched filter:** An LTI system whose impulse response is the time reverse of the signal to which it is matched.

**Phase response:** The amount of phase shift given to a steady state sinusoidal input by a filter or linear time-invariant system. This is the argument of the Fourier transform of the impulse response of the system at the frequency of the sinusoidal input.

**Properties of convolution:** Properties of the convolution operation given in [Table 99.2](#) result from the form of the defining integral (continuous-time case) or sum (discrete-time case). They can be used to simplify application of the convolution integral or sum.

**Signal:** Usually a function of time, but also may be a function of spatial and time variables. Signals can be classified in many different ways. Two classifications used here are continuous time and discrete time.

**Shifting:** An operation used in evaluating the convolution integral or sum. It consists of shifting the folded signal by the other one, multiplying point-by-point, and integrating.

**Stable:** A system is stable if every bounded input results in a bounded output. For an LTI system, stability means that the impulse response is **absolutely integrable**.

**Superposition:** A term that can refer to the superposition integral or sum, which is identical to the convolution integral or sum except that it refers to the response of an LTI system, or can apply to the property of superposition that defines a linear system.

**Time-invariant system:** A system whose properties do not change with time. When expressed in terms of the impulse response of a time-invariant linear system, this means that the impulse response is a function of a single variable, because the unit impulse function that is applied to give the impulse response can be applied at time zero.

**Two-dimensional convolution:** The process of convolution applied to signals dependent on two variables, usually spatial.

## Further Information

The convolution integral finds application in linear system analysis and signal processing. In the book by Ziemer, Tranter, and Fannin [1993] chapter 2 is devoted to the convolution integral and its application to continuous-time linear system analysis, whereas chapter 8 includes material on the discrete-time convolution sum.

The *IEEE Signal Processing Magazine* has tutorial articles on various aspects of signal processing, whereas the *IEEE Transactions on Signal Processing* include research papers on all aspects of signal processing. One notable and timely application of convolution is to wavelet transform theory, which has many potential applications including signal and image compression. The April 1992 issue of the *IEEE Signal Processing Magazine* contains a tutorial article on wavelet transforms.

100.1 Response Components

100.2 Internal (Asymptotic) and External (BIBO) Stability

100.3 Unstable and Marginally Stable Responses

100.4 Structural Integrity

**Raymond T. Stefani**

*California State University, Long Beach*

The output response of a linear system has two components: the zero-state response caused by the input and the zero-input response caused by the initial conditions. It is desirable that each of those responses be well behaved. The speed of an automobile, for example, must provide a comfortable ride for the passengers. The term *stability* refers to how those two response components behave. The following sections define types of stability, relationships between stability types, and methods of determining the type of stability for a given system. Several response examples are provided.

## 100.1 Response Components

---

Figure 100.1 shows the two kinds of response components for a linear system. The **zero-state** component occurs when the initial condition vector  $x_0$  is zero and the input  $r$  is nonzero.

Conversely, the **zero-input** response occurs when the input  $r$  is zero but the initial condition vector  $x_0$  is nonzero. Then, when both inputs are nonzero, a typical system has a response containing both zero-input and zero-state responses.

**Figure 100.1** Zero-state and zero-input components.

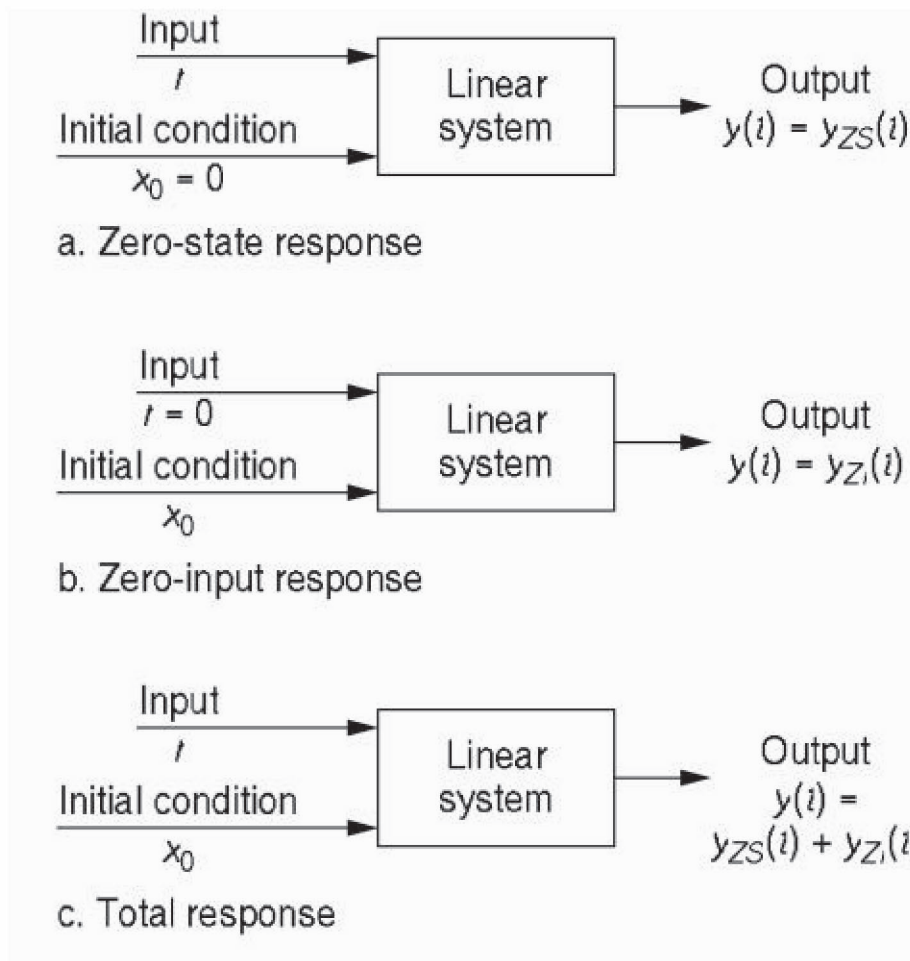

Table 100.1 shows the Laplace transform and resulting time response where the zero-state and zero-input responses are defined using classical mathematics (based on transfer functions) and state variable mathematics (based on system matrices). In the time domain the state variable–based description is

$$dx/dt = Ax + Br \quad (100.1)$$

$$y = Cx \quad (100.2)$$

The classical transfer function can be related to the  $(A, B, C)$  system by

$$H(s) = Y(s)/R(s) = C[sI - A]^{-1}B \quad (100.3)$$

**Table 100.1** Classical and State Variable Forms for Zero-State and Zero-Input Responses

	Laplace	Time
<b>Zero State</b>		
Classical(general)	$H(s)R(s) = \frac{N(s)}{D(s)}R(s)$	$\int_0^t h(\tau)r(t-\tau) d\tau$
Classical (impulse)	$H(s)$	$h(t)$
State variable (general)	$C\phi(s)BR(s)$	$\int_0^t C\phi(\tau)Br(t-\tau) d\tau$
State variable (impulse)	$C\phi(s)B$	$C\phi(t)B$
<b>Zero Input</b>		
Classical	$H_1(s) = \frac{N_1(s, x_0)}{D(s)}$	$h_1(t)$
State variable	$C\phi(s)x_0$	$C\phi(t)x_0$
Transfer function = $H(s) = C\phi(s)B$		
Resolvent matrix = $\phi(s) = [sI - A]^{-1}$		
Characteristic polynomial = $D(s) =  sI - A $		
Initial state vector = $x_0$		

An important type of zero-state response is the **impulse response** in which the input  $r$  is a unit impulse function  $\delta(t)$  whose Laplace transform  $R(s)$  equals 1. Notice in Table 100.1 the close relationship between the form of the zero-state impulse response  $C\phi(t)B$  and the zero-input response  $C\phi(t)x_0$ . Thus stability definitions based on the impulse response bear a close relationship to stability definitions based on the zero-input response.

## 100.2 Internal (Asymptotic) and External (BIBO) Stability

Stability definitions relate either to the zero-input response (**internal stability**) or to the zero-state response (**external stability**). The latter is called *external* because performance depends on the external input as it influences the external output (internal performance is ignored). Table 100.2 contains two commonly used stability definitions: asymptotic stability relates to zero-input (internal) stability, whereas the bounded-input, bounded-output (BIBO) stability relates to zero-state (external) stability.

**Table 100.2** Stability Definitions for Linear Systems

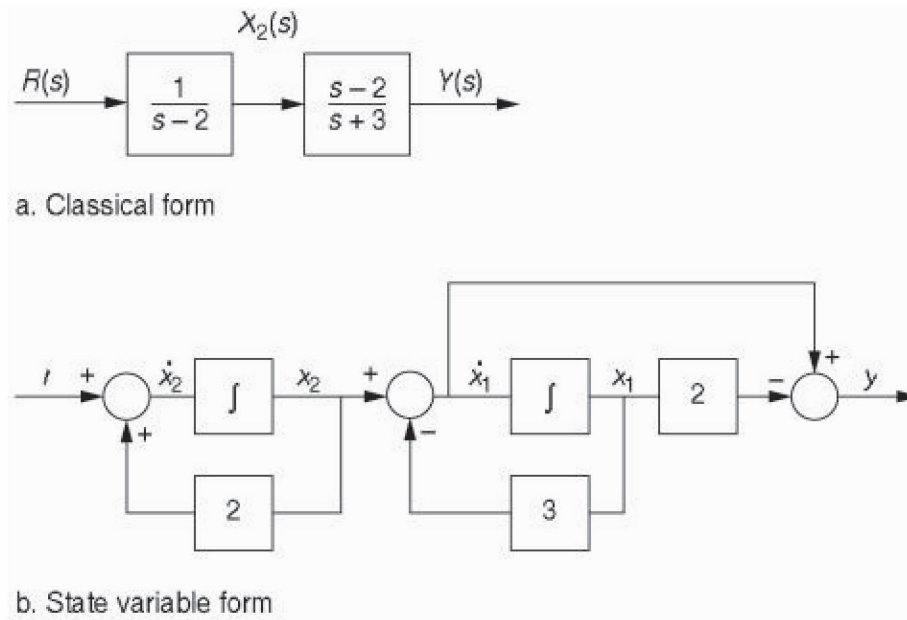

Type of Stability	Requirement	Necessary and Sufficient Condition
Asymptotic (internal) (zero input)	$C\phi(t)x_0 \rightarrow 0$ as $t \rightarrow \infty$ for all $x_0$	All eigenvalues of $A$ (closed-loop poles) are in the LHP
BIBO (external) (zero state)	If $ r(t)  \leq M_1 < \infty$ then $ y(t)  \leq M_2 < \infty$	$\int_0^\infty  h(t) dt \leq M_2 < \infty$ (all poles of $H(s)$ are in the LHP)

Asymptotic stability implies that the zero-input response tends to zero for all initial conditions. The necessary and sufficient condition for asymptotic stability is that all the eigenvalues  $A$  are in the left half plane (LHP). BIBO stability implies that all bounded inputs will cause the output to be bounded. The necessary and sufficient condition for BIBO stability is that the integral of the magnitude of the impulse response is bounded, which occurs if all the poles of  $H(s)$  are in the

LHP. These two stability definitions will result in different conclusions when there are right half plane (RHP) poles that cancel out of  $H(s)$ , obscuring internal responses that may not be bounded.

Figure 100.2 shows a system in both classical form and state variable form. From the classical form, notice that  $H(s) = 1/(s + 3)$  (an RHP pole cancels out), so the impulse response of  $y(t)$  is  $e^{-3t}$  (whose integral is bounded), causing the system to be BIBO (externally) stable. However, for an impulse input,  $X_2(s)$  is  $1/(s - 2)$  and  $x_2(t)$  is  $e^{2t}$ , which is obviously not bounded. That second (undesirable) effect is predictable from the state variable description

**Figure 100.2** Condition 1 (BIBO stable but asymptotically unstable).

$$A = \begin{bmatrix} -3 & 1 \\ 0 & 2 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad C = [-5 \quad 1] \quad (100.4)$$

Although  $H(s) = C[sI - A]^{-1}B = 1/(s + 3)$ , passing the test for BIBO stability, the eigenvalues of  $A$  are  $-3$  and  $2$ , failing the test for asymptotic stability.

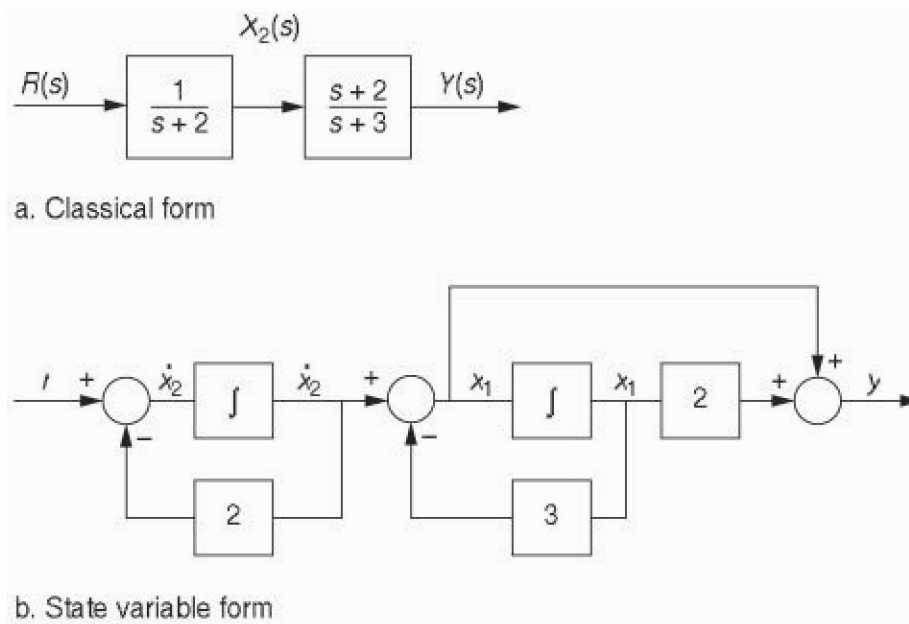

Table 100.3 shows that asymptotic (internal) stability always implies BIBO (external) stability but that BIBO stability implies asymptotic stability only if no RHP poles cancel from the transfer function. For example, Fig. 100.3 shows another system in both classical form and state variable form. From the classical form, notice that  $H(s) = 1/(s + 3)$  (no RHP poles cancel this time, just one LHP pole), so the impulse response of  $y(t)$  is  $e^{-3t}$  (whose integral is bounded), causing the system to be BIBO (externally) stable. Now, for an impulse input,  $X_2(s)$  is  $1/(s + 2)$  and  $x_2(t)$  is  $e^{-2t}$ , which is also bounded. From the state variable description,

**Table 100.3** Equivalence of Stability Types

Equivalence	Requirement
Asymptotic $\rightarrow$ BIBO	Always
BIBO $\rightarrow$ asymptotic	No cancellation of RHP poles in $H(s)$

**Figure 100.3** Condition 2 (BIBO stable and asymptotically stable).

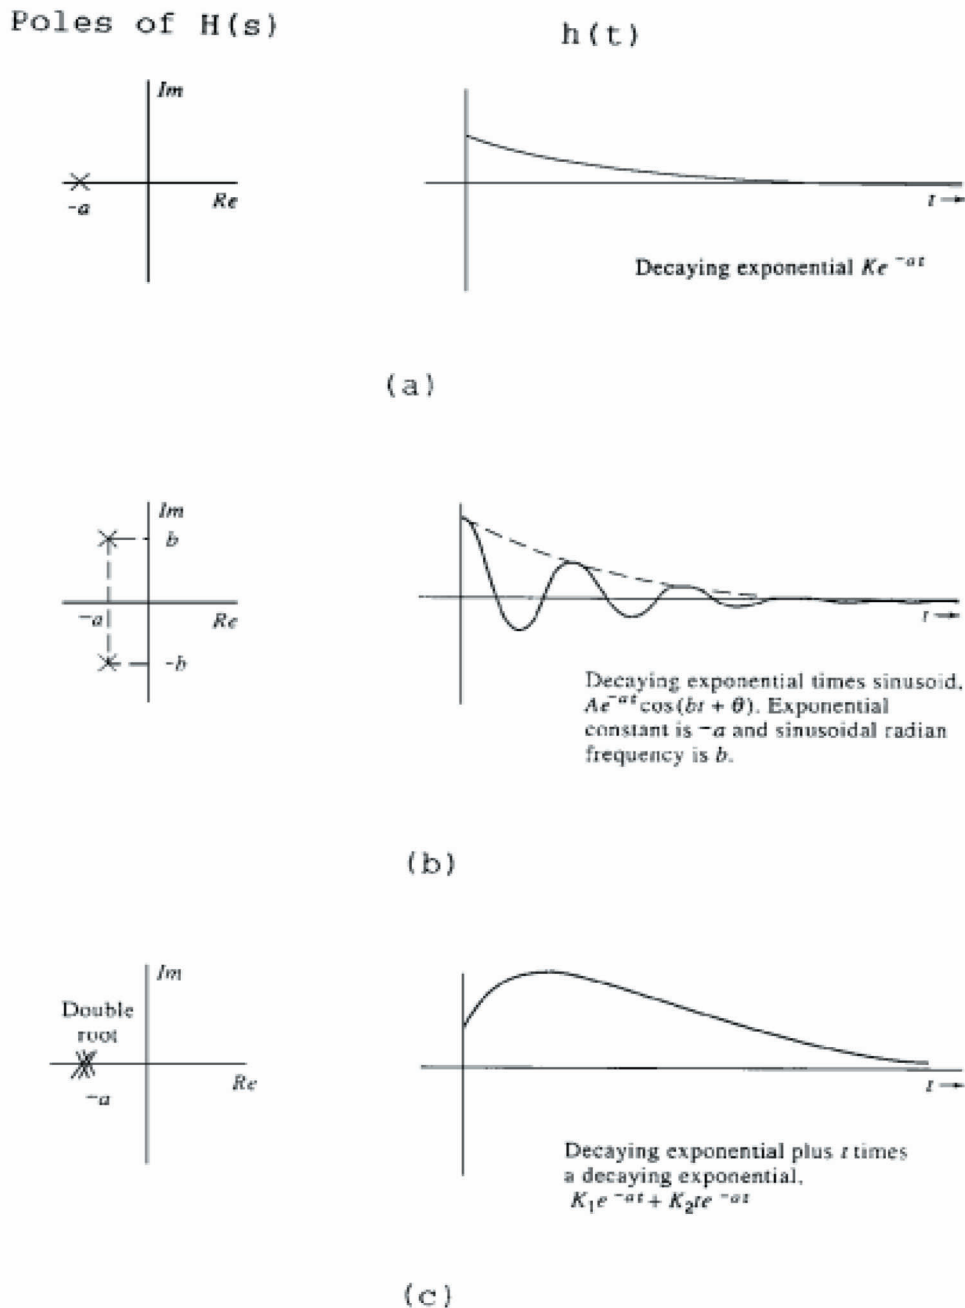

$$A = \begin{bmatrix} -3 & 1 \\ 0 & -2 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad C = [-1 \quad 1] \quad (100.5)$$

As before,  $H(s) = C[sI - A]^{-1}B = 1/(s + 3)$ , passing the test for BIBO stability; but now the eigenvalues of  $A$  are  $-3$  and  $-2$ , also passing the test for asymptotic stability.

Figure 100.4 shows a number of stable  $H(s)$  functions and the corresponding impulse responses  $h(t)$ . The step responses would differ by a constant.

**Figure 100.4** Impulse response of stable BIBO systems. (Adapted from Stefani, R. T., Savant, C. J., Shahian, B., and Hostetter, G. H. 1994. Design of Feedback Control Systems, 3rd ed, Saunders College, Boston, MA.)

**Figure 100.4**

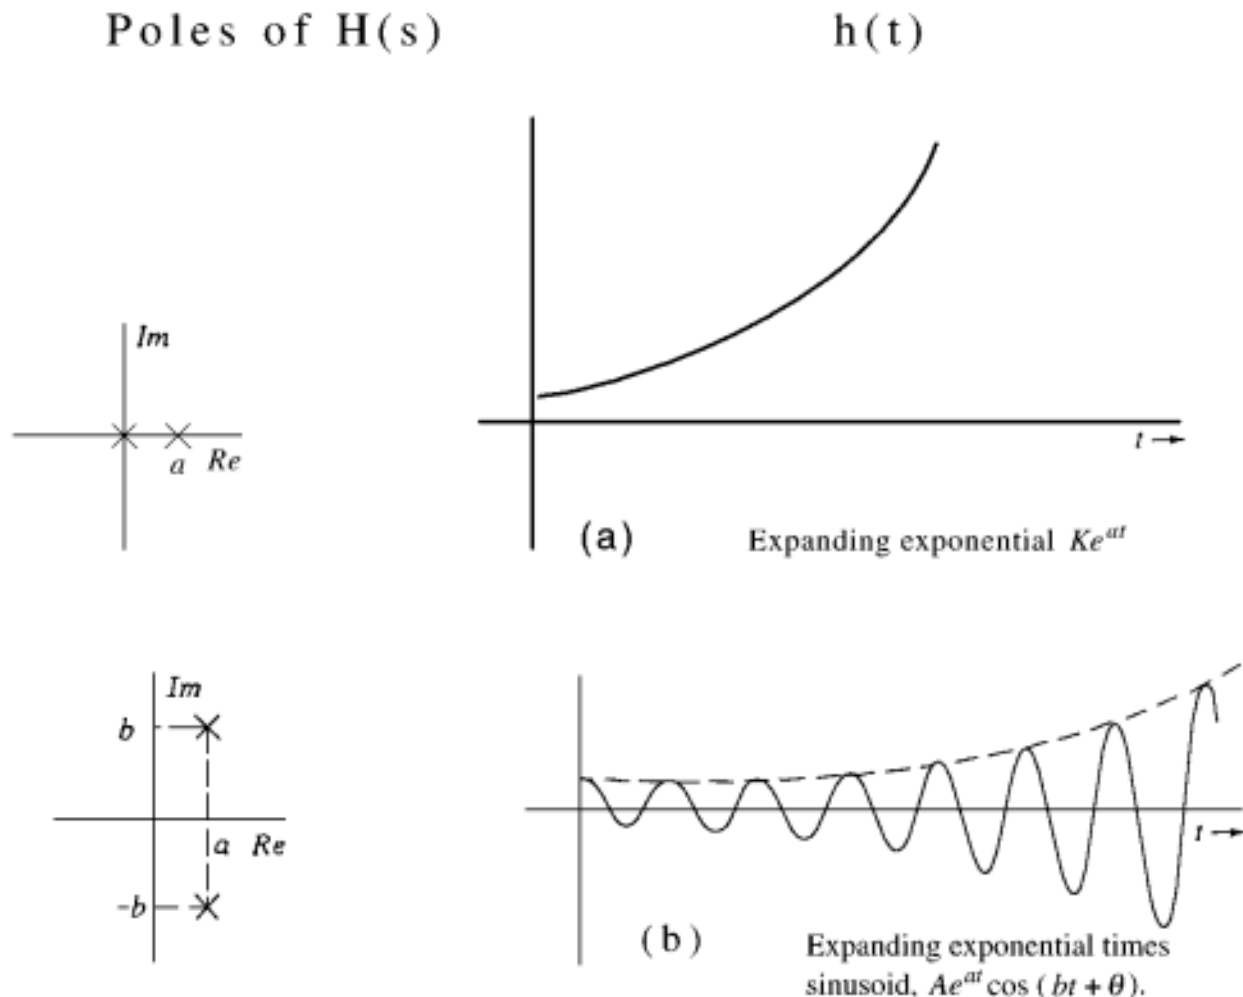

## 100.3 Unstable and Marginally Stable Responses

Systems that do not pass the tests for stability may be classified as **unstable** or **marginally stable**, as in Table 100.4. As before, BIBO and asymptotic stability may differ if certain poles of  $H(s)$  are canceled by zeros at the same place. An unstable system has a BIBO response that is unbounded for all bounded inputs and a zero-input response that diverges for at least one initial condition. A system is unstable for closed loop poles (BIBO) and eigenvalues (asymptotic) that are RHP and/or repeated along the imaginary axis (IA). Figure 100.5 shows a number of unstable (BIBO)  $H(s)$  functions and the corresponding impulse responses  $h(t)$ .

**Table 100.4** Unstable and Marginally Stable Definitions for Linear Systems

Type of Stability	Requirement	Necessary and Sufficient Condition
Unstable (asymptotic)	$C\phi(t)x_0 \rightarrow \infty$ as $t \rightarrow \infty$ for at least one $x_0$	At least one eigenvalue of $A$ in RHP and/or repeated IA
Unstable (BIBO)	If $ r(t)  \leq M_1 < \infty$ then $ y(t)  \rightarrow \infty$	At least one pole of $H(s)$ in RHP and/or repeated IA
Marginally stable (asymptotic)	$C\phi(t)x_0 \rightarrow C_0$ $0 <  C_0  < \infty$ as $t \rightarrow \infty$ for all $x_0$	One eigenvalue of $A$ at 0 and/or nonrepeated complex conjugate IA; the rest are LHP
Marginally stable (BIBO)	For some but not all $ r(t)  \leq M_1 < \infty$ then $ y(t)  \leq M_2 < \infty$	One pole of $H(s)$ at 0 and/or nonrepeated complex conjugate IA; the rest are LHP

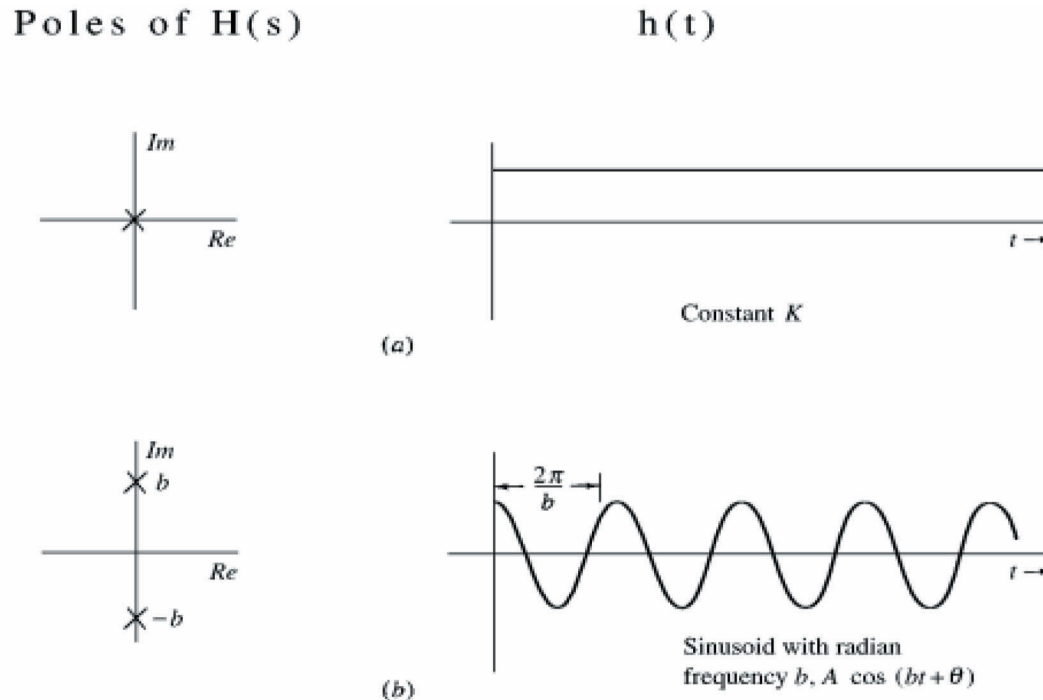

**Figure 100.5** Impulse response of unstable BIBO systems. (Adapted from Stefani, R. T., Savant, C. J., Shahian, B., and Hostetter, G. H. 1994. *Design of Feedback Control Systems*, 2nd ed. Saunders College, Boston, MA.)

A marginally stable system has a BIBO response that is bounded for some inputs but unbounded for others and a zero-input response that is bounded (going neither to zero nor infinity) for all initial conditions. A system is marginally stable for closed loop poles (BIBO) and eigenvalues (asymptotic) that are IA and nonrepeated. Figure 100.6 shows two marginally stable (BIBO)  $H(s)$  functions and the corresponding impulse responses  $h(t)$ . For Fig. 100.6(a),  $H(s) = 1/s$ , so the zero-state impulse response is a constant (which is bounded). However, if the input is a step, the zero-state response becomes  $1/s^2$  and the time response for this case is the same as the impulse response in Fig. 100.5(c), which is obviously unbounded. Similarly, the example of Fig. 100.6(b) has a bounded sinusoidal impulse response for IA poles of  $H(s)$ , but if the bounded  $r(t)$  is also sinusoidal and the IA poles of  $R(s)$  are at the same place as for that  $H(s)$ , then the multiple IA poles of  $Y(s)$  create a time response like that of Fig. 100.5(d), which is unbounded.

**Figure 100.6** Impulse response of marginally stable BIBO systems. (Adapted from Stefani, R. T., Savant, C. J., Shahian, B., and Hostetter, G. H. 1994. *Design of Feedback Control Systems*, 2nd ed. Saunders College, Boston, MA.)

## 100.4 Structural Integrity

A stable system always has a bounded BIBO response; however, that response can have very large values. For example, multiple (LHP) poles often create momentarily large outputs, even though the system is considered stable [see Fig. 100.4(c)]. These large outputs can exceed structural limits. For example, a famous bridge over the Tacoma Narrows collapsed in 1939 because of winds that created lifting forces whose  $R(s)$  had poles near the bridge's  $H(s)$  poles. When a building or bridge collapses during an earthquake, the cause may be similar. Reinforcing a building or bridge moves the poles of  $H(s)$  away from those of  $R(s)$ , thus maintaining the response within structural limits. An engineer must examine more than just stability when ensuring that a design results in a satisfactory time response.

### Defining Terms

**External stability:** Stability based on the bounded-input, bounded-output relationship, ignoring the performance of internal states. This stability is based on the poles of the transfer function, which may contain RHP pole cancellations.

**Impulse response:** The zero-state response of a system to a unit impulse input whose Laplace transform is 1.

**Internal stability:** Stability based on the performance of all the states of the system, and therefore on all the eigenvalues of the system. This type of stability will differ from external stability if

RHP poles cancel from the transfer function.

**Marginally stable:** For external stability, the response is bounded for some but not all bounded inputs.

**Unstable:** For external stability, the output is unbounded for all bounded inputs.

**Zero input:** Response component calculated by setting the input to zero.

**Zero state:** Response component calculated by setting the initial state to zero.

### **Rolf Johansson**

*Department of Automatic ControlLund Institute of Technology*

A digital system (or discrete-time system or sampled-data system) is a device such as a digital controller or a digital filter or, more generally, a system intended for digital computer implementation and usually with some periodic interaction with the environment and with a supporting methodology for analysis and design. Of particular importance for modeling and analysis are recurrent algorithms—for example, difference equations in input-output data—and the  $z$  transform is important for the solution of such problems.

The  **$z$  transform** is being used in the analysis of linear time-invariant systems and discrete-time signals—for example, for digital control or filtering—and may be compared to the Laplace transform as used in the analysis of continuous-time signals and systems, a useful property being that the convolution of two time-domain signals is equivalent to multiplication of their corresponding  $z$  transforms. The  $z$  transform is important as a means to characterize a linear time-invariant system in terms of its pole-zero locations, its transfer function and Bode diagram, and its response to a large variety of signals. In addition, it provides important relationships between temporal and spectral properties of signals. The  $z$  transform generally appears in the analysis of difference equations as used in many branches of engineering and applied mathematics.

## **101.1 The $z$ Transform**

---

The  $z$  transform of the sequence  $\{x_k\}_{-\infty}^{+\infty}$  is defined as the generating function

$$X(z) = \mathcal{L}\{x\} = \sum_{k=-\infty}^{\infty} x_k z^{-k} \quad (101.1)$$

where the variable  $z$  has the essential interpretation of a forward shift operator so that

$$\mathcal{L}\{x_{k+1}\} = z\mathcal{L}\{x_k\} = zX(z) \quad (101.2)$$

The  $z$  transform is an infinite power series in the complex variable  $z^{-1}$  where  $\{x_k\}$  constitutes a sequence of coefficients. As the  $z$  transform is an infinite power series, it exists only for those values of  $z$  for which this series converges and the *region of convergence* of  $X(z)$  is the set of  $z$  for which  $X(z)$  takes on a finite value. A sufficient condition for existence of the  $z$  transform is convergence of the power series

$$\sum_{k=-\infty}^{\infty} |x_k| \cdot |z^{-k}| < \infty \quad (101.3)$$

The region of convergence for a finite-duration signal is the entire  $z$  plane except  $z = 0$  and  $z = \infty$ . For a one-sided infinite-duration sequence  $\{x_k\}_{k=0}^{\infty}$ , a number  $r$  can usually be found so that the power series converges for  $|z| > r$ . Then, the *inverse  $z$  transform* can be derived as

$$x_k = \frac{1}{2\pi i} \oint X(z) z^{k-1} dz \quad (101.4)$$

where the contour of integration encloses all singularities of  $X(z)$ . In practice it is standard procedure to use tabulated results; some standard  $z$  transform pairs are to be found in [Table 101.1](#).

**Table 101.1** Properties of the  $z$ 

$z$ transform	$\mathcal{Z}(\{f_k\}) = F(z)$	
Convolution	$\mathcal{Z}(\{f_k * g_k\}) = \mathcal{Z}(\{f_k\}) \cdot \mathcal{Z}(\{g_k\})$	
	$\mathcal{Z}(\{f_k \cdot g_k\}) = \mathcal{Z}(\{f_k\}) * \mathcal{Z}(\{g_k\})$	
Forward shift	$\mathcal{Z}(\{f_{k+1}\}) = z\mathcal{Z}(\{f_k\}) = zF(z)$	
Backward shift	$\mathcal{Z}(\{f_{k-1}\}) = z^{-1}\mathcal{Z}(\{f_k\}) = z^{-1}F(z)$	
Linearity	$\mathcal{Z}(\{af_k + bg_k\}) = a\mathcal{Z}(\{f_k\}) + b\mathcal{Z}(\{g_k\})$	
Multiplication	$\mathcal{Z}(\{a^k f_k\}) = F(a^{-1}z)$	
Final value	$\lim_{k \rightarrow \infty} f_k = \lim_{z \rightarrow 1} (1 - z^{-1})F(z)$	
Initial value	$f_0 = \lim_{z \rightarrow \infty} F(z)$	

	Time Domain		$z$ Transform
Impulse	$\delta_k = \begin{cases} 1, & k = 0 \\ 0, & k \neq 0 \end{cases}$	$\Leftrightarrow$	$\mathcal{Z}\{\delta_k\} = 1, \quad z \in \mathbb{C}$
Step function	$\sigma_k = \begin{cases} 0, & k < 0 \\ 1, & k \geq 0 \end{cases}$	$\Leftrightarrow$	$\mathcal{Z}\{\sigma_k\} = \frac{z}{z-1}, \quad  z  > 1$
Ramp function	$x_k = k \cdot \sigma_k$	$\Leftrightarrow$	$X(z) = \frac{z}{(z-1)^2}, \quad  z  > 1$
Exponential	$x_k = a^k \cdot \sigma_k$	$\Leftrightarrow$	$X(z) = \frac{z}{z-a}, \quad  z  >  a $
Sinusoid	$x_k = \sin \omega k \cdot \sigma_k$	$\Leftrightarrow$	$X(z) = \frac{z \sin \omega}{z^2 - 2z \cos \omega + 1}, \quad  z  > 1$

## 101.2 Digital Systems and Discretized Data

Periodic sampling of signals and subsequent computation or storing of the results requires the computer to schedule sampling and to handle the resulting sequences of numbers. A measured variable  $x(t)$  may be available only as periodic observations of  $x(t)$  as sampled with a time interval

$T$  (the sampling period). The sample sequence can be represented as

$$\{x_k\}_{-\infty}^{\infty}; \quad x_k = x(kT) \quad \text{for} \quad k = \dots, -1, 0, 1, 2, \dots \quad (101.5)$$

and it is important to ascertain that the sample sequence adequately represents the original variable  $x(t)$ ; see [Fig. 101.1](#). For ideal sampling it is required that the duration of each sampling be very short and the sampled function may be represented by a sequence of infinitely short impulses  $\delta(t)$  (the Dirac impulse). Let the sampled function of time be expressed thus:

$$x_{\Delta}(t) = x(t) \cdot T \sum_{k=-\infty}^{\infty} \delta(t - kT) = x(t) \cdot \sqcup_T(t) \quad (101.6)$$

where

$$\sqcup\sqcup_T(t) \triangleq T \sum_{k=-\infty}^{\infty} \delta(t - kT) \quad (101.7)$$

and where the sampling period  $T$  is multiplied to ensure that the averages over a sampling period of the original variable  $x$  and the sampled signal  $x_{\Delta}$ , respectively, are of the same magnitude. A direct application of the discretized variable  $x_{\Delta}(t)$  in Eq. (101.6) verifies that the spectrum of  $x_{\Delta}$  is related to the  $z$  transform  $X(z)$  as

$$X_{\Delta}(i\omega) = \mathcal{F}\{x(t) \cdot \sqcup\sqcup_T(t)\} = T \sum_{k=-\infty}^{\infty} x_k \exp(-i\omega kT) = TX(e^{i\omega T}) \quad (101.8)$$

Obviously, the original variable  $x(t)$  and the sampled data are not identical, and thus it is necessary to consider the distortive effects of discretization. Consider the spectrum of the sampled signal  $x_{\Delta}(t)$  obtained as the Fourier transform

$$X_{\Delta}(i\omega) = \mathcal{F}\{x_{\Delta}(t)\} = \mathcal{F}\{x(t)\} * \mathcal{F}\{\sqcup\sqcup_T(t)\} \quad (101.9)$$

where

$$\mathcal{F}\{\sqcup\sqcup_T(t)\} = \sum_{k=-\infty}^{\infty} \delta\left(\omega - \frac{2\pi}{T}k\right) = \frac{T}{2\pi} \sqcup\sqcup_{2\pi/T}(\omega) \quad (101.10)$$

so that

$$X_{\Delta}(i\omega) = \mathcal{F}\{x(t)\} * \mathcal{F}\{\sqcup\sqcup_T(t)\} = \sum_{k=-\infty}^{\infty} X\left[i\left(\omega - \frac{2\pi}{T}k\right)\right] \quad (101.11)$$

Thus, the Fourier transform  $X_{\Delta}$  of the sampled variable has a periodic extension of the original spectrum  $X(i\omega)$  along the frequency axis with a period equal to the sampling frequency  $\omega_s = 2\pi/T$ . There is an important result based on this observation known as *the Shannon sampling theorem*, which states that the continuous-time variable  $x(t)$  may be reconstructed from the samples  $\{x_k\}_{-\infty}^{+\infty}$  if and only if the sampling frequency is at least twice that of the highest frequency for which  $X(i\omega)$  is nonzero. The original variable  $x(t)$  may thus be recovered as

$$x(t) = \sum_{k=-\infty}^{\infty} x_k \frac{\sin \frac{\pi}{T}(t - kT)}{\frac{\pi}{T}(t - kT)} \quad (101.12)$$

The formula given in Eq. (101.12) is called *Shannon interpolation*, which is often quoted though it is valid only for infinitely long data sequences and though it would require a noncausal filter to reconstruct the continuous-time signal  $x(t)$  in real-time operation. The frequency  $\omega_n = \omega_s/2 = \pi/T$  is called the *Nyquist frequency* and indicates the upper limit of distortion-free sampling. A nonzero spectrum beyond this limit leads to interference between the sampling frequency and the sampled signal (*aliasing*); see Fig. 101.2.

**Figure 101.1** A continuous-time signal  $x(t)$  and a sampling device that produces a sample sequence  $\{x_k\}$ .

**Figure 101.2** Illustration of aliasing appearing during sampling of a sinusoid  $x(t) = \sin 2\pi \cdot 0.9t$  at the insufficient sampling frequency 1 Hz (sampling period  $T = 1$ ) (*upper graph*). The sampled signal exhibits aliasing with its major component similar to a signal  $x(t) = \sin 2\pi \cdot 0.1t$  sampled with the same rate (*lower graph*).

## The Discrete Fourier Transform

Consider a finite length sequence  $\{x_k\}_{k=0}^{N-1}$  that is zero outside the interval  $0 \leq k \leq N-1$ .

Evaluation of the  $z$  transform  $X(z)$  at  $N$  equally spaced points on the unit circle

$z = \exp(i\omega_k T) = \exp[i(2\pi/NT)kT]$  for  $k = 0, 1, \dots, N-1$  defines the *discrete Fourier transform* (DFT) of a signal  $x$  with a sampling period  $h$  and  $N$  measurements

$$X_k = \text{DFT} \{x(kT)\} = \sum_{l=0}^{N-1} x_l \exp(-i\omega_k lT) = X(e^{i\omega_k T}) \quad (101.13)$$

Notice that the discrete Fourier transform  $\{X_k\}_{k=0}^{N-1}$  is only defined at the discrete frequency points

$$\omega_k = \frac{2\pi}{NT}k, \quad \text{for } k = 0, 1, \dots, N-1 \quad (101.14)$$

In fact, the discrete Fourier transform adapts the Fourier transform and the  $z$  transform to the practical requirements of finite measurements. Similar properties hold for the discrete Laplace transform with  $z = \exp(sT)$ , where  $s$  is the Laplace transform variable.

### 101.3 The Transfer Function

Consider the following discrete-time linear system with input sequence  $\{u_k\}$  (stimulus) and output sequence  $\{y_k\}$  (response). The dependency of the output of a linear system is characterized by the convolution-type equation and its  $z$  transform,

$$y_k = \sum_{m=0}^{\infty} h_m u_{k-m} + v_k = \sum_{m=-\infty}^k h_{k-m} u_m + v_k, \quad k = \dots, -1, 0, 1, 2, \dots$$

$$Y(z) = H(z)U(z) + V(z) \quad (101.15)$$

where the sequence  $\{v_k\}$  represents some external input of errors and disturbances and with  $Y(z) = \mathcal{L}\{y\}$ ,  $U(z) = \mathcal{L}\{u\}$ ,  $V(z) = \mathcal{L}\{v\}$  as output and inputs. The *weighting function*  $h(kT) = \{h_k\}_{k=0}^{\infty}$ , which is zero for negative  $k$  and for reasons of causality is sometimes called *pulse response* of the digital system (compare *impulse response* of continuous-time systems). The pulse response and its  $z$  transform, the *pulse transfer function*,

$$H(z) = \mathcal{L}\{h(kT)\} = \sum_{k=0}^{\infty} h_k z^{-k} \quad (101.16)$$

determine the system's response to an input  $U(z)$ ; see Fig. 101.3. The pulse transfer function  $H(z)$  is obtained as the ratio

$$H(z) = \frac{X(z)}{U(z)} \quad (101.17)$$

and provides the frequency domain input-output relation of the system. In particular, the Bode diagram is evaluated as  $|H(z)|$  and  $\arg H(z)$  for  $z = \exp(i\omega_k T)$  and for  $|\omega_k| < \omega_n = \pi/T$  — that is, when  $H(z)$  is evaluated for frequency points up to the Nyquist frequency  $\omega_n$  along the unit circle.

**Figure 101.3** Block diagram with an assumed transfer function relationship  $H(z)$  between input  $U(z)$ , disturbance  $V(z)$ , intermediate  $X(z)$ , and output  $Y(z)$ .

## State-Space Systems

Alternatives to the input-output representations by means of transfer functions are the state-space representations. Consider the following finite dimensional discrete state-space equation with a state vector  $x_k \in \mathcal{R}^n$ , input  $u_k \in \mathcal{R}^p$ , and observations  $y_n \in \mathcal{R}^m$ .

$$\begin{cases} x_{k+1} = \Phi x_k + \Gamma u_k \\ y_k = C x_k + D u_k \end{cases}, \quad k = 0, 1, \dots \quad (101.18)$$

with the pulse transfer function

$$H(z) = C(zI - \Phi)^{-1}\Gamma + D \quad (101.19)$$

and the output variable

$$Y(z) = C \sum_{k=0}^{\infty} \Phi^k z^{-k} x_0 + H(z)U(z) \quad (101.20)$$

where possible effects of initial conditions  $x_0$  appear as the first term. Notice that the initial conditions  $x_0$  can be viewed as the net effects of the input in the time interval  $(-\infty, 0)$ .

## 101.4 Digital Systems Described by Difference Equations(ARMAX Models)

---

An important class of nonstationary stochastic processes is one in which some deterministic response to an external input and a stationary stochastic process are superimposed. This is relevant, for instance, when the external input cannot be effectively described by some probabilistic distribution. A discrete-time model can be formulated in the form of a difference equation with an external input  $\{u_k\}$  that is usually considered to be known:

$$\begin{aligned} y_k = & -a_1 y_{k-1} - \cdots - a_n y_{k-n} \\ & + b_1 u_{k-1} + \cdots + b_n u_{k-n} \\ & + w_k + c_1 w_{k-1} + \cdots + c_n w_{k-n} \end{aligned} \quad (101.21)$$

Application of the  $z$  transform permits formulation of Eq. (101.21) as

$$A(z^{-1})Y(z) = B(z^{-1})U(z) + C(z^{-1})W(z) \quad (101.22)$$

where

$$\begin{aligned} A(z^{-1}) &= 1 + a_1 z^{-1} + \cdots + a_n z^{-n} \\ B(z^{-1}) &= 1 + b_1 z^{-1} + \cdots + b_n z^{-n} \\ C(z^{-1}) &= 1 + c_1 z^{-1} + \cdots + c_n z^{-n} \end{aligned} \quad (101.23)$$

Stochastic models including the  $A$  polynomial, according to Eq. (101.22) and Eq. (101.23), are known as **autoregressive models (AR)** and models including the  $C$  polynomial are known as **moving-average models (MA)**, whereas the  $B$  polynomial determines the effects of the external input ( $X$ ). Notice that the term *moving average* is here somewhat misleading, as there is no restriction that the coefficients should add to 1 or that the coefficients are nonnegative. An alternative description is *finite impulse response* or *all-zero filter*.

Thus, the full model of Eq. (101.22) is an **autoregressive moving average model** with external input (ARMAX) and its pulse transfer function  $H(z) = B(z^{-1})/A(z^{-1})$  is stable if and only if the *poles*<sup>34</sup> that is, the complex numbers  $z_1, \dots, z_n$  solving the equation  $A(z^{-1}) = 0$  — are strictly inside the unit circle, that is,  $|z_i| < 1$ . The *zeros* of the system—that is, the complex numbers  $z_1, \dots, z_n$  solving the equation  $B(z^{-1}) = 0$  — may take on any value without any instability arising, although it is preferable to obtain zeros located strictly inside the unit circle, that is,  $|z_i| < 1$  (*minimum-phase zeros*). By linearity  $\{y_k\}$  can be separated into one purely deterministic process  $\{x_k\}$  and one purely stochastic process  $\{v_k\}$ :

$$\begin{cases} A(z^{-1})X(z) = B(z^{-1})U(z) \\ A(z^{-1})V(z) = C(z^{-1})W(z) \end{cases} \quad \text{and} \quad \begin{cases} y_k = x_k + v_k \\ Y(z) = X(z) + V(z) \end{cases} \quad (101.24)$$

The type of decomposition [Eq. (101.24)] that separates the deterministic and stochastic processes is known as the *Wold decomposition*.

## 101.5 Prediction and Reconstruction

---

Consider the problem of predicting the output  $d$  steps ahead when the output  $\{y_k\}$  is generated by the ARMA model,

$$A(z^{-1})Y(z) = C(z^{-1})W(z) \quad (101.25)$$

which is driven by a zero-mean white noise  $\{w_k\}$  with covariance  $\mathcal{E}\{w_i w_j\} = \sigma_w^2 \delta_{ij}$ . In other words, assuming that observations  $\{y_k\}$  are available up to the present time, how should the output  $d$  steps ahead be predicted optimally? Assume that the polynomials  $A(z^{-1})$  and  $C(z^{-1})$  are mutually prime with no zeros for  $|z| \geq 1$ . Let the  $C$  polynomial be expanded according to the *Diophantine equation*,

$$C(z^{-1}) = A(z^{-1})F(z^{-1}) + z^{-d}G(z^{-1}) \quad (101.26)$$

which is solved by the two polynomials

$$\begin{aligned} F(z^{-1}) &= 1 + f_1 z^{-1} + \cdots + f_{n_F} z^{-n_F}, & n_F &= d - 1 \\ G(z^{-1}) &= g_0 + g_1 z^{-1} + \cdots + g_{n_G} z^{-n_G}, & n_G &= \max(n_A - 1, n_C - d) \end{aligned} \quad (101.27)$$

Interpretation of  $z^{-1}$  as a *backward shift operator* and application of Eqs. (101.25) and (101.26) permit the formulation

$$y_{k+d} = F(z^{-1})w_{k+d} + \frac{G(z^{-1})}{C(z^{-1})}y_k \quad (101.28)$$

Let us, by  $\hat{y}_{k+d|k}$ , denote linear  $d$ -step predictors of  $y_{k+d}$  based upon the measured information available at time  $k$ . As the zero-mean term  $F(z^{-1})w_{k+d}$  of Eq. (101.28) is unpredictable at time  $k$ , it is natural to suggest the following  $d$ -step predictor

$$\hat{y}_{k+d|k} = \frac{G(z^{-1})}{C(z^{-1})}y_k \quad (101.29)$$

The prediction error satisfies

$$\begin{aligned} \varepsilon_{k+d} &= (\hat{y}_{k+d|k} - y_{k+d}) \\ &= \frac{G(z^{-1})}{C(z^{-1})}y_k - \frac{A(z^{-1})F(z^{-1}) + z^{-d}G(z^{-1})}{C(z^{-1})}y_{k+d} \\ &= -F(z^{-1})w_{k+d} \end{aligned} \quad (101.30)$$

Let  $\mathcal{E}\{\cdot \mid \mathcal{F}_k\}$  denote the *conditional mathematical expectation* relative to the measured information available at time  $k$ . The conditional mathematical expectation and the covariance of the  $d$ -step prediction relative to available information at time  $k$  is

$$\begin{aligned}\mathcal{E}\{\hat{y}_{k+d|k} - y_{k+d} \mid \mathcal{F}_k\} &= \mathcal{E}\{-F(z^{-1})w_{k+d} \mid \mathcal{F}_k\} = 0 \\ \mathcal{E}\{(\hat{y}_{k+d|k} - y_{k+d})^2 \mid \mathcal{F}_k\} &= \mathcal{E}\{[F(z^{-1})w_{k+d}]^2 \mid \mathcal{F}_k\} \\ &= \mathcal{E}\{(w_{k+d} + f_1 w_{k+d-1} + \cdots + f_{d-1} w_{k+1})^2 \mid \mathcal{F}_k\} \\ &= (1 + f_1^2 + \cdots + f_{n_F}^2) \sigma_w^2 = 0\end{aligned}\tag{101.31}$$

It follows that the predictor of Eq. (101.29) is unbiased and that the prediction error only depends on future, unpredictable noise components. It is straightforward to show that the predictor of Eq. (101.29) achieves the lower bound of Eq. (101.31) and that the predictor of Eq. (101.29) is optimal in the sense that the prediction error variance is minimized.

**Example 101.13** **An Optimal Predictor for a First-Order Model.** Consider for the first-order ARMA model

$$y_{k+1} = -a_1 y_k + w_{k+1} + c_1 w_k \tag{101.32}$$

The variance of a one-step-ahead predictor  $\hat{y}_{k+1|k}$  is

$$\begin{aligned}\mathcal{E}\{(\hat{y}_{k+1|k} - y_{k+1})^2 \mid \mathcal{F}_k\} &= \mathcal{E}\{(\hat{y}_{k+1|k} + a_1 y_k - c_1 w_k)^2 \mid \mathcal{F}_k\} \\ &\quad + \mathcal{E}\{w_{k+1}^2 \mid \mathcal{F}_k\} \\ &= \mathcal{E}\{(\hat{y}_{k+1|k} + a_1 y_k - c_1 w_k)^2 \mid \mathcal{F}_k\} + \sigma_w^2 \geq \sigma_w^2\end{aligned}\tag{101.33}$$

The optimal predictor satisfying the lower bound in Eq. (101.33) is obtained from Eq. (101.33) as

$$\hat{y}_{k+1|k}^o = -a_1 y_k + c_1 w_k \tag{101.34}$$

which, unfortunately, is not realizable as it stands because  $w_k$  is not available to measurement. Therefore, the noise sequence  $\{w_k\}$  has to be substituted by some function of the observed variable  $\{y_k\}$ . A linear predictor chosen according to Eq. (101.29) is

$$\hat{y}_{k+1|k} = \frac{G(z^{-1})}{C(z^{-1})} y_k = \frac{c_1 - a_1}{1 + c_1 z^{-1}} y_k \tag{101.35}$$

## 101.6 The Kalman Filter

---

Consider the linear state-space model

$$\begin{aligned} x_{k+1} &= \Phi x_k + v_k, & x_k &\in \mathcal{R}^n \\ y_k &= C x_k + w_k, & y_k &\in \mathcal{R}^m \end{aligned} \quad (101.36)$$

where  $\{v_k\}$  and  $\{w_k\}$  are assumed to be independent zero-mean white-noise processes with covariances  $\Sigma_v$  and  $\Sigma_w$ , respectively. It is assumed that  $\{y_k\}$  but not  $\{x_k\}$  is available to measurement and that it is desirable to predict  $\{x_k\}$  from measurements of  $\{y_k\}$ .

Introduce the state predictor,

$$\begin{aligned} \hat{x}_{k+1|k} &= \Phi \hat{x}_{k|k-1} - K_k (\hat{y}_k - y_k), & \hat{x}_{k|k-1} &\in \mathcal{R}^n \\ \hat{y}_k &= C \hat{x}_{k|k-1}, & y_k &\in \mathcal{R}^m \end{aligned} \quad (101.37)$$

The predictor of Eq. (101.37) has the same dynamics matrix  $\Phi$  as the state-space model of Eq. (101.36) and, in addition, there is a correction term  $K_k(\hat{y}_k - y_k)$  with a factor  $K_k$  to be chosen. The prediction error is

$$\tilde{x}_{k+1|k} = \hat{x}_{k+1|k} - x_{k+1} \quad (101.38)$$

The prediction-error dynamics is

$$\tilde{x}_{k+1} = (\Phi - K_k C) \tilde{x}_k + v_k - K_k w_k \quad (101.39)$$

The mean prediction error is governed by the recursive equation

$$\mathcal{E}\{\tilde{x}_{k+1}\} = (\Phi - K_k C) \mathcal{E}\{\tilde{x}_k\} \quad (101.40)$$

and the mean square error of the prediction error is governed by

$$\begin{aligned} \mathcal{E}\{\tilde{x}_{k+1} \tilde{x}_{k+1}^T\} &= \mathcal{E}\{[(\Phi - K_k C) \tilde{x}_k + v_k - K_k w_k][(\Phi - K_k C) \tilde{x}_k + v_k - K_k w_k]^T\} \\ &= (\Phi - K_k C) \mathcal{E}\{\tilde{x}_k \tilde{x}_k^T\} (\Phi - K_k C)^T + \Sigma_v + K_k \Sigma_w K_k \end{aligned} \quad (101.41)$$

If we denote

$$\begin{aligned} P_k &= \mathcal{E}\{\tilde{x}_k \tilde{x}_k^T\} \\ Q_k &= \Sigma_v + C P_k C^T \end{aligned} \quad (101.42)$$

then Eq. (101.41) is simplified to

$$P_{k+1} = \Phi P_k \Phi^T - K_k C P_k \Phi - \Phi^T P_k C^T K_k^T + \Sigma_v + K_k Q_k K_k^T \quad (101.43)$$

By completing squares of terms containing  $K_k$  we find

$$\begin{aligned} P_{k+1} &= \Phi P_k \Phi^T + \Sigma_v - \Phi P_k C^T Q_k^{-1} C P_k \Phi^T \\ &\quad + (K_k - \Phi P_k C^T Q_k^{-1}) Q_k (K_k - \Phi P_k C^T Q_k^{-1})^T \end{aligned} \quad (101.44)$$

where only the last term depends on  $K_k$ . Minimization of  $P_{k+1}$  can be done by choosing  $K_k$  such that the positive semidefinite  $K_k$ -dependent term in Eq. (101.44) disappears. Thus  $P_{k+1}$  achieves its lower bound for

$$K_k = \Phi P_k C^T (\Sigma_w + C P_k C^T)^{-1} \quad (101.45)$$

and the *Kalman filter* (or *Kalman-Bucy filter*) takes the form

$$\begin{aligned} \hat{x}_{k+1|k} &= \Phi \hat{x}_{k|k-1} - K_k (\hat{y}_k - y_k) \\ \hat{y}_k &= C \hat{x}_{k|k-1} \\ K_k &= \Phi P_k C^T (\Sigma_w + C P_k C^T)^{-1} \\ P_{k+1} &= \Phi P_k \Phi^T + \Sigma_v - \Phi P_k C^T (\Sigma_w + C P_k C^T)^{-1} C P_k \Phi^T \end{aligned} \quad (101.46)$$

which is the optimal predictor in the sense that the mean square error [Eq. (101.41)] is minimized in each step.

**Example 101.234 Kalman Filter for a First-Order System.** Consider the state-space model

$$\begin{aligned} x_{k+1} &= 0.95x_k + v_k \\ y_k &= x_k + w_k \end{aligned} \quad (101.47)$$

where  $\{v_k\}$  and  $\{w_k\}$  are zero-mean white-noise processes with covariances  $\mathcal{E}\{v_k^2\} = 1$  and  $\mathcal{E}\{w_k^2\} = 1$ , respectively.

The Kalman filter takes on the form

$$\begin{aligned} \hat{x}_{k+1|k} &= 0.95\hat{x}_{k|k-1} - K_k (\hat{x}_{k|k-1} - y_k) \\ K_k &= \frac{0.95P_k}{1 + P_k} \\ P_{k+1} &= 0.95^2 P_k + 1 - \frac{0.95^2 P_k^2}{1 + P_k} \end{aligned} \quad (101.48)$$

The result of one such realization is shown in Fig. 101.4.

**Figure 101.4** Kalman filter applied to one-step-ahead prediction of  $x_{k+1}$  in Eq. (101.47). The observed variable  $\{y_k\}$ , the state  $\{x_k\}$ , and the predicted state  $\{\hat{x}_k\}$ , the estimated variance  $\{P_k\}$  and  $\{K_k\}$ , and the prediction error  $\{\tilde{x}_k\}$  are shown in a 100-step realization of the stochastic process. (Source: Johansson, R. 1993. *System Modeling and Identification*. Prentice Hall, Englewood Cliffs, NJ.)

## Defining Terms

**Autoregressive model (AR):** An autoregressive time series of order  $n$  is defined via  $y_k = -\sum_{m=1}^n a_m y_{k-m} + w_k$ . The sequence  $\{w_k\}$  is usually assumed to consist of zero-mean identically distributed stochastic variables  $w_k$ .

**Autoregressive moving average model (ARMA):** An autoregressive moving average time series of order  $n$  is defined via  $y_k = -\sum_{m=1}^n a_m y_{k-m} + \sum_{m=0}^n c_m w_{k-m}$ . The sequence  $\{w_k\}$  is usually assumed to consist of zero-mean identically distributed stochastic variables  $w_k$ .

**Discrete Laplace transform:** The discrete Laplace transform is counterpart to the Laplace transform with application to discrete signals and systems. The discrete Laplace transform is obtained from the  $z$  transform by means of the substitution  $z = \exp(sT)$ , where  $T$  is the

sampling period.

**Moving average process (MA):** A moving average time series of order  $n$  is defined via  $y_k = \sum_{m=0}^n c_m w_{k-m}$ . The sequence  $\{w_k\}$  is usually assumed to consist of zero-mean identically distributed stochastic variables  $w_k$ .

**Rational model:** AR, MA, ARMA, and ARMAX are commonly referred to as rational models.

**Time series:** A sequence of random variable  $\{y_k\}$ , where  $k$  belongs to the set of positive and negative integers.

**$z$  transform:** A generating function applied to sequences of data and evaluated as a function of the complex variable  $z$  with interpretation of frequency.

## Further Information

Early theoretical efforts developed in connection with servomechanisms and radar applications [Hurewicz, 1947]. Tsytkin [1950] introduced the discrete Laplace transform and the formal  $z$  transform definition was introduced by Ragazzini and Zadeh [1952] with further developments by Jury [1956]. Much of prediction theory was originally developed by Kolmogorov [1939] and Wiener [1949] whereas state-space methods were forwarded by Kalman and Bertram [1958]. Pioneering textbooks on time-series analysis and spectrum analysis are provided by Box and Jenkins [1970] and Jenkins and Watts [1968].

Detailed accounts of time-series analysis and the  $z$  transform and their application to signal processing are to be found in

CIRCUITS ARE FUNDAMENTAL to electrical engineering. The circuit problem deals with predicting the behavior of a system of interconnected physical elements such as resistors, capacitors, inductors, and independent and dependent sources. Kirchhoff made the first comprehensive investigation of the circuit problem in 1847 and provided a solution to a resistive circuit. Maxwell pointed out in 1892 that Kirchhoff's formulation omitted the concept of potential, and he devised two very effective methods for solving the circuit problem, now termed Maxwell's *mesh* and *nodal* methods. They are still widely used today.

The most important periodic signals, as far as electrical engineers are concerned, are the familiar sine and cosine functions known as the *sinusoids*. They are not only found throughout nature, as in the motion of a pendulum and in the vibrations of strings, but they also can approximate a generator voltage or current. In fact, any periodic signal can be represented as a series of sinusoids, the individual frequencies of which are multiples of the frequency known as the *fundamental frequency*.

Circuits are designed to perform certain functions. The most common functions are to separate, pass, or suppress a group of signals from a mixture of signals. A device with such a function is

referred to as a *filter*. On a larger scale, televisions and radios are typical examples of electrical filters. When a television is tuned to a particular channel, it will only pass those signals transmitted by that channel and will block all other signals. On a smaller scale, filters are basic electronic components used in the design of communication systems such as telephone, television, radio, radar, and computer. In fact, electrical filters permeate modern technology so much that it is difficult to find an electronic system that does not employ a filter in one form or another.

Electrical safety is a very broad and diverse topic. Everyone has experienced some form of electrical shock. Whether that shock was from a harmless electrostatic discharge or from accidental contact with an energized electrical circuit, the response was probably the same. For safe and sustained operation of an electrical device, grounding and shielding are two very important factors that must be considered in its design. The primary purposes of grounding and shielding circuits are to prevent shock hazard, to protect circuits, and to reduce electromagnetic interference.

A traditional problem in electrical engineering is to deliver electrical energy to consumers in a manner that is economic, reliable, and safe. In addition, it must conform to regulatory standards. An important use of electricity is to drive electric motors in the AC steady state. To reduce fluctuation, power is delivered to the load using what is known as a *three-phase* system. A single fault does not result in an interruption of power to the customers. A residential customer is supplied from a two-wire, one-phase, overhead lateral, whereas the commercial and industrial customers are supplied from the three-phase, four-wire overhead primary feeder.

In this section, we introduce the basics of these topics. No engineering graduate is equipped to understand the literature or advance practice without a knowledge of these fundamentals.

[102.1 Resistors](#)[102.2 Capacitors](#)[102.3 Inductors](#)**Henry Domingos***Clarkson University*

Passive components such as resistors, capacitors, and inductors can be an integral part of a more complex unit such as an operational amplifier, digital integrated circuit, or microwave circuit. However, this chapter deals with discrete components purchased as individual parts. Their importance lies in the fact that virtually every piece of electronic equipment incorporates a multitude of discrete passive components, and sale of these components parallels the fortunes of the electronics industry as a whole.

Although passive components have been in use for hundreds of years, one should not assume they represent a static industry: There is a continuing evolution in the design and fabrication of these parts to make them smaller and cheaper with better performance and better reliability. In fact, the useful life of modern components exceeds by far that of the electronic equipment they are used in. Failure is more often the result of misapplication. The continuous improvement in quality, price, performance, and general usefulness contributes to greater convenience and functionality for consumers at a lower and lower price.

## 102.1 Resistors

---

Resistance is a property of a device that relates the current through the device with the voltage or electric potential across it. It is a dissipative property in that energy is converted from electrical energy to heat. The resistance of a device is directly related to the **resistivity** of the material of which it is composed. The resistivity is a relative property that varies from that of good conductors such as aluminum or copper (resistivity  $\approx 10^{-6}$  ohm-cm) to semiconductors such as silicon ( $\approx 10^{-3} - 10^{+3}$  ohm-cm) to that of good insulators such as alumina ( $\approx 10^{14}$  ohm-cm). The resistance of a device is determined by its resistivity and its geometry. [Figure 102.1](#) and Eq. (102.1) show the relationship for objects of uniform resistivity and cross-sectional area.

$$R = \rho \frac{L}{A} \quad (102.1)$$

In Eq. (102.1)  $R$  is the resistance in ohms,  $\rho$  is the resistivity in ohm-cm,  $L$  is the length in cm, and  $A$  is the cross-sectional area in  $\text{cm}^2$ . For example, #12 AWG copper wire has a diameter of 0.0808 in. and a resistivity of  $1.724 \times 10^{-6}$  ohm-cm. Using Eq. (102.1) and converting units as appropriate, the resistance of 1000 feet of wire is 1.588 ohms.

**Figure 102.1** Resistance of a conductor with uniform resistivity and cross section is given by Eq. (102.1).

When resistive films are deposited on substrates or impurities are implanted in layers in silicon devices, the resistivity is not uniform and/or the thickness of the layer may not be known accurately. It is convenient then to define a **sheet resistance** that takes into account the average resistivity and the thickness so that the resistance is given by

$$R = R_s \frac{L}{W} \quad (102.2)$$

where  $R_s$  is the sheet resistance in ohms per square (the "square" is dimensionless),  $L$  is the length of the film, and  $W$  its width. Suppose, for example, a resistor ink is silk-screened onto a ceramic substrate and fired so that its sheet resistance is 100 ohms per square. If the width of the resistor is 10 mils (a mil is one thousandth of an inch), the length required to make a 1500-ohm resistor is, from Eq. (102.2),  $L = 150$  mils.

Using the concepts of resistivity and sheet resistance, a discrete resistor can be fabricated in a variety of ways. The common types are carbon composition resistors, wire-wound resistors, and film resistors. Carbon composition resistors were at one time the most popular type. They are low

priced, high in reliability, and available in a wide range of resistance values. The drawbacks are poor long-term stability and tolerance of only 5% or larger. The resistor is fabricated from a silica-loaded resin with resistivity controlled by the addition of carbon particles. Axial leads are inserted and the outer shell, of the same material as the core, minus the carbon granules, insulates the assembly.

Wire-wound resistors are power wire wounds or precision wire wounds. In either case the resistance wire is either a nickel-chromium alloy with a resistivity of  $1.33 \cdot 10^{-4}$  ohm-cm for high resistance values, or a copper-nickel alloy with a resistivity of  $5 \cdot 10^{-5}$  ohm-cm for lower resistances. Power wire wounds are intended to operate at higher power dissipation and are composed of single layers of bare wire with substrates and packages of high-temperature materials. Precision resistors are stable, highly accurate components. The wire is multilayered, and therefore must be insulated, and all materials can be low temperature. The main disadvantages of wire-wound resistors are the high cost and low operating frequency.

Film-type resistors are made from various resistive materials deposited on an insulating substrate. Film thicknesses range from 0.005 micrometers deposited by evaporation for precision film resistors to as much as 100 micrometers deposited as a resistive ink. Sheet resistances range from 10 to 10 000 ohms per square. The final resistance value can be adjusted by cutting a spiral path through the resistive film until the desired value is reached. The resistors are stable, accurate, and low cost and are the most popular types today. Resistor networks, chip resistors, and film resistors deposited directly on a hybrid substrate provide a wide selection of styles.

The important specifications for a resistor are the resistance value, the tolerance, and the power rating. For carbon composition resistors the resistance value and tolerance are indicated by the familiar color code in [Table 102.1](#). Values range from 1 ohm to 100 megohms. Power rating ranges from 1/20 watt to 2 watts. The power rating is somewhat misleading since the temperature rise is the crucial variable, not the power dissipation. A 2 W resistor cannot dissipate 2 W if it is conformably coated and situated where cooling air is restricted. On the other hand, if a suitable heat sink is provided and forced air cooling is available, the rating could be higher than specified. Under pulse conditions the instantaneous power can be orders of magnitude larger than its nominal rating.

**Table 102.1 Resistor Color Code**

Color	First Band, <sup>a</sup> Significant Figure	Second Band, Significant Figure	Third Band, Multiplier	Fourth Band, <sup>b</sup> Tolerance (%)	Fifth Band, <sup>b</sup> Failure Rate (%/1000 h)
Black	0	0	1	—	—
Brown	1	1	10	—	1
Red	2	2	10 <sup>2</sup>	—	0.1
Orange	3	3	10 <sup>3</sup>	—	0.01
Yellow	4	4	10 <sup>4</sup>	—	0.001
Green	5	5	10 <sup>5</sup>	—	—
Blue	6	6	10 <sup>6</sup>	—	—
Violet	7	7	10 <sup>7</sup>	—	—
Gray	8	8	10 <sup>8</sup>	—	—

Silver	—	—	0.01	10	—
Gold	—	—	0.1	5	—
None	—	—	—	20	—

<sup>a</sup>The first band is the one closest to one end of the resistor. A first band wider than the others indicates a wire-wound resistor.

<sup>b</sup>Certain MIL parts.

No resistance is ideal, and over wide frequency ranges the parasitic inductance and capacitance limit the usefulness. [Figure 102.2](#) shows a common equivalent circuit for a resistor. The series inductance can be large for wire-wound resistors and limits their usefulness to frequencies less than about 50 to 100 kHz. For other resistors the leads constitute the main source of inductance, estimated to be of the order of 20 nH per inch. In general, low values of resistance and thin films tend to have lower inductance. Capacitance tends to dominate at high frequencies and with higher values of resistance. [Figure 102.3](#) illustrates typical variation of impedance of a resistor with frequency.

**Figure 102.2** At high frequencies the effects of parasitic capacitance and inductance of a resistor must be accounted for. This shows one possible equivalent representation.

**Figure 102.3** Variation of total impedance of a resistor with frequency for a typical film resistor.

Other resistor characteristics include temperature coefficient, voltage coefficient, stability, and noise. For a discussion of these the reader is referred to Dorf [1993] and Harper [1977].

## 102.2 Capacitors

**Capacitance** is a property that exists between two conductors separated by a **dielectric**. With equal but opposite charges on the two conductors a potential difference can be measured between them, and the capacitance is defined by the equation

$$C = \frac{Q}{V} \quad (102.3)$$

$C$  is the capacitance in farads,  $Q$  is the magnitude of the charge on either plate in coulombs, and  $V$  is the voltage between the plates in volts. The capacitance in the ideal case of two plane-parallel plates is given by

$$C = \varepsilon \frac{A}{d} \quad (102.4)$$

where  $\varepsilon$  is the **permittivity** of the dielectric in farads per meter,  $A$  is the area of each plate in meters squared, and  $d$  is the plate separation in meters.  $\varepsilon$  is equal to  $\varepsilon_r \varepsilon_0$ , where  $\varepsilon_r$  is the relative permittivity (sometimes referred to as the *dielectric constant*,  $k$ ) = 1 for vacuum,  $\approx 1$  for air, and ranging from 2 to 10 for common dielectrics.  $\varepsilon_0$  is the permittivity of free space, equal to  $8.854 \cdot 10^{-12}$  farads per meter. All **capacitors** use appropriate values of  $\varepsilon$ ,  $A$ , and  $d$  in Eq. (102.4) to achieve the wide range of values available in commercial capacitors.

The constitutive relationship between voltage and current in a capacitor is

$$v(t) = v_0 + \frac{1}{C} \int_0^t i \, dt \quad (102.5)$$

where  $v(t)$  is the instantaneous voltage across the capacitor,  $v_0$  is the initial voltage on the capacitor at  $t = 0$ , and  $i$  is the instantaneous current through the capacitor. By differentiating Eq. (102.5),

$$i(t) = C \frac{dv}{dt} \quad (102.6)$$

Unlike a resistor, an ideal capacitor does not dissipate energy. Instead, it accumulates energy during the charging process and releases energy to the electrical circuit as it discharges. The energy stored on a capacitor is given by

$$W = \frac{1}{2} CV^2 = \frac{1}{2} \frac{Q^2}{C} \quad (102.7)$$

where  $W$  is in joules.

There are two main classes of capacitors—electrolytic and electrostatic. Electrolytic capacitors include aluminum and tantalum types, used in applications where large capacitance values are needed. Electrostatic capacitors include plastic, ceramic disk, ceramic chip, mica, and glass. Aluminum electrolytics are constructed from high-purity aluminum foils that are chemically etched to increase the surface area, then anodized to form the dielectric. The thickness of this anodized layer determines the voltage rating of the capacitor. If only one foil is anodized, the capacitor is a polarized unit, and the instantaneous voltage cannot be allowed to reverse polarity.

Porous paper separates the two foils and is saturated with a liquid electrolyte; therefore, the unit must be sealed, and leakage is a common failure mode. During extended periods of storage the anodized layer may partially dissolve, requiring the unit to be reformed before rated voltage can be applied. Aluminum electrolytics exhibit a large series inductance, which limits the useful range of frequencies to about 20 kHz. They also have a large leakage current. Nevertheless, because of low cost and very large values of capacitance (up to 1 F), they are a popular choice for filtering applications.

Tantalum electrolytics are available in foil, wet slug, and solid varieties. All types require a tantalum electrode to be anodized, but the means used to make electrical contact to the plates differs in each case. The overall characteristics are superior to those of aluminum, but the cost is greater. Because of their small physical size and large capacitance they are used for the same applications as aluminum electrolytics.

The common type of plastic capacitor is the metalized film type, made by vacuum deposition of aluminum a fraction of a micron thick directly onto a plastic dielectric film. Common film types include polyester, polycarbonate, polypropylene, and polysulfone. Although the relative permittivity is low, the films can be made extremely thin, resulting in a large capacitance per unit volume. This type of capacitor exhibits an interesting self-healing feature. If breakdown should happen to occur—for instance, at a defect in the film or during a momentary electrical overstress—the metalization around the breakdown site will act like a fuse and vaporize, clearing the breakdown and restoring operation to an equal or higher voltage capability.

Plastic film capacitors have good electrical characteristics and are capable of operation at higher voltages and much higher frequencies than electrolytic capacitors. They have found wide application in filtering, bypassing, coupling, and noise suppression.

Ceramic capacitors employ ferroelectric dielectrics—commonly, barium titanate—that have an extremely high relative permittivity, 200 to 100 000. For disk capacitors the appropriate combination of powders is mixed, pressed into disks, and sintered at high temperatures. Electrodes are silk-screened on, leads are attached, and a protective coating applied. By varying the area, thickness (limited, to maintain mechanical strength), and especially the dielectric formulation, wide ranges of capacitance value are achieved. Very high voltage capability is also an option by increasing the thickness.

Ceramic chip capacitors are made from a slurry containing the dielectric powder and cast onto stainless-steel or plastic belts. After drying, electrodes are printed on the sheets, which are then arranged in a stack and fired. Electrodes are attached and the unit is encapsulated. By adjusting the number of plates and the plate area a wide range of values can be obtained. The extremely small size makes this type especially useful in hybrid integrated circuits and on printed circuit boards.

Mica and glass capacitors are used whenever high quality and excellent stability with respect to temperature and aging are required, and where high frequency operation is required. They are used in tuning circuits and for coupling where high performance and reliability are essential. Mica capacitors are made from sheets of mica that are alternately stacked with foils. Alternate foils are extended and folded over the ends. After leads are attached the unit is encapsulated. Glass capacitors are made from glass ribbons that are stacked alternately with foils. Leads are attached and the entire assembly is sealed in glass at high temperature and pressure.

Capacitors used in power system applications employ oil-impregnated paper as a dielectric.

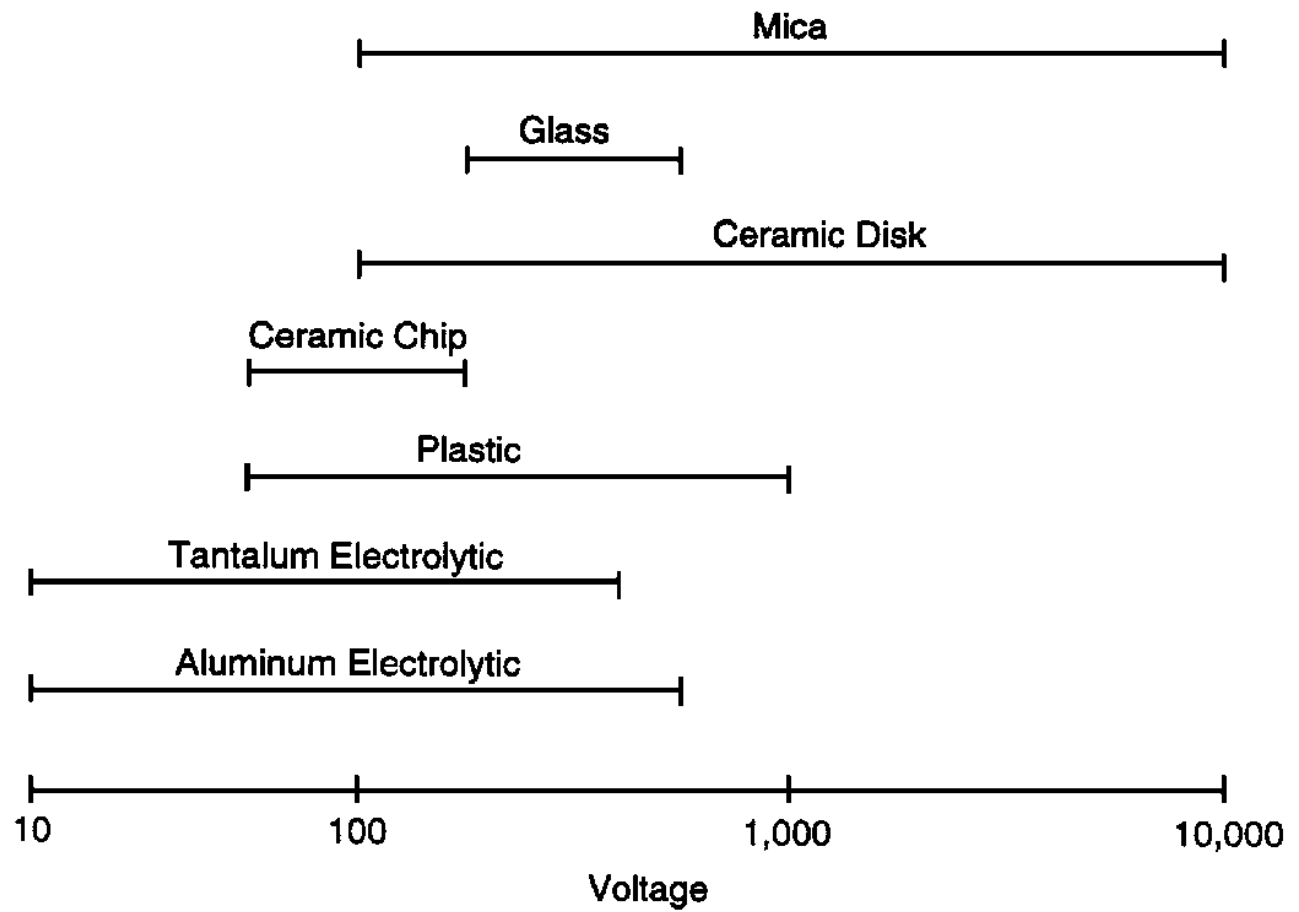

Because of the very high voltage ratings, these capacitors are shipped and stored with a shorting bar across the terminals as a safety precaution. Even though a capacitor has been discharged after high voltage operation or testing, it is possible for charge and voltage to re-accumulate by a phenomenon known as *dielectric absorption*.

Figures 102.4, 102.5, and 102.6 show ranges of capacitance values, voltage ratings, and frequency ranges for the different capacitors described in this section.

**Figure 102.4** Range of values for various types of capacitors.

**Figure 102.5** Voltage ratings of various capacitors.

**Figure 102.6** Frequency range of various capacitors.

All capacitors dissipate a small amount of power due to resistive losses in the conductors, leakage current across the dielectric, and losses in the dielectric under AC operation. If the capacitor is represented by its capacitance value in series with a resistor to simulate these losses, the resistance is called the **equivalent series resistance (ESR)**. Capacitance bridges often measure the **dissipation factor (DF)**, which is given by

$$DF = 2\pi f C_s R_s \quad (102.8)$$

where  $C_s$  is the series capacitance,  $f$  is the frequency in hertz, and  $R_s$  is the ESR. The reciprocal of the dissipation factor is the **quality factor (Q)** of the capacitor.

## 102.3 Inductors

**Inductance** is the property of a device that relates a magnetic field to the current that produces it. In Fig. 102.7, the current  $I$  flowing in a counterclockwise direction in the coil produces, by the right-hand rule, a magnetic flux. The inductance of the coil is defined by

$$L = \frac{\Phi}{I} \quad (102.9)$$

where  $L$  is the inductance in henrys,  $\Phi$  is the flux in webers, and  $I$  is the current in amperes.

**Figure 102.7** Magnetic flux produced by a current-carrying conductor. The inductance is defined by Eq. (102.9).

In an **inductor** the instantaneous voltage and current are related by the equation

$$v(t) = L \frac{di}{dt} \quad (102.10)$$

where  $v(t)$  is the instantaneous voltage in volts and  $di/dt$  is the rate of change of current with respect to time in amperes per second. Alternatively,

$$i(t) = i_0 + \frac{1}{L} \int_0^t v \, dt \quad (102.11)$$

where  $i_0$  is the initial current through the inductor at  $t = 0$ .

The energy stored in an inductor is

$$W = \frac{1}{2} I^2 L \quad (102.12)$$

Since the finite resistance of the wire in an inductor causes some energy loss, the quality factor, or  $Q$ , of an inductor—relating energy stored and energy dissipated—is an important quantity. It is

given by

$$Q = \frac{2\pi f L}{R} \quad (102.13)$$

where  $f$  is the frequency in hertz and  $R$  is the series resistance of the inductor.

In general, it is not possible to find an exact analytical expression for the inductance of a configuration. A number of empirical formulas are given as follows, and some general principles can be stated.

1. The inductance is proportional to the size of the coil. Thus larger loops have larger inductance.
2. Inductance is proportional to the number of turns squared. In Fig. 102.7, if there are two turns, the flux is doubled; if the flux is changing, then twice the induced voltage will appear in each turn, for a total of four times the voltage in a one-turn loop.
3. The inductance is proportional to the permeability of the surrounding medium. Most materials have a permeability  $\mu_0$  very close to that of free space;  $\mu_0 = 4 \cdot 10^{-4}$  henrys per meter. Magnetic materials have a permeability ranging from about 100 to 100 000 times  $\mu_0$ . They are used to concentrate and intensify the flux in transformers, motors, relays, and inductors.

Approximate formulas for the inductance of several configurations can be given. The internal inductance per unit length of a round solid wire is

$$L = \frac{\mu_0}{8\pi} \quad (102.14)$$

The inductance per unit length of two parallel wires carrying current in opposite directions is

$$L = 0.4 \cdot 10^{-6} \ln \left( \frac{2D}{d} \right) \quad (102.15)$$

where  $D$  is the center-to-center spacing of the wires and  $d$  is the diameter of the wire. For a coaxial cable the inductance per unit length is

$$L = \frac{\mu_0}{2\pi} \ln \left( \frac{r_b}{r_a} \right) \quad (102.16)$$

where the subscripts  $b$  and  $a$  refer to the radius of the outer and inner conductors, respectively. For a circular loop of wire,

$$L = \mu_0 a \left( \ln \left( \frac{8a}{r} \right) - 1.75 \right) \quad (102.17)$$

where  $a$  is the radius of the loop and  $r$  is the radius of the wire. For a solenoid consisting of a single layer of turns,

$$L = \frac{\mu_0 N^2 A}{0.45d + l} \quad (102.18)$$

where  $N$  is the number of turns,  $A$  is the cross-sectional area of the solenoid,  $d$  is the diameter of the solenoid, and  $l$  is its length.

In many cases the objective is to minimize the parasitic inductance of a layout. To achieve this one should minimize the area of current-carrying loops and use rectangular or flat conductors.

## Defining Terms

**Capacitance:** A property of an arrangement of two conductors equal to the charge on a conductor divided by the voltage between them.

**Capacitor:** An electronic component that accumulates charge and energy in an electric circuit.

**Dielectric:** An insulating material, for example, between the plates of a capacitor.

**Dissipation factor (DF):** The ratio of the energy dissipated per cycle to two times the maximum energy stored at a given frequency. The lower DF is, the more nearly ideal the capacitor is.

**Equivalent series resistance (ESR):** The resistance in series with a capacitor that accounts for energy loss in a nonideal capacitor.

**Inductance:** The property of a conductor arrangement that relates the magnetic flux to the current in the conductor.

**Inductor:** A passive component that stores energy in its magnetic field whenever it is conducting a current.

**Permittivity:** The property of a material that relates the electric field intensity to the electric flux density. The capacitance between two conductors is directly proportional to the permittivity of the dielectric between them.

**Quality factor (Q):** A value equal to two times the ratio of the maximum stored energy to the energy dissipated per cycle at a given frequency in a capacitor or inductor. The larger the value of  $Q$ , the more nearly ideal the component is. For a capacitor,  $Q$  is the inverse of DF.

**Resistivity:** The property of a material that relates current flow to electric field. The current density is equal to the electric field divided by the resistivity.

**Sheet resistance:** Sheet resistance (or sheet resistivity) is the average resistivity of a layer of material divided by its thickness. If the layer has the same length as width, the resistance between opposite edges of the "square" is numerically equal to the sheet resistance, regardless of the size of the square.

Circuits that contain only resistive elements can be described by a set of algebraic equations that are obtained by systematically applying Kirchhoff's current and voltage laws to the circuit. When a circuit contains energy storage elements—that is, inductors and capacitors—Kirchhoff's laws are still valid, but their application leads to a differential equation (DE) model of the circuit instead of an algebraic model. A DE model can be solved by classical DE methods, by time-domain convolution, and by Laplace transform methods.

### 103.1 RL Circuits

---

A series RL circuit can be analyzed by applying Kirchhoff's voltage law to the single loop that contains the elements of the circuit. For example, writing Kirchhoff's voltage law for the circuit in [Fig. 103.1](#) leads to the following first-order DE stating that the voltage drop across the inductor and the resistor must equal the voltage drop across the voltage source:

$$L \frac{di}{dt} + i(t)R = v_g(t) \quad (103.1)$$

This DE belongs to a family of linear, constant-coefficient, ordinary differential equations. Various approaches can be taken to find the solution for  $i(t)$ , the current through the elements of the circuit. The first is to solve the DE by classical (time-domain) methods; the second is to solve the equation by using Laplace transform theory. [A third approach, waveform convolution, will not be considered here (see [Ziemer et al., 1993](#)).]

**Figure 103.1** Series RL circuit.

The complete time-domain solution to the DE is formed as the sum of two parts, called the **natural solution** and the **particular solution**:

$$i(t) = i_N(t) + i_P(t) \quad (103.2)$$

The natural solution,  $i_N(t)$ , is obtained by solving the (homogeneous) DE with the sources (or forcing functions) turned off. The circuit in this example has the following homogeneous DE:

$$L \frac{di}{dt} + i(t)R = 0 \quad (103.3)$$

The solution to this equation is the exponential form:  $i_N(t) = K e^{st}$ , where  $K$  is an arbitrary constant. To verify this solution, substitute  $K e^{st}$  into Eq. (103.3) and form

$$LK s e^{st} + RK e^{st} = 0 \quad (103.4)$$

Rearranging gives:

$$[sL + R]K e^{st} = 0 \quad (103.5)$$

The factor  $K e^{st}$  can be canceled because the factor  $e^{st}$  is nonzero, and the constant  $K$  must be nonzero for the solution to be nontrivial. This reduction leads to the characteristic equation

$$sL + R = 0 \quad (103.6)$$

The **characteristic equation** of this circuit specifies the value of  $s$  for which  $i_N(t) = K e^{st}$  solves Eq. (103.3). By inspection,  $s = -R/L$  solves Eq. (103.6), and  $i_N(t) = K e^{-t/\tau}$  satisfies Eq. (103.3), and  $\tau = L/R$  is called the *time constant* of the circuit. The value  $s = -R/L$  is called the **natural frequency** of the circuit.

In general, higher-order circuits (those with higher-order differential equation models and corresponding higher-order algebraic characteristic equations) will have several natural frequencies, some of which may have a complex value—that is,  $s = \sigma + j\omega$ —where  $\sigma$  is an exponential damping factor and  $\omega$  is the undamped frequency of oscillation. The natural frequencies of a circuit play a key role in governing the dynamic response of the circuit to an input by determining the form and the duration of the transient waveform of the response [Ciletti, 1988].

The particular solution of this circuit's DE model is a function  $i_P(t)$  that satisfies Eq. (103.1) for a given source  $v_g(t)$ . For example, the constant input signal  $v_g(t) = V$  has the particular solution  $i_P(t) = V/R$ . [This can be verified by substituting this expression into Eq. (103.1).] The complete solution to the differential equation when  $v_g(t) = V$  is given by

$$i(t) = K e^{(-R/L)t} + V/R = K e^{-t/\tau} + V/R \quad (103.7)$$

The sources that excite physical circuits are usually modeled as being turned off before being applied at some specific time, say  $t_0$ , and the objective is to find a solution to its DE model for  $t \geq t_0$ . This leads to consideration of boundary conditions that constrain the behavior of the circuit and determine the unknown parameters in the solution of its DE model. The boundary conditions of the DE model of a physical circuit are determined by the energy that is stored in the circuit when the source is initially applied. For example, the inductor current in Fig. 103.1 could have the constraint given as  $i(t_0) = i_0$ , where  $i_0$  is a constant. If a circuit is modeled by a constant-coefficient DE, the time of application can be taken to be  $t_0 = 0$  without any loss in generality. (Note: The physical conditions that created  $i_0$  are not of concern.)

The value of the parameter  $K$  in Eq. (103.7) is specified by applying the given boundary condition to the waveform of Eq. (103.7), as follows:

$$i(0^+) = i_0 = K + V/R \quad (103.8)$$

and so  $K = i_0 - V/R$ .

The response of the circuit to the applied input signal is the complete solution of the DE for  $t \geq 0$  evaluated with coefficients that conform to the boundary conditions. In the RL circuit example the complete response to the applied step input is

$$i(t) = [i_0 - V/R] e^{-t/\tau} + V/R, \quad t \geq 0 \quad (103.9)$$

The waveforms of  $i(t)$  and  $v(t)$ , the inductor voltage, are shown in Fig. 103.2 for the case in which the circuit is initially at rest, that is,  $i_0 = 0$ . The time axis in the plot has been normalized by  $\tau$ .

**Figure 103.2** Waveforms of  $v(t)$  and  $i(t)$  in the series RL circuit.

The physical effect of the inductor in this circuit is to provide inertia to a change in current in the series path that contains the inductor. An inductor has the physical property that its current is a continuous variable whenever the voltage applied across the terminals of the inductor has a bounded waveform (that is, no impulses). The current flow through the inductor is controlled by the voltage that is across its terminals. This voltage causes the accumulation of magnetic flux, which ultimately determines the current in the circuit. The initial voltage applied across the inductor is given by  $v(0^+) = V - i(0^+)R$ . If the inductor is initially relaxed—that is,  $i(0^-) = 0$ —the continuity property of the inductor current dictates that  $i(0^+) = i(0^-) = 0$ . So  $v(0^+) = V$ . All of the applied voltage initially appears across the inductor. When this voltage is applied for an interval of time, a magnetic flux accumulates and current is established through the inductor. Mathematically, the integration of this voltage causes the current in the circuit. The current waveform in [Fig. 103.2](#) exhibits exponential growth from its initial value of 0 to its final (steady state) value of  $V/R$ . The inductor voltage decays from its initial value to its steady state value of 0, and the inductor appears to be a "short circuit" to the steady state DC current.

## 103.2 RC Circuits

A capacitor acts like a reservoir of charge, thereby preventing rapid changes in the voltage across its terminals. A capacitor has the physical property that its voltage must be a continuous variable when its current is bounded. The DE model of the parallel RC circuit in [Fig. 103.3](#) is described according to Kirchhoff's current law by

$$C \frac{dv}{dt} + \frac{v}{R} = i_g(t) \quad (103.10)$$

Taking the one-sided Laplace transform [Ziemer, 1993] of this differential equation gives

$$sCV(s) - Cv(0^-) + \frac{V(s)}{R} = I_g(s) \quad (103.11)$$

where  $V(s)$  and  $I_g(s)$  denote the Laplace transforms of the related time-domain variables. (Note that the Laplace transform of the derivative of a variable explicitly incorporates the initial condition of the variable into the model of the circuit's behavior.) Rearranging this algebraic equation gives the following:

$$V(s) = \frac{I_g(s)}{sC + 1/R} + \frac{Cv(0)}{sC + 1/R} \quad (103.12)$$

$$V(s) = I_g(s)H(s) + \frac{v(0)}{s + 1/(RC)} \quad (103.13)$$

where the  $s$ -domain function

$$H(s) = \frac{1}{sC + (1/R)} = \frac{1/C}{s + (1/RC)} \quad (103.14)$$

is called the input/output **transfer function** of the circuit. The expression in Eq. (103.13) illustrates an important property of linear circuits: the response of a linear RLC circuit variable is the superposition of the effect of the applied source and the effect of the initial energy stored in the circuit's capacitors and inductors. Another important fact is that the roots of the denominator polynomial of  $H(s)$  are the natural frequencies of the circuit (assuming no cancellation between numerator and denominator factors).

**Figure 103.3** Parallel RC circuit.

If a circuit is initially relaxed—that is, all capacitors and inductors are de-energized [set  $v(0^-) = 0$  in Eq. (103.13)], then the transfer function defines the ratio of the Laplace transform of the circuit's response to the Laplace transform of its stimulus. Alternatively, the transfer function and the Laplace transform of the input signal determine the Laplace transform of the output signal according to the simple product

$$V(s) = I_g(s)H(s) \quad (103.15)$$

The transfer function of a circuit can define a voltage ratio, a current ratio, a voltage-to-current ratio (impedance) or a current-to-voltage ratio (admittance). In this circuit  $H(s)$  relates the output (response of the capacitor voltage) to the input (i.e., the applied current source). Thus,  $H(s)$  is actually a generalized impedance function. If a circuit is initially relaxed its transfer function contains all of the information necessary to determine the response of the circuit to any given input signal.

Suppose that the circuit has an initial capacitor voltage and that the applied source in Eq. (103.13) is given by  $i_g(t) = Iu(t)$ , a step of height  $I$ . The Laplace transform [Ciletti, 1988] of the step waveform is given by  $I_g(s) = I/s$ , so the Laplace transform of  $v(t)$ , denoted by  $V(s)$ , is given by

$$V(s) = \frac{I/(sC)}{s + 1/(RC)} + \frac{v(0^-)}{s + 1/(RC)} \quad (103.16)$$

This expression for  $V(s)$  can be expanded algebraically into partial fractions as

$$V(s) = \frac{IR}{s} - \frac{IR}{s + 1/(RC)} + \frac{v(0^-)}{s + 1/(RC)} \quad (103.17)$$

Associating the  $s$ -domain Laplace transform factor  $1/(s + a)$  with the time-domain function  $e^{-at}u(t)$  and taking the inverse Laplace transform of the individual terms of the expansion gives

$$v(t) = IR + [v(0^-) - IR]e^{-t/(RC)}, \quad t \geq 0 \quad (103.18)$$

When the source is applied to this circuit, the capacitor charges from its initial voltage to the steady state voltage given by  $v(\infty) = IR$ . The response of  $v(t)$  is shown in Fig. 103.4 with  $\tau = RC$  and  $v_o = v(0^-)$ . The capacitor voltage follows an exponential transition from its initial value to its steady state value at a rate determined by its time constant,  $\tau$ . A similar analysis would show that the response of the capacitor current is given by

$$i(t) = [I - v(0^-)/R]e^{-t/RC}, \quad t \geq 0 \quad (103.19)$$

**Figure 103.4** Step response of an initially relaxed RC circuit.

Capacitors behave like short circuits to sudden changes in current. The initial capacitor voltage determines the initial resistor current by Ohm's law:  $v(0^+)/R$ . Any initial current supplied by the source in excess of this amount will pass through the capacitor as though it were a short circuit. As the capacitor builds voltage, the resistor draws an increasing amount of current and ultimately conducts all of the current supplied by the constant source. In steady state the capacitor looks like

an open circuit to the constant source— $i(\infty) = 0$ —and it conducts no current.

### 103.3 RLC Circuits

---

Circuits that contain inductors and capacitors exhibit dynamical effects that combine the inductor's inertia to sudden changes in current with the capacitor's inertia to sudden changes in voltage. The topological arrangement of the components in a given circuit determines the behavior that results from the interaction of the currents and voltages associated with the individual circuit elements.

The parallel RLC circuit in Fig. 103.5(a) has an  $s$ -domain counterpart [see Fig. 103.5(b)], sometimes referred to as a *transformed circuit*, that is obtained by replacing each time-domain variable by its Laplace transform, and each physical component by a Laplace transform model of the component's voltage-current relationship. Here, for example, the physical capacitor is replaced by a model that accounts for the impedance of the capacitor and the capacitor's initial voltage. The additional sources account for the possibly nonzero initial values of capacitor voltage and inductor current. Algebraic expressions of Kirchhoff's laws are written from the Laplace model of the circuit. Applying Kirchhoff's current law to the circuit of Fig. 103.5 gives

$$sCV(s) + \frac{V(s)}{sL} + \frac{V(s)}{R} = I_g(s) + Cv(0^-) - i(0^-) \quad (103.20)$$

Algebraic manipulation of this expression gives

$$V(s) = \frac{(s/C)I_g(s)}{s^2 + (s/RC) + (1/LC)} + \frac{s/C[Cv(0^-) - i(0^-)]}{s^2 + (s/RC) + (1/LC)} \quad (103.21)$$

The transfer function relating the source current to the capacitor voltage is obtained directly from Eq. (103.21), with  $v(0^-) = 0$  and  $i(0^-) = 0$ :

$$H(s) = \frac{s/C}{s^2 + (s/RC) + (1/LC)} \quad (103.22)$$

Because  $V(s)$  represents the response of a second-order circuit, the form of its partial fraction expansion depends on the natural frequencies of the circuit. These are obtained by solving for the roots of the characteristic equation:

$$s^2 + \frac{s}{RC} + \frac{1}{LC} = 0 \quad (103.23)$$

The roots are

$$s_1 = \frac{-1}{2RC} + \sqrt{\left[\frac{1}{2RC}\right]^2 - \frac{1}{LC}} \quad (103.24)$$

$$s_2 = \frac{-1}{2RC} - \sqrt{\left[\frac{1}{2RC}\right]^2 - \frac{1}{LC}} \quad (103.25)$$

To illustrate the possibilities of the second-order response, we let  $i_g(t) = u(t)$ , and  $I_g(s) = 1/s$ .

**Figure 103.5** Parallel RLC circuit.

### Case 1: Overdamped Circuit

If both roots of the second-order characteristic equation are real valued the circuit is said to be *overdamped*. The physical significance of this term is that the circuit response to a step input exhibits exponential decay and does not oscillate. The form of the step response of the circuit's capacitor voltage is

$$v(t) = K_1 e^{s_1 t} + K_2 e^{s_2 t} \quad (103.26)$$

and  $K_1$  and  $K_2$  are chosen to satisfy the initial conditions imposed by  $v(0^-)$  and  $i(0^-)$ .

### Case 2: Critically Damped Circuit

When the two roots of a second-order characteristic equation are identical the circuit is said to be *critically damped*. The circuit in this example is critically damped when  $s_1 = s_2 = -1/(2RC)$ . In this case, Eq. (103.21) becomes

$$V(s) = \frac{I/C}{[s + (1/2RC)]^2} + \frac{s}{C} \frac{[Cv(0^-) - i(0^-)]}{[s + (1/2RC)]^2} \quad (103.27)$$

The partial fraction expansion of this expression is

$$V(s) = \frac{1/C}{[s + (1/2RC)]^2} + \frac{1}{C} \frac{[Cv(0^-) - i(0^-)]}{s + (1/2RC)} - \frac{1}{2RC^2} \frac{[Cv(0^-) - i(0^-)]}{[s + (1/2RC)]^2} \quad (103.28)$$

Taking the inverse Laplace transform of  $V(s)$  gives

$$v(t) = \frac{1}{C}te^{-t/(2RC)} + \frac{1}{C}[Cv(0^-) - i(0^-)]e^{-t/(2RC)} - \frac{1}{2RC^2}[Cv(0^-) - i(0^-)]te^{-t/(2RC)} \quad (103.29)$$

The behavior of the circuit in this case is called *critically damped* because a reduction in the amount of damping in the circuit would cause the circuit response to oscillate.

### Case 3: Underdamped Circuit

The component values in this case are such that the roots of the characteristic equation are a complex conjugate pair of numbers. This leads to a response that is oscillatory, having a damped frequency of oscillation,  $\omega_d$ , given by

$$\omega_d = \sqrt{\frac{1}{LC} + \left[\frac{1}{2RC}\right]^2} \quad (103.30)$$

and a damping factor,  $\alpha$ , given by

$$\alpha = \frac{1}{2RC} \quad (103.31)$$

The form of the response of the capacitor voltage to a unit step input current source is

$$v(t) = 2|K|e^{-\alpha t} \sin(\omega_d t + \varphi) \quad (103.32)$$

where the parameters  $K$  (a nonnegative constant) and  $\varphi$  are chosen to satisfy initial conditions.

A comparison of overdamped, critically damped, and underdamped responses of the capacitor voltage is given in [Fig. 103.6](#) for a unit step input, with the circuit initially relaxed. Additional insight into the behavior of RL, RC, and RLC circuits can be obtained by examining the response of the current in the series RL, RC, and RLC circuits for corresponding component values. For example, [Fig. 103.7](#) shows the waveforms of the step response of  $i(t)$  for the following component values:  $R = 4 \, \Omega$ ,  $L = 1 \, \text{H}$ , and  $C = 1 \, \text{F}$ . The RL circuit has a time constant of 0.25 s, the RC circuit has a time constant of 2.00 s, and the overdamped RLC circuit has time constants of 0.29 s and 1.69 s. The inductor in the RL circuit blocks the initial flow of current, the capacitor in the RC circuit blocks the steady state flow of current, and the RLC circuit exhibits a combination of both behaviors. Note that the time constants of the RLC circuit are bounded by those of the RL and RC circuits.

**Figure 103.6** Overdamped, critically damped, and underdamped responses of a parallel RLC circuit with a step input.

**Figure 103.7** A comparison of current in series RL, RC, and RLC circuits.

## RLC Circuit – Frequency Response

A circuit's transfer function defines a relationship between the frequency-domain (spectral) characteristics of any input signal and the frequency-domain characteristics of its corresponding output signal. In many engineering applications circuits are used to shape the spectral characteristics of a signal. For example, in a communications application the frequency response could be chosen to eliminate noise from a signal. The frequency response of a circuit consists of the graphs of  $|H(j\omega)|$  and  $\theta(j\omega)$ , the magnitude response, and the phase response, respectively, of the transfer function of a given circuit voltage or current. The term  $|H(j\omega)|$  determines the ratio of the amplitude of the *sinusoidal steady state response* of the circuit to a sinusoidal input, and  $\theta(j\omega)$  determines the phase shift (manifest as a time-axis translation) between the input and the output waveforms. Values of  $|H(j\omega)|$  and  $\theta(j\omega)$  are obtained by taking the magnitude and angle, respectively, of the complex value  $H(j\omega)$ .

The magnitude and phase responses play an important role in filter theory, where for distortionless transmission (i.e., the filter output waveform is a scaled and delayed copy of the input waveform) it is necessary that  $|H(j\omega)| = K$ , a constant (flat response), and  $\theta(j\omega)$  be linear over the pass band of a signal that is to be passed through a filter.

In the parallel RC circuit of [Fig. 103.3](#), the transfer function relating the capacitor voltage to the current source has

$$H(j\omega) = \frac{R}{1 + j\omega RC} \quad (103.33)$$

The arithmetic of complex numbers gives the following

$$|H(j\omega)| = \frac{R}{\sqrt{1 + \omega^2 R^2 C^2}} \quad (103.34)$$

$$\theta(j\omega) = \angle H(j\omega) = -\tan^{-1}(\omega RC) \quad (103.35)$$

The graphs of  $|H(j\omega)|$  and  $\theta(j\omega)$  are shown in [Fig. 103.8](#). The capacitor voltage in the parallel RC circuit has a "low pass" filter response, meaning that it will pass low frequency sinusoidal signals without significant attenuation provided that  $\omega < \omega_o$  [ $\omega_o = 1/(RC)$ ], the cutoff frequency of the filter. The approximate linearity of the phase response within the passband is also evident.

**Figure 103.8** Magnitude and phase response of a parallel RC circuit.

A filter's component values determine its cutoff frequency. An important design problem is to determine the values of the components so that a specified cutoff frequency is realized by the circuit. Here, increasing the size of the capacitor lowers the cutoff frequency, or, alternatively, reduces the bandwidth of the filter. Other typical filter responses that can be formed by RL, RC, and RLC circuits (with and without op amps) are high-pass, band-pass, and band-stop filters.

## Defining Terms

**Characteristic equation:** The equation obtained by setting the denominator polynomial of a transfer function equal to zero. The equation defines the natural frequencies of a circuit.

**Generalized impedance:** An  $s$ -domain transfer function in which the input signal is a circuit's current and the output signal is a voltage in the circuit.

**Natural frequency:** A root of the characteristic polynomial. A natural frequency corresponds to a mode of exponential time-domain behavior.

**Natural solution:** The solution to the unforced differential equation.

**Particular solution:** The solution to the differential equation for a particular forcing function.

**Steady state response:** The response of a circuit after sufficient time has elapsed to allow the transient response to become insignificant.

**Transient response:** The response of a circuit prior to its entering the steady state.

**Transfer function:** An  $s$ -domain function that determines the relationship between an exponential forcing function and the particular solution of a circuit's differential equation model. It also describes a relationship between the  $s$ -domain spectral description of a circuit's input signal and the spectral description of its output signal.

# Node Equations and Mesh Equations

---

## 104.1 Node Equations

## 104.2 Mesh Equations

**James A. Svoboda**

*Clarkson University*

Node equations and mesh equations are sets of simultaneous equations that are used to analyze electric circuits. Engineers have been writing and solving node equations and mesh equations for a long time. For example, procedures for formulating node equations and mesh equations are found in textbooks from the late 1950s and 1960s [Seshu and Balabanian, 1959; Seshu and Reed, 1961; Desoer and Kuh, 1969]. This longevity is likely due to two facts. First, node equations and mesh equations are easy to write. Second, the node equations and the mesh equations are both relatively small sets of simultaneous equations.

Electric circuits are interconnections of electrical devices, for example, resistors, independent and dependent sources, capacitors, inductors, op amps, and so on. Circuit behavior depends both on how the devices work and on how the devices are connected together. **Constitutive equations** describe how the devices in the circuit work. Ohm's law is an example of a constitutive equation. The Kirchhoff's law equations describe how the devices are connected together to form the circuit. Both the node equations and the mesh equations efficiently organize the information provided by the constitutive equations and the Kirchhoff's law equations.

In order to better appreciate the advantages of using node and mesh equations, an example will be done without them. The constitutive equations and Kirchhoff's law equations comprise a set of simultaneous equations. In this first example, illustrated in Fig. 104.1, these equations are used to analyze an electric circuit. This example also illustrates the use of MathCAD to solve simultaneous equations. The availability of such a convenient method of solving equations influences the way that node equations and mesh equations are formulated.

### Solving a Circuit using Branch Equations

Guess the values of the branch voltages and currents. Any guess will do. A good guess is not required. In this example,  $V_4$  is known to be 12. Zero is a suitable guess for the other branch voltages and currents.

$I_1 := 0$	$V_1 := 0$	$I_2 := 0$	$V_2 := 0$
$I_3 := 0$	$V_3 := 0$	$I_4 := 0$	$V_4 := 12$
$I_5 := 0$	$V_5 := 0$	$I_6 := 0$	$V_6 := 0$

Enter the equations describing the branches of the network. The word "Given" marks the beginning of these equations.

Given

Enter the Kirchhoff's Current Law (KCL) equations. (Use <ALT>= for the wiggly equal signs.)

$I_1 + I_2 + I_4 = 0$	$-I_2 + I_3 + I_5 = 0$	$-I_1 - I_3 + I_6 = 0$
-----------------------	------------------------	------------------------

Enter the Kirchhoff's Voltage Law (KVL) equations.

$V_1 - V_3 - V_2 = 0$	$V_2 + V_5 - V_4 = 0$	$V_3 + V_6 - V_5 = 0$
-----------------------	-----------------------	-----------------------

Enter the Constitutive Equations.

$V_1 = 3 \cdot I_1$	$V_2 = 4 \cdot I_2$	$V_3 = 5 \cdot I_3$	$V_4 = 12$
$I_5 = 2 \cdot I_2$	$V_6 = 5 \cdot V_1$		

Ask MathCAD to solve these equations. The word "Find" marks the end of the equations.

Find( $I_1, I_2, I_3, I_4, I_5, I_6, V_1, V_2, V_3, V_4, V_5, V_6$ ) =

The circuit shown in Fig. 104.1 consists of six devices. Two variables—a branch current and a voltage—are associated with each branch. There are 12 variables associated with this small circuit! The constitutive equations describe each of the six devices:

$$\begin{aligned} v_1 &= 3i_1, & v_2 &= 4i_2, & v_3 &= 5i_3, \\ v_4 &= 12, & i_5 &= 2i_2, & v_6 &= 5v_1 \end{aligned} \quad (104.1)$$

Kirchhoff's laws provide six more equations:

$$\begin{aligned} i_1 + i_2 + i_4 &= 0, & -i_2 + i_3 + i_5 &= 0, & -i_1 - i_3 + i_6 &= 0, \\ v_1 - v_3 - v_2 &= 0, & v_2 + v_5 - v_4 &= 0, & v_3 + v_6 - v_5 &= 0 \end{aligned} \quad (104.2)$$

Although it is not practical to solve 12 equations in 12 unknowns by hand, these equations can easily be solved using a personal computer with appropriate software. Figure 104.1 includes a screen dump that illustrates the use of MathCAD [Wieder, 1992] to solve these equations.

Writing all of these equations is tedious and the process becomes more tedious as the size of the circuit increases. It would be convenient to use a smaller set of simultaneous equations, hence the interest in node equations and mesh equations. The size of the set of simultaneous equations is very important when the equations must be solved by hand. Most contemporary treatments of node equations and mesh equations [Dorf, 1993; Irwin, 1993; Nilsson, 1993] describe procedures that result in as small a set of equations as possible. The availability of the personal computer with appropriate software reduces, but does not eliminate, the importance of the size of the set of equations.

## 104.1 Node Equations

This section describes a procedure for obtaining node equations to represent a connected circuit. This procedure is based on the observation that an independent set of equations can be obtained by applying Kirchhoff's current law (KCL) at all of the nodes of the circuit except for one node [Seshu and Balabanian, 1959; Seshu and Reed, 1961; Desoer and Kuh, 1969]. The node at which KCL is not applied is called the **reference node**.

The voltage at any node, with respect to the reference node, is called the **node voltage** at that node. Figure 104.2 shows that the current in a resistor can be expressed in terms of the voltages at the nodes of the resistor. This is accomplished in three steps. First, in Fig. 104.2(a), the node voltages corresponding to the nodes of the resistor are labeled. Next, in Fig. 104.2(b), the branch voltage is expressed in terms of the node voltages (notice the polarities of the voltages). Finally, in Fig. 104.2(c), Ohm's law is used to express the branch current in terms of the node voltages (notice the polarities of the branch voltage and current).

**Figure 104.2** Expressing branch voltages and currents as functions of node voltages.

Consider writing simultaneous equations to represent the circuit shown in Fig. 104.3. When the reference node is selected as shown in Fig. 104.3, the node voltages are  $v_1$ ,  $v_2$ , and  $v_3$ . The resistor currents have been expressed in terms of the node voltages using the technique described in Fig. 104.2. Since all of the branch currents have been labeled, a set of simultaneous equations can now be obtained by applying KCL at all of the nodes except for the reference node.

$$\begin{aligned} .001 &= \frac{v_1 - v_2}{2000} + \frac{v_1 - v_3}{1000} \\ .002 &= .003 + \frac{v_1 - v_2}{2000} \\ \frac{v_1 - v_3}{1000} &= .003 + \frac{v_3}{3000} \end{aligned} \quad (104.3)$$

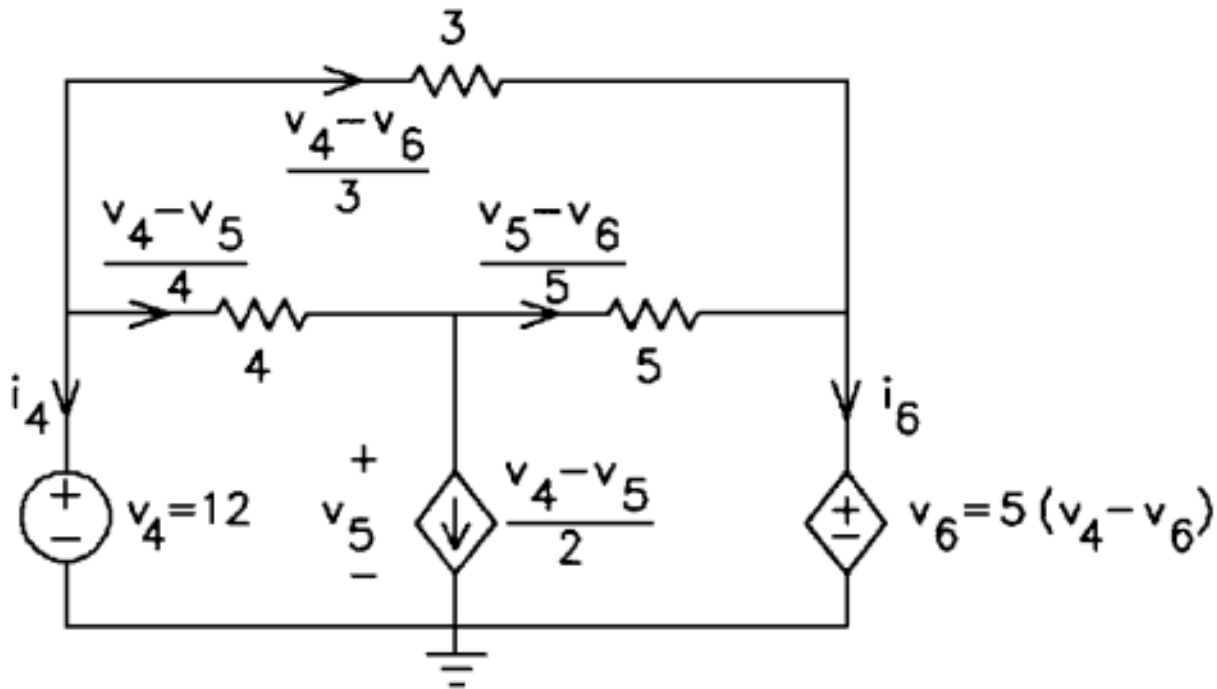

The independent variables in these equations are node voltages and so this set of simultaneous equations is called the *node equations*. Representing the branch voltages and branch currents as functions of the node voltages made it possible to represent this circuit by a smaller set of variables, the node voltages.

**Figure 104.3** A circuit consisting of resistors and current sources.

Consider again the circuit shown in [Fig. 104.1](#). This circuit contains two voltage sources (one independent and one dependent). In general, there is no easy way to express the current in a voltage source as a function of the node voltages. Since the size of the set of simultaneous equations is not of critical importance, it is appropriate to add the currents of the voltage sources to the list of independent variables. The circuit has been redrawn in [Fig. 104.4](#). A reference node has been selected and labeled. The independent variables, that is, the node voltages and currents in the voltage sources, have been labeled.

**Figure 104.4** Writing node equations for the circuit from Fig. 104.1.

The voltage across each voltage source can be expressed in two ways. The source voltage is given by the constitutive equation. The branch voltage is the difference of the node voltages at the nodes of the voltage source. These expressions must be equivalent so the branch voltage can be equated to the source voltage. In Fig. 104.4 this means that

$$v_4 = 12 \quad \text{and} \quad v_6 = 5(v_4 - v_6) \quad (104.4)$$

The circuit in Fig. 104.4 contains two dependent sources. Dependent sources will not be a problem if the controlling variables of the dependent sources are first expressed as functions of the independent variables of the circuit. In Fig. 104.4 this means that  $i_2$  and  $v_1$  must be expressed as functions of  $v_4, v_5, v_6, i_4$ , and  $i_6$ .

$$i_2 = \frac{v_4 - v_5}{4} \quad \text{and} \quad v_1 = v_4 - v_6 \quad (104.5)$$

Next the controlled variables of the dependent source can be expressed as functions of the independent variables of the circuit:

$$i_5 = 2 \left( \frac{v_4 - v_5}{4} \right) = \frac{v_4 - v_5}{2} \quad \text{and} \quad v_6 = 5(v_4 - v_6) \quad (104.6)$$

Now all of the branch currents have been labeled. Apply KCL at all of the nodes except the reference node to get

$$\begin{aligned}\frac{v_4 - v_6}{3} + \frac{v_4 - v_5}{4} + i_4 &= 0 \\ -\frac{v_4 - v_5}{4} + \frac{v_4 - v_5}{2} + \frac{v_5 - v_6}{5} &= 0 \quad (104.7) \\ -\frac{v_5 - v_6}{5} - \frac{v_4 - v_6}{3} + i_6 &= 0\end{aligned}$$

Equations (104.4) and (104.7) comprise the node equations representing this circuit.

In summary, the following procedure is used to write node equations:

1. Choose and label the reference node. Label the independent variables: node voltages and voltage source currents.
2. Express branch currents as functions of the independent variables and the input variables.
3. Express the branch voltage of each voltage source as the difference of the node voltages at its nodes. Equate the branch voltage to the voltage source voltage.
4. Apply KCL at each node except for the reference node.

## 104.2 Mesh Equations

Mesh equations are formulated by applying Kirchhoff's voltage law (KVL) to each **mesh** of a circuit. A **mesh current** is associated with each mesh. [Figure 104.5](#) shows how to express the branch voltage and branch current of a resistor as functions of the mesh currents.

**Figure 104.5** Expressing branch voltages and currents as functions of mesh currents.

The procedure for formulation of mesh equations is analogous to the procedure for formulating node equations:

1. Label the independent variables: mesh currents and current source voltages.
2. Express branch voltages as functions of the independent variables and the input variables.
3. Express the branch current of each current source as the difference of the mesh currents of its meshes. Equate the branch current to the current source current.

4. Apply KVL to each mesh.

As an example, consider again the circuit shown in Fig. 104.1. This circuit is redrawn in Fig. 104.6 to show the mesh currents  $i_1$ ,  $i_2$ , and  $i_3$ . The branch voltage of the current source,  $v_5$ , is also labeled, because it will be added to the list of independent variables. In Fig. 104.6, the branch voltages have been expressed as functions of the independent variables  $i_1$ ,  $i_2$ ,  $i_3$ , and  $v_5$ .

**Figure 104.6** Writing mesh equations for the circuit from Fig. 104.1.

mesh\_eqn.MCD4

### Solving a Circuit using Mesh Equations

Guess the values of the mesh currents and current source voltage. Any guess will do. A good guess is not required.

$i1 := 0$        $i2 := 0$        $i3 := 0$        $v5 := 0$

Given

branch current =  $i2 - i3 = 2 \cdot (i2 - i1)$  = current source current

Apply KVL to each mesh.

$$-4 \cdot (i2 - i1) + 3 \cdot i1 - 5 \cdot (i3 - i1) \approx 0 \quad -12 + 4 \cdot (i2 - i1) + v5 \approx 0$$

$$-v5 + 5 \cdot (i3 - i1) + 15 \cdot i1 \approx 0$$

$$\text{Find}(i1, i2, i3, v5) = \begin{bmatrix} 0.667 \\ -1.333 \\ 2.667 \\ 20 \end{bmatrix}$$

The current in the dependent current source can be expressed in two ways. This source current is given by the constitutive equation. This branch current is also the difference of two mesh currents. These expressions must be equal so

$$i2 - i3 = 2(i2 - i1) \quad (104.8)$$

Next, apply KVL to each mesh to get

$$\begin{aligned}-4(i_2 - i_1) + 3i_1 - 5(i_3 - i_1) &= 0 \\ -12 + 4(i_2 - i_1) + v_5 &= 0 \\ -v_5 + 5(i_3 - i_1) + 15i_1 &= 0\end{aligned}\quad (104.9)$$

Equations (104.8) and (104.9) comprise the mesh equations. [Figure 104.6](#) illustrates the use of MathCAD to solve the circuit using mesh equations.

## Defining Terms

**Constitutive equations:** Equations that describe the relationship between the branch current and branch voltage of an electric device. Ohm's law is an example of a constitutive equation.

**Mesh:** A loop that does not contain any branch in its interior. Only planar circuits have meshes. Redrawing a planar circuit can change the meshes [[Seshu and Reed, 1961](#); [Desoer and Kuh, 1969](#)].

**Mesh current:** A current associated with a mesh. This current circulates around the mesh.

**Node voltage:** The voltage at any node, with respect to the reference node.

**Reference node:** An independent set of equations can be obtained by applying KCL at all of the nodes of the circuit except for one node. The node at which KCL is not applied is called the *reference node*. Any node of the circuit can be selected to be the reference node. In electronic circuits, where one node of the network is the ground node of the power supplies, the reference node is almost always selected to be the ground node.

## Sinusoidal Excitation and Phasors

---

### 105.1 Sinusoidal Source

### 105.2 Phasor

### 105.3 Passive Circuit Elements in Phasors Domain

Resistor • Inductor • Capacitor • Sinusoidal Responses

**Muhammad H. Rashid**

*Purdue University*

A sinusoidal forcing function known as a **sinusoid** is one of the most important excitations. In electrical engineering, the carrier signals for communications are sinusoids, and the sinusoid is also the dominant signal in the power industry. Sinusoids abound in nature, as, for example, in the motion of a pendulum, in the bouncing of a ball, and in the vibrations of strings and membranes.

Because of the importance of sinusoids, the output response of a circuit due to a sinusoidal input signal is an important criterion in determining the performance of a circuit. In this section, we will define a sinusoidal function, represent it in a phasor form, and then illustrate the techniques for determining the sinusoidal responses.

### 105.1 Sinusoidal Source

---

A sinusoidal source (independent or dependent) produces a signal that varies sinusoidally with time. In electrical engineering, it is normally a voltage or a current. A sinusoid can be expressed as a sine function or a cosine function. There is no clear-cut choice for the use of either function. However, the sine function is more commonly used. Using a sine function, the instantaneous voltage, which is shown in [Fig. 105.1](#), can be represented by

$$v(t) = V_m \sin \omega t \quad (105.1)$$

where  $V_m$  is the maximum amplitude, and  $\omega$  is the *angular* or *radian frequency* in rad/s.

**Figure 105.1** Three sinusoids with different phase angles.

A sinusoid is a *periodic* function defined generally by the property

$$v(t + T) = v(t) \quad (105.2)$$

where  $T$  is the period, the time for one complete cycle. That is, the function goes through one complete cycle every  $T$  seconds and is then repeated. The period  $T$  is related to the angular frequency  $\omega$  by

$$T = \frac{2\pi}{\omega} \quad (105.3)$$

In 1 s, the function goes through  $1/T$  cycles, or periods. The *frequency* is then

$$f = \frac{1}{T} = \frac{\omega}{2\pi} \quad (105.4)$$

The number of cycles per second, or *hertz* (abbreviated Hz), named for the German physicist Heinrich R. Hertz (1857–1894), is the standard unit of frequency. The frequency and the angular frequency are related by

$$\omega = 2\pi f \quad (105.5)$$

So far, we have assumed that a sinusoid starts at  $t = 0$ . However, it could be phase shifted by an angle  $\phi$  and has the more general expression given by

$$v(t) = V_m \sin(\omega t + \phi) \quad (105.6)$$

where  $\phi$  is the *phase angle*, or simply *phase*. Since  $\omega t$  is in radians,  $\phi$  should also be expressed in radians. However, it is often convenient to specify  $\phi$  in degrees. That is,

$$v(t) = V_m \sin\left(\omega t + \frac{\pi}{3}\right) \quad (105.7)$$

or

$$v(t) = V_m \sin(\omega t + 60^\circ) \quad (105.8)$$

is acceptable, although Eq. (105.8) is mathematically inconsistent. While computing the value of  $\sin(\omega t + \phi)$ , one should use the same units (radians or degrees) for both  $\omega t$  and  $\phi$ . If  $\phi$  has a positive value, the sinusoid is said to have a *leading phase angle*. If  $\phi$  has a negative value, it is said to have a *lagging phase angle*.

## 105.2 Phasor

---

A **phasor** is a complex number that represents the amplitude and phase angle of a sinusoidal function. It transforms a sinusoidal function from time domain to the complex number domain. The phasor concept, which is generally credited to electrical engineer Charles Proteus Steinmetz (1865–1923), is based on the Euler's exponential function of the trigonometric function

$$e^{j\theta} = \cos \theta + j \sin \theta \quad (105.9)$$

Thus, a cosine function may be regarded as the real part of the exponential function and a sine function as the imaginary part of the exponential function. That is,

$$\cos \theta = \operatorname{Re} (e^{j\theta}) \quad (105.10)$$

$$\sin \theta = \operatorname{Im} (e^{j\theta}) \quad (105.11)$$

Therefore, we can write the sinusoidal voltage function of Eq. (105.6) as

$$v(t) = V_m \sin(\omega t + \phi) \quad (105.12)$$

$$= V_m \operatorname{Im} \left\{ e^{j(\omega t + \phi)} \right\} = \operatorname{Im} \left\{ (V_m e^{j\phi}) e^{j\omega t} \right\} \quad (105.13)$$

which indicates that the coefficient of the exponential  $e^{j\omega t}$  is a complex number. It is the *phasor representation*, or *phasor transform*, of the sinusoidal function and is represented by a boldface letter. Thus, the phasor  $\mathbf{V}$  becomes

$$\mathbf{V} = V_m e^{j\phi} \quad (\text{exponential form}) \quad (105.14)$$

$$= V_m \cos \theta + j V_m \sin \theta \quad (\text{polar form}) \quad (105.15)$$

Since phasors are used extensively in analysis of electrical engineering circuits, the exponential function  $e^{j\phi}$  is abbreviated in a shorthand notation for the sake of simplicity

as

$$e^{j\phi} = 1 \angle \phi \quad (105.16)$$

A graphical relationship between a phasor and sinusoid is shown in Fig. 105.2. A unit phasor may be regarded as a unit vector having an initial phase displacement of  $\phi$  and rotating in the counterclockwise direction at an angular speed of  $\omega$ .

**Figure 105.2** Rotating phasor.

## 105.3 Passive Circuit Elements in Phasors Domain

If we want to find the response of an electrical circuit due to a sinusoidal forcing function, first we need to establish the relationship between the phasor voltage across and the phasor current through passive elements such as the resistor, inductor, and capacitor.

### Resistor

Let us assume that a sinusoidal current of

$$i(t) = I_m \sin(\omega t + \theta) \quad (105.17)$$

where  $I_m$  is the maximum amplitude of the current in amperes, and  $\theta$  is the phase angle of the current.

Using Ohm's law for the resistor in Fig. 105.3(a), the instantaneous voltage across the terminals of the resistor is related to its instantaneous current by

$$v(t) = Ri(t) = R \{ I_m \sin(\omega t + \theta) \} = RI_m \sin(\omega t + \theta) \quad (105.18)$$

which can be represented as a phasor by

$$V = RI_m e^{j\theta} = RI_m \angle \theta \quad (105.19)$$

Since  $I_m \angle \theta = \mathbf{I}$  is the phasor representation of the current, we can write

$$V = RI \quad (105.20)$$

That is, the phasor voltage across the terminals of a resistor is the resistor times the phasor current. [Figure 105.3\(b\)](#) shows the  $\mathbf{V}$  and  $\mathbf{I}$  relationship of a resistor. A resistor has no phase shift between the voltage and its current. The current is said to be in time phase with the voltage, as shown in [Fig. 105.3\(c\)](#).

**Figure 105.3** Voltage-current relationships of a resistor.

## Inductor

Assuming a sinusoidal current of  $i = I_m \sin(\omega t + \theta)$ , the voltage across an inductor shown in [Fig. 105.4\(a\)](#) is related to its current by

$$v = L \frac{di}{dt} = \omega L I_m \cos(\omega t + \theta) \quad (105.21)$$

Using the trigonometric identity of  $\cos A = \sin(A + \pi/2)$ , Eq. (105.21) can be rewritten as

$$v = \omega L I_m \sin\left(\omega t + \theta + \frac{\pi}{2}\right) \quad (105.22)$$

The phasor representation of the voltage given by Eq. (105.22) is

$$\begin{aligned}
 V &= \omega L I_m e^{j(\theta + \pi/2)} = \omega L I_m \angle(\theta + \pi/2) \\
 &= \omega L I_m e^{j\theta} e^{j\pi/2} \\
 &= \omega L I_m e^{j\theta} (\cos \pi/2 + j \sin \pi/2) \\
 &= j\omega L I_m e^{j\theta} = j\omega L I
 \end{aligned}
 \tag{105.23}$$

Thus, the phasor voltage across the terminals of an inductor equals  $j\omega L$  times the phasor current. Since the operator  $j$  gives a phase shift of  $+90^\circ$ , then  $jI = jI \angle \theta = I_m \angle(\theta + \pi/2)$ . That is, the current lags behind the voltage by  $90^\circ$ , or the voltage leads the current by  $90^\circ$ . The voltage and current relationship in the phasor domain is shown in Fig. 105.4(b) and in the time domain in Fig. 105.4(c).

**Figure 105.4** Voltage-current relationships of an inductor.

## Capacitor

Assuming a sinusoidal voltage of  $v = V_m \sin(\omega t + \phi)$ , the current through a capacitor shown in Fig. 105.5(a) is related to its voltage by

$$i = C \frac{dv}{dt} = j\omega C V_m \cos(\omega t + \phi) \tag{105.24}$$

Using the trigonometric identity, Eq. (105.24) can be rewritten as

$$i = \omega C V_m \sin\left(\omega t + \phi + \frac{\pi}{2}\right) \tag{105.25}$$

The phasor representation of the current given by Eq. (105.25) is

$$I = j\omega CV \quad (105.26)$$

Thus, the phasor current through a capacitor equals  $j\omega C$  times the phasor voltage. That is, the voltage lags behind the current by  $90^\circ$ , or the current leads the voltage by  $90^\circ$ . The voltage and current relationship in the phasor domain is shown in Fig. 105.5(b) and in the time domain in Fig. 105.5(c).

**Figure 105.5** Voltage-current relationships of a capacitor.

## Sinusoidal Responses

We can conclude from the previous discussions that the phasor relationship between the voltage and the current of an element takes the general form of

$$V = ZI \quad (105.27)$$

where  $Z$  is the **impedance** of the circuit element. That is, the impedance of a resistor is  $R$ , the impedance of an inductor is  $j\omega L$ , and the impedance of a capacitor is  $1/j\omega C$ . Thus, for a circuit having  $L$  and/or  $C$ , the impedance  $Z$  will be a complex number with a real part  $R$  and an imaginary

part  $X$  such that

$$\mathbf{Z} = R + jX = Z\angle\theta \quad (105.28)$$

where

$$Z = [R^2 + X^2]^{1/2} \quad (105.29)$$

and

$$\theta = \tan^{-1}(X/R) \quad (105.30)$$

If the Kirchhoff's voltage law for a set of  $n$  sinusoidal voltages in the time domain is given by

$$v_1 + v_2 + v_3 + v_4 + \cdots + v_n = 0 \quad (105.31)$$

then the equivalent statement in the phasor domain can be written as

$$\mathbf{V}_1 + \mathbf{V}_2 + \mathbf{V}_3 + \mathbf{V}_4 + \cdots + \mathbf{V}_n = 0 \quad (105.32)$$

Similarly, if the Kirchhoff's current law for a set of  $n$  sinusoidal currents in the time domain is given by

$$i_1 + i_2 + i_3 + i_4 + \cdots + i_n = 0 \quad (105.33)$$

then the equivalent statement in the phasor domain can be written as

$$\mathbf{I}_1 + \mathbf{I}_2 + \mathbf{I}_3 + \mathbf{I}_4 + \cdots + \mathbf{I}_n = 0 \quad (105.34)$$

Let us consider the  $RLC$  circuit shown in [Fig. 105.6](#). We will use the phasor concept in finding its current in response to an input source voltage of  $v_s = V_m \sin(\omega t + \phi)$ . We use the phasor notation

$$\mathbf{V}_s = V_m \angle \phi \quad (105.35)$$

Applying the Kirchhoff's voltage law, we get

$$\mathbf{V}_s = (R + j\omega L + 1/j\omega C)\mathbf{I} = \mathbf{Z}\mathbf{I} \quad (105.36)$$

where  $\mathbf{Z}$  is the total impedance of the series loop formed by  $R$ ,  $L$ , and  $C$ . That is,

$$\begin{aligned} Z &= R + j(\omega L - 1/\omega C) = [R^2 + (\omega L - 1/\omega C)^2]^{1/2} \angle \theta \\ &= Z \angle \theta \end{aligned} \quad (105.37)$$

where  $Z$  is the impedance magnitude and is given by

$$Z = [R^2 + (\omega L - 1/\omega C)^2]^{1/2} \quad (105.38)$$

and  $\theta$  is the impedance angle given by

$$\theta = \tan^{-1} \left( \frac{\omega L - 1/\omega C}{R} \right) \quad (105.39)$$

Dividing the phasor voltage by the phasor impedance gives the phasor current as

$$I = \frac{V_s}{Z} = \frac{V_s \angle \phi}{Z \angle \theta} = \frac{V_s \angle \phi - \theta}{Z} \quad (105.40)$$

which indicates that the current lags the input voltage by an angle of  $\theta$ . Converting to the time domain, the current is given by

$$i = \frac{V_m}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}} \sin(\omega t + \phi - \theta) \quad (105.41)$$

**Figure 105.6** A series *RLC* circuit.

Let us consider the parallel *RLC* circuit shown in [Fig. 105.7](#). Applying the Kirchhoff's current

law at the node  $a$ , we get

$$I = I_1 + I_2 + I_3 \quad (105.42)$$

Since the three impedances are:  $Z_R = R$ ,  $Z_1 = R_1 + j\omega L$ , and  $Z_C = 1/j\omega C$ , we can substitute for  $I$  by using Ohm's law. That is,

$$I = \frac{V_s \angle \phi}{R} + \frac{V_s \angle \phi}{R_1 + j\omega L} + \frac{V_s \angle \phi}{1/j\omega C}$$

$$I = V_s \angle \phi \left[ \frac{1}{R} + \frac{1}{\sqrt{R_1^2 + (\omega L)^2}} \angle \theta_1 + j\omega C \right] \quad (105.43)$$

where  $\theta_1$  is the impedance angle of  $R_1$  and  $L$ , and it is given by

$$\theta_1 = \tan^{-1} \frac{\omega L}{R_1} \quad (105.44)$$

Equation (105.42) can be written as

$$I = V_s \angle \phi Y \angle -\theta = V_s Y \angle (\phi - \theta) \quad (105.45)$$

where  $Y \angle -\theta$  is the equivalent admittance of  $R$ ,  $R_1$ , and  $L$  such that it is related to the equivalent impedance  $Z$  by

$$Y \angle -\theta = \frac{1}{Z \angle \theta} = \frac{1}{R} + \frac{1}{R_1 + j\omega L} + j(\omega C) \quad (105.46)$$

Equation (105.43) can be written in the time domain as

$$i(t) = V_m Y \sin(\omega t + \phi - \theta) \quad (105.47)$$

where  $\theta$  is the impedance angle of  $(R_1 + j\omega L)$ , which is in parallel with  $R$  and  $1/j\omega C$ . In converting from the phasor domain to the time domain, we have assumed that the maximum amplitude of a sinusoid is the magnitude of its phasor representation. However, in practice, the magnitude of a sinusoid is normally quoted in its root-mean-square (rms) value, which is defined by

$$V_{\text{rms}} = \sqrt{\frac{1}{T} \int V_m^2 \cos^2(\omega t + \phi) dt} \quad (105.48)$$

which, after completing the integration and simplification, becomes

$$V_{\text{rms}} = \frac{V_m}{\sqrt{2}} \quad (105.49)$$

Thus,  $v = V_m \sin(\omega t + \phi) = \sqrt{2}V_{\text{rms}} \sin(\omega t + \phi)$ , and it will be represented in a phasor form by  $V_{\text{rms}} \angle \phi$ . For example,  $170 \sin(\omega t + \phi) \equiv (170/\sqrt{2}) \angle \phi = 120 \angle \phi$ .

## ELECTRO-MAGNETIC MOTOR

*Nikola Tesla*

*Patented May 1, 1888*

*#381,968*

Tesla was an electrical genius from Serbo-Croatia. He is credited with over 700 inventions; this one perhaps his most important. He invented what is now known as the induction motor. It ran from alternating current (AC) and had no commutating brushes to burn up like the direct current (DC) motors used up to that time. An AC induction motor was inherently synchronous and therefore ran at a constant speed regardless of load; a great advantage in industrial applications.

Westinghouse bought the rights to this invention in July 1888. Through the 1890's, the induction motor's application to industry helped force the eventual world-wide domination by AC power systems which up to that time had been DC systems like those promoted by Edison. (© 1995, DewRay Products, Inc. Used with permission.)

## Defining Terms

**Impedance:** An impedance is a measure of the opposition to a current flow due to a sinusoidal voltage source. It is a complex number and has a real and an imaginary part.

**Phasor:** A phasor is the vector representation of a sinusoid in the complex domain. It represents the amplitude and the phase angle of a sinusoid.

**Sinusoid:** A sinusoid is a sinusoidal time-dependent periodic forcing function which has a maximum amplitude and can also have a phase delay.

## 106.1 Relationships between Voltages and Currents

## 106.2 Line Voltages

## 106.3 Power Relationship

## 106.4 Balanced Source and Balanced Load

## 106.5 Other Types of Interconnections

**Norman Balabanian***University of Florida, Gainesville*

A very important use of electricity is the driving of industrial equipment, such as electric motors, in the AC steady state. Suppose that the instantaneous AC voltage and current of such a load is given by

$$\begin{aligned}v(t) &= \sqrt{2}|V| \cos(\omega t + \alpha) \\i(t) &= \sqrt{2}|I| \cos(\omega t + \beta)\end{aligned}\quad (106.1)$$

Then the power to the load at any instant of time is

$$p(t) = |V||I|[\cos(\alpha - \beta) + \cos(2\omega t + \alpha + \beta)] \quad (106.2)$$

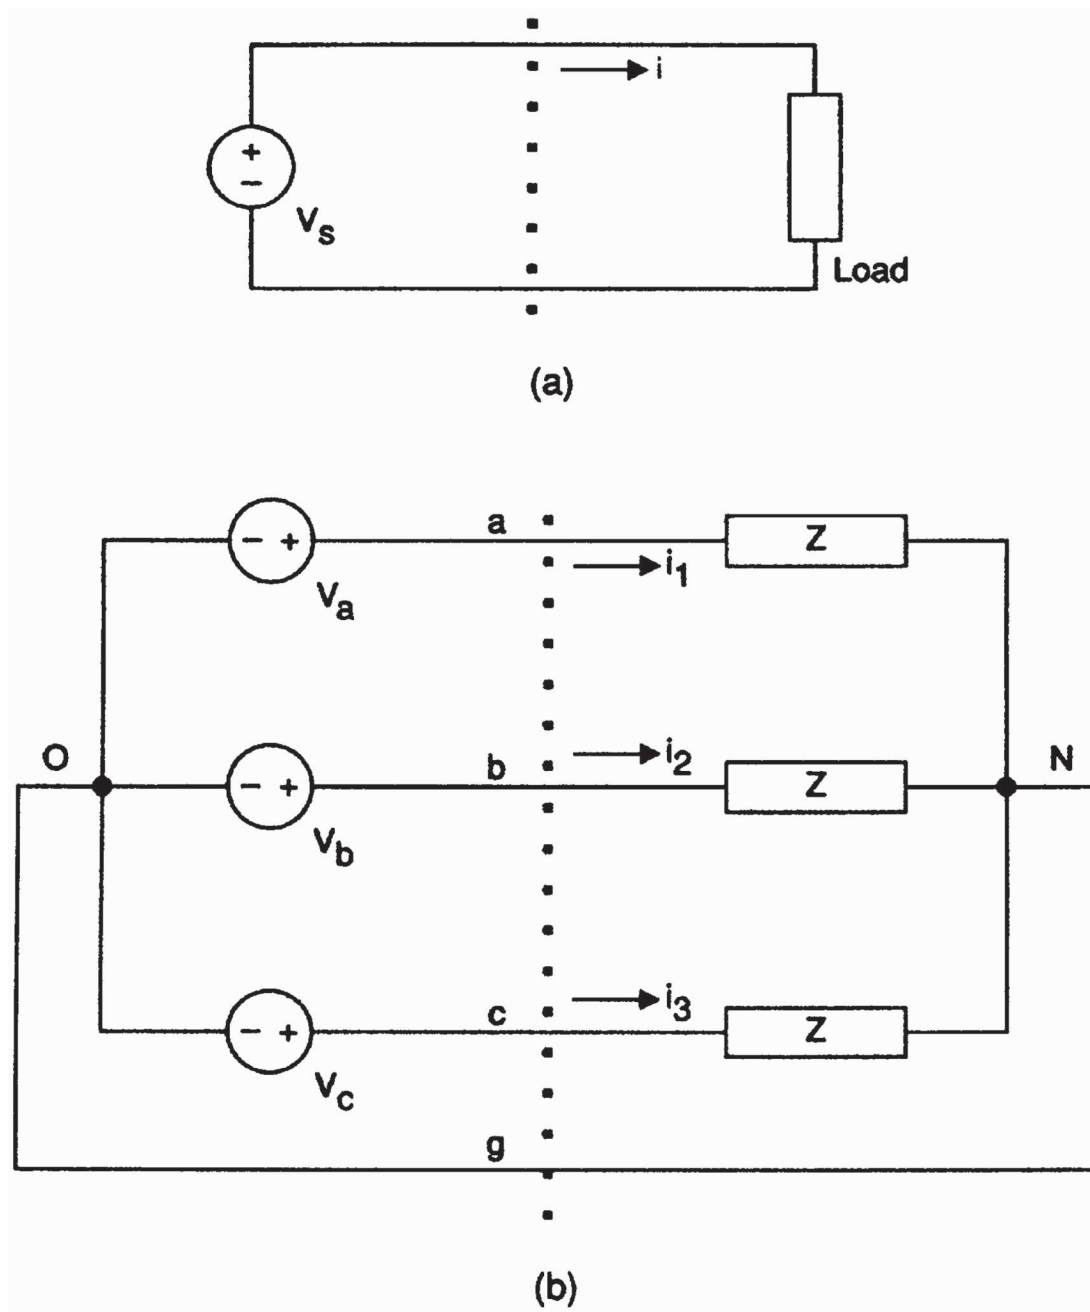

The instantaneous power has a constant term and a sinusoidal term at twice the frequency. The quantity in brackets fluctuates between a minimum value of  $\cos(\alpha - \beta) - 1$  and a maximum value of  $\cos(\alpha - \beta) + 1$ . This fluctuation of power delivered to the load has a great disadvantage when the load is an electric motor. A motor operates by receiving electric power and transmitting mechanical (rotational) power at its shaft. If the electric power is delivered to the motor in spurts, the motor is likely to vibrate. For satisfactory operation in such a case, a physically larger motor, with a larger shaft and flywheel, will be needed to provide more inertia for smoothing out the fluctuations than would be the case if the delivered power were constant.

This problem is overcome in practice by the use of what is called a *three-phase* system. This chapter will provide a brief discussion of three-phase power systems.

Consider the circuit in [Fig. 106.1](#). This is an interconnection of three AC sources to three loads connected in such a way that each source/load combination shares the return connection from O to N. The three sources can be viewed collectively as a single source, and the three loads—which are assumed to be identical—can be viewed collectively as a single load. Each of the individual

sources and loads is referred to as one *phase* of the three-phase system.

**Figure 106.1** Flow of power from source to load.

## 106.1 Relationships between Voltages and Currents

The three sources are assumed to have the same frequency; for this reason, they are said to be *synchronized*. It is also assumed that the three phase voltages have the same rms values and that the phase difference between each pair of voltages is  $\pm 120^\circ$  ( $2\pi/3$  rad). Thus, the voltages can be written:

$$\begin{aligned} v_a &= \sqrt{2}|V| \cos(\omega t + \alpha_1) & \leftrightarrow & V_a = |V|e^{j0^\circ} \\ v_b &= \sqrt{2}|V| \cos(\omega t + \alpha_2) & \leftrightarrow & V_b = |V|e^{-j120^\circ} \\ v_c &= \sqrt{2}|V| \cos(\omega t + \alpha_3) & \leftrightarrow & V_c = |V|e^{j120^\circ} \end{aligned} \quad (106.3)$$

The **phasors** representing the sinusoids have also been shown. For convenience the angle  $v_a$  has been chosen as the reference for angles;  $v_b$  *lags*  $v_a$  by  $120^\circ$  and  $v_c$  *leads*  $v_a$  by  $120^\circ$ . ■

Observe that the principle value of the angle lying between  $\pm 180^\circ$  is used. One could add  $360^\circ$  to the negative angle and use the value  $240^\circ$  instead.

There are two options for choosing the sequence of the phases. Once the particular phase that is to be the reference for angles is chosen and named "a," there are two possible sequences for the other two: either "abc" or "acb." This fact is hardly earthshaking; all it means is that the leading and lagging angles can be interchanged. Obviously, nothing fundamental is different in the second sequence. Hence, the discussion that follows is limited to the *abc phase sequence*.

Because the loads are identical, the rms values of the three currents shown in Fig. 106.1 will also be the same and the phase difference between each pair of them will be  $\pm 120^\circ$ . Thus, the currents can be written as

$$\begin{aligned} i_1 &= \sqrt{2}|I| \cos(\omega t + \beta_1) & \leftrightarrow & I_1 = |I|e^{j\beta_1} \\ i_2 &= \sqrt{2}|I| \cos(\omega t + \beta_2) & \leftrightarrow & I_2 = |I|e^{j(\beta_1 - 120^\circ)} \\ i_3 &= \sqrt{2}|I| \cos(\omega t + \beta_3) & \leftrightarrow & I_3 = |I|e^{j(\beta_1 + 120^\circ)} \end{aligned} \quad (106.4)$$

Perhaps a better form of visualizing the voltages and currents is a graphical one. Phasor diagrams for the voltages and the currents are shown separately in Fig. 106.2. The value of angle  $\beta_1$  will depend on the load. Something significant is clear from these diagrams. First,  $V_2$  and  $V_3$  are each the other's conjugate. So if they are added, the imaginary parts cancel and the sum will be real, as illustrated by the construction in the voltage diagram. Furthermore, the construction shows this sum to be negative and equal in magnitude to  $V_1$ . Hence, *the sum of the three voltages is zero*. The same is true of the sum of the three currents, as can be established graphically by a similar construction. The same results can be confirmed analytically by converting the phasor voltages and currents into rectangular form.

**Figure 106.2** Voltage and current phasor diagrams.

By Kirchhoff's current law applied at node N in Fig. 106.1, we find that the current in the return line is the sum of the three currents in Eq. (106.4). But since this sum was found to be zero, *the return line carries no current*. Hence, it can be removed entirely without affecting the operation of the system. The resulting circuit is redrawn in Fig. 106.3. It can be called a *three-wire* three-phase system. Because of its geometrical form, this connection of both the sources and the loads is said to be a **wye (Y) connection**, even though it is an upside-down Y.

**Figure 106.3** Wye-connected three-phase system.

Notice that the circuit in Fig. 106.3 is planar, with no lines crossing any other lines. That simplicity has been achieved at a price. Notice how the sequence (abc) of sources has been laid out

geometrically. Clearly, with the connections shown, the sequence of the loads is not the same as that of the sources. Having the same sequence would require interchanging the connections of the b and c sources with the bottom two loads. Doing that would result in one branch crossing another. However, nothing fundamental would change with either connection, assuming equal loads.

# SYSTEM OF DISTRIBUTION BY ALTERNATING CURRENTS

Charles P. Steinmetz

Patented January 29, 1895

#533,244

By the 1890's, Edison's light bulb had taken over the lighting of big cities, but his high-voltage DC method of supplying power had not. Alternating current (AC) was becoming the standard power source. It was cheaper and more efficient to transmit AC over long distances because it could be transformed up to high voltages and low currents (thinner wires, less losses) for transmission and then transformed back down to lower voltages for household current.

Steinmetz, while at General Electric's laboratory in Schenectady, New York, developed the system for 3-phase AC. This permitted polyphase industrial motors and machines to operate on the same system as single-phase electric light. This system of power distribution is substantially the same one in use throughout the world today. (©1993, DewRay Products, Inc. Used with permission.)

## 106.2 Line Voltages

---

In the three-wire three-phase system in Fig. 106.3, the neutral point O is not accessible, so phase voltages cannot be measured. The voltages that *are* available for measurement are the *line-to-line* or simply the *line* voltages:  $V_{ab}$ ,  $V_{bc}$ , and  $V_{ca}$ . By Kirchhoff's voltage law,

$$\begin{aligned} V_{ab} &= V_a - V_b = |V| - |V|e^{-j120^\circ} = \sqrt{3}|V|e^{j30^\circ} \\ V_{bc} &= V_b - V_c = |V|e^{-j120^\circ} - |V|e^{j120^\circ} = \sqrt{3}|V|e^{-j90^\circ} \\ V_{ca} &= V_c - V_a = |V|e^{j120^\circ} - |V| = \sqrt{3}|V|e^{j150^\circ} \end{aligned} \quad (106.5)$$

The interesting result is that all the line-voltage magnitudes are equal at  $\sqrt{3}$  times the phase-voltage magnitude. Thus, a 220 V line voltage corresponds to a phase voltage of 127 V. The line-voltage angles have the same mutual relationships as the phase-voltage angles; they are separated by  $\pm 120^\circ$ .

## 106.3 Power Relationship

---

The instantaneous power delivered by each of the sources has the form given in Eq. (106.2), consisting of a constant term representing the average power and a double-frequency sinusoidal term. The latter, being sinusoidal, can be represented by a phasor also. The only caveat is that a different frequency is involved here, so this power phasor should not be mixed with the voltage and current phasors in the same diagram or calculations. Let  $|S| = |V||I|$  be the apparent power delivered by each of the three sources, and let the three power phasors be  $S_a$ ,  $S_b$ , and  $S_c$ , respectively. Then,

$$\begin{aligned} S_a &= |S|e^{j(\alpha_1 + \beta_1)} = |S|e^{j\beta_1} \\ S_b &= |S|e^{j(\alpha_2 + \beta_2)} = |S|e^{j(-120^\circ + \beta_1 - 120^\circ)} = |S|e^{j(\beta_1 + 120^\circ)} \\ S_c &= |S|e^{j(\alpha_3 + \beta_3)} = |S|e^{j(120^\circ + \beta_1 + 120^\circ)} = |S|e^{j(\beta_1 - 120^\circ)} \end{aligned} \quad (106.6)$$

It is evident that the phase relationships between these three phasors are the same as the ones between the voltages and the currents. That is, the second leads the first by  $120^\circ$  and the third lags the first by  $120^\circ$ . Hence, just as with the voltages and the currents, the sum of these three power phasors will also be zero. This is a very significant result. It constitutes the motivation for using three-phase power over the pulsating power of a single-phase system. Although the instantaneous power delivered by each load has a constant component and a sinusoidal component, when the

three powers are added, the sinusoidal components add to zero, leaving only the constants. Thus, the total power delivered to the three loads is constant.

To determine the value of this constant power, let's use Eq. (106.2) as a model. The contribution of the  $k$ th source to the total (constant) power is  $|S| \cos(\alpha_k - \beta_k)$ . It can be easily verified that  $\alpha_k - \beta_k = \alpha_1 - \beta_1 = -\beta_1$ . The first equality follows from the relationships between the  $\alpha$  values from Eq. (106.3) and between the  $\beta$  values from Eq. (106.4). The choice of  $\alpha_1 = 0$  leads to the last equality. Hence, each phase contributes an equal amount to the total average power. If  $P$  is the total average power, then

$$P = P_a + P_b + P_c = 3P_a = 3|V||I| \cos(\alpha_1 - \beta_1) \quad (106.7)$$

Although the angle  $\alpha_1$  has been set equal to zero, it is shown in this equation for the sake of generality.

A similar result can be obtained for the reactive power. The reactive power of the  $k$ th phase is  $|S| \sin(\alpha_k - \beta_k) = |S| \sin(\alpha_1 - \beta_1)$ . If  $Q$  is the total reactive power, then

$$Q = 3|S| \sin(\alpha_1 - \beta_1)$$

## 106.4 Balanced Source and Balanced Load

What has just been described is a *balanced* three-phase three-wire power system. The three sources in practice are not three independent sources but consist of three different parts of the same generator. The same is true of the loads. ■

An AC power generator consists of (a) a *rotor* that is rotated by a *prime mover* (say a turbine) and produces a magnetic field that also rotates, and (b) a *stator* on which is wound one or more coils of wire. In three-phase systems the number of coils is three. The rotating magnetic field induces a voltage in each of the coils. The frequency of the induced voltage depends on the number of magnetic poles created on the rotor and the speed of rotation. These are fixed so as to "synchronize" with the 60 Hz frequency of the power system. The 120° leading and lagging phase relationships between these voltages is obtained by distributing the conductors of the coils around the circumference of the stator so that they are separated geometrically by 120°. Thus, the three sources described in the text are in reality a single physical device, a single generator. Similarly, the three loads might be the three windings on a three-phase motor, again a single physical device. Or they might be the windings of a three-phase transformer.

What has been described is ideal in a number of ways. First, the circuit can be *unbalanced* for example, by the loads being somewhat unequal. Second, since the real devices whose ideal model is a voltage source are coils of wire, each source should be accompanied by a branch consisting of the coil inductance and resistance. Third, since the power station (or the distribution transformer at some intermediate point) may be at some distance from the load, the parameters of the physical line carrying the power (the line inductance and resistance) must also be inserted in series between the source and the load.

The analysis of this chapter does not apply to an unbalanced system. An entirely new analytical

technique is required to do full justice to such a system.■

The technique for analyzing unbalanced circuits utilizes what are called *symmetrical components*.

An understanding of balanced circuits is a prerequisite to tackling the unbalanced case.

The last two of the conditions that make the circuit less than ideal (winding and line impedances) introduce algebraic complications but change nothing fundamental in the preceding theory. If these two conditions are taken into account, the appropriate circuit takes the form shown in Fig. 106.4. Here the internal impedance of a source (the winding impedance labeled  $Z_w$ ) and the line impedance  $Z_l$  connecting that source to its load are both connected in series with the corresponding load. Thus, instead of the impedance in each phase being  $Z$ , it is  $Z + Z_w + Z_l$ . Hence, the rms value of each current is

$$|I| = \frac{|V|}{|Z + Z_w + Z_l|} \quad (106.8)$$

instead of  $|V|/|Z|$ . All other previous results remain unchanged—namely, that the sum of the phase currents add to zero and that the sum of the phase powers is a constant. The detailed calculations just become a little more complicated.

**Figure 106.4** Three-phase circuit with nonzero winding and line impedances.

## 106.5 Other Types of Interconnections

All of the preceding development was based on both the sources and the loads being connected in a wye connection. Although the upside-down Y structure looks geometrically a little different from an upside-down tee circuit, electrically, the two are exactly the same. The wye is not, however, the only possible way to connect the phases of a three-phase system. Another possibility, the **delta connection**, so named because it looks like the Greek letter  $\Delta$ , is shown in Fig. 106.5. (In this figure the boxes can represent either sources or impedances.)

**Figure 106.5** Wye connection and delta connection.

By proper choice of the branch parameters, a tee can be made equivalent to a pi ( $\Pi$ ) at the terminals. We note that the delta is just an upside-down pi. As a pi, the junction between A and B is usually extended as the common terminal of a two-port.

If the structures in Fig. 106.5 are to be equivalent, the line voltages  $V_{ab}$ ,  $V_{bc}$ , and  $V_{ca}$  should be the same in both circuits. Similarly, the currents into the terminals should be the same in both. Note that, in the delta connection, the phase voltages are not evident; the only voltages available are the line voltages. Thus the voltages in the delta are the line voltages given in Eq. (106.3). In the wye the phase currents are also the currents in the lines. For the delta, however, the line currents are the difference between two phase currents, as noted in Fig. 106.5. For the line currents, a set of equations similar to Eq. (106.5) can be written in terms of the phase currents. Since the same  $120^\circ$  difference of angle exists between the phase currents as between the phase voltages, we would expect that the result for currents would be similar to the result for voltages in Eq. (106.5)—namely, that the line-current magnitudes in a delta connection would be  $\sqrt{3}$  times the phase-current magnitudes.

In a three-phase circuit the sources, the loads, or both, can be replaced by a delta equivalent; four different three-phase circuits can therefore be imagined: wye-wye, wye-delta, delta-wye, and delta-delta. There are no fundamental differences in analyzing each of these four circuits.

**Example.** A balanced, 120 V, three-wire three-phase transmission system in a wye-wye connection is represented by the circuit in Fig. 106.4. Assume that the winding impedances are

negligible but that the line impedances are given by  $Z_l = 0.1 + j0.2$  . Each load impedance is  $Z = 20 + j5$  . The following quantities are to be determined: (a) the line current magnitude; (b) the magnitude of the voltage across each load; (c) the average power, reactive power, and apparent power delivered to the load by each phase; (d) the average power, reactive power, and apparent power delivered by each source; and (e) the fraction of the power delivered by the system that is lost in the lines.

**Solution.** The solution is completely straightforward. First, the line current is found by dividing the phase voltage by the sum of the load and line impedances; the load voltage follows from the product of the load impedance by the line current. Thus,

$$|I| = \frac{120}{\sqrt{(20 + 0.1)^2 + (5 + 0.2)^2}} = 5.78 \text{ A}$$

$$|V_L| = |I||Z| = 5.78\sqrt{20^2 + 5^2} = 119.16 \text{ V}$$

The power calculations then follow:

$$|S_L| = |V_L||I| = 119.16(5.78) = 688.7 \text{ VA or}$$

$$|S_L| = |I|^2|Z_L| = 5.78^2\sqrt{20^2 + 5^2} = 688.7 \text{ VA}$$

$$P_L = R_L|I|^2 = 20(5.78)^2 = 668.2 \text{ W}$$

$$Q_L = X_L|I|^2 = 5(5.78)^2 = 167.0 \text{ VAR}$$

$$= \sqrt{|S_L|^2 - P_L^2} = \sqrt{688.7^2 - 668.2^2} = 166.8 \text{ VAR}$$

Perhaps the best way to find the power delivered by the sources is to determine the power lost in the line and then add this to the load power. Carrying out this approach leads to the following result:

$$P_l = 0.1|I|^2 = 3.34 \text{ W} \qquad P_s = 3.34 + 668.2 = 671.5 \text{ W}$$

$$Q_l = 0.2|I|^2 = 6.68 \text{ VAR} \qquad Q_s = 6.68 + 167.0 = 173.7 \text{ VAR}$$

Finally, the fraction of the source power that is lost in the line is  $3.34/671.5 = 0.005$  or 0.5%.

## Defining Terms

**Delta connection:** The sources or loads in a three-phase system connected end-to-end, forming a closed path, like the Greek letter  $\Delta$ .

**Phasor:** A complex number representing a sinusoid; its magnitude and angle are the rms value and the phase of the sinusoid, respectively.

**Wye connection:** The three sources or loads in a three-phasor system connected to have one common point, like the letter Y.

[107.1 Fundamentals](#)[107.2 Applications](#)Simple RL and RC Filters • Compound Filters • Constant- $k$  Filters •  $m$ -Derived Filters**Albert J. Rosa***University of Denver*

A **filter** is a frequency-sensitive two-port circuit that transmits signals in a band of frequencies and rejects (or attenuates) signals in other bands. The electric filter was invented during the First World War by two engineers working independently of each other—the American engineer G. A. Campbell and the German engineer K. W. Wagner. These devices were developed to serve the growing areas of telephone and radio communication. Today, filters are found in all types of electrical and electronic applications from power to communications. Filters can be both active and passive. In this section we will confine our discussion to those filters that employ no active devices for their operation. The main advantage of passive filters over active ones is that they require no power (other than the signal) to operate.

---

## 107.1 Fundamentals

The basis for filter analysis involves the determination of a filter circuit's sinusoidal steady state response from its transfer function  $T(j\omega)$ . [Some references use  $H(j\omega)$  for the transfer function.] The filter's transfer function  $T(j\omega)$  is a complex function and can be represented through its gain  $|T(j\omega)|$  and phase  $\angle T(j\omega)$  characteristics. The gain and phase responses show how the filter alters the amplitude and phase of the input signal to produce the output response. The two characteristics of the filter's transfer function can be used to describe its frequency response. The terminology used to describe the gain and phase characteristics shows how the circuit modifies the input amplitude and phase angle to produce the output sinusoid. The two characteristics describe the *frequency response* of the circuit since they depend on the frequency of the input sinusoid. The signal-processing performance of devices, circuits, and systems is often specified in terms of frequency response. The gain and phase functions can be expressed mathematically or graphically as *frequency-response* plots. [Figure 107.1](#) shows examples of gain and phase responses versus frequency,  $\omega$ .

**Figure 107.1** Low-pass filter characteristics showing passband, stopband, and the cutoff frequency,  $\omega_C$  .

The terminology used to describe the frequency response of circuits and systems is based on the form of the gain plot. For example, at high frequencies the gain in [Fig. 107.1](#) falls off so that output signals in this frequency range are reduced in amplitude. The range of frequencies over which the output is significantly attenuated is called the *stopband*. At low frequencies the gain is essentially constant and there is relatively little attenuation. The frequency range over which there is little attenuation is called a *passband*. The frequency associated with the boundary between a passband and an adjacent stopband is called the *cutoff frequency* ( $\omega_C = 2\pi f_C$ ) . In general, the transition from the passband to the stopband, called the *transition band*, is gradual, so the precise location of

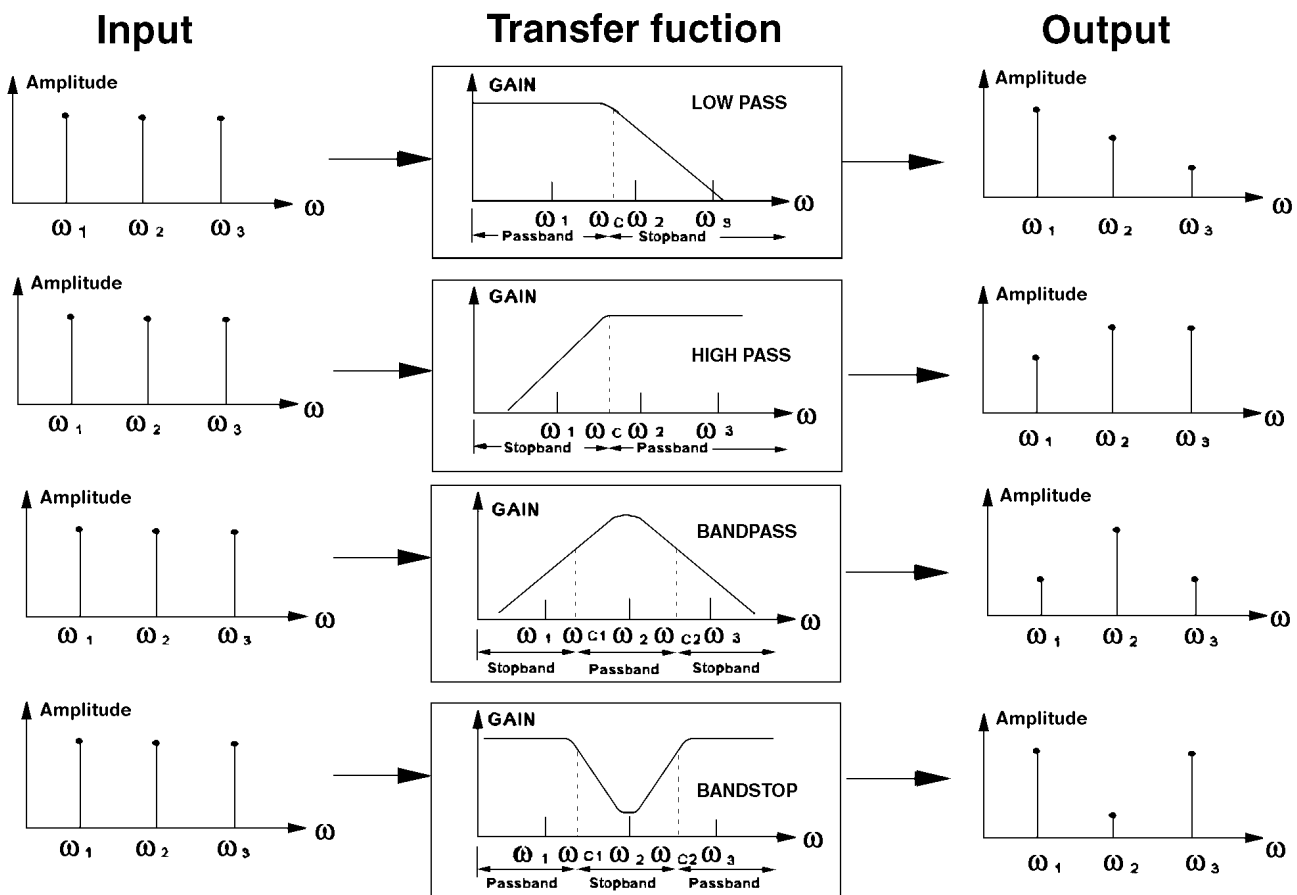

the cutoff frequency is a matter of definition. The most widely used approach defines the cutoff frequency as the frequency at which the gain has decreased by a factor of  $1/\sqrt{2} = 0.707$  from its maximum value in the passband.

This definition is based on the fact that the power delivered to a resistance by a sinusoidal current or voltage waveform is proportional to the square of its amplitude. At a cutoff frequency the gain is reduced by a factor of  $1/\sqrt{2}$  and the square of the output amplitude is reduced by a factor of one half. For this reason the cutoff frequency is also called the *half-power frequency*.

There are four prototypical filters. These are *low pass* (LP), *high pass* (HP), *band pass* (BP), and *bandstop* (BS). Figure 107.2 shows how the amplitude of an input signal consisting of three separate frequencies is altered by each of the four prototypical filter responses. The low-pass filter passes frequencies below its cutoff frequency  $\omega_C$ , called its *passband*, and attenuates the frequencies above the cutoff, called its *stopband*. The high-pass filter passes frequencies above the cutoff frequency  $\omega_C$  and attenuates those below. The band-pass filter passes those frequencies that lie between two cutoff frequencies,  $\omega_{C1}$  and  $\omega_{C2}$ , its *passband*, and attenuates those frequencies that lie outside the passband. Finally, the band-reject filter attenuates those frequencies that lie in its reject or stopband, between  $\omega_{C1}$  and  $\omega_{C2}$ , and passes all others.

**Figure 107.2** Four prototype filters and their effects on an input signal consisting of three frequencies.

The *bandwidth* of a gain characteristic is defined as the frequency range spanned by its passband. For the band-pass case in Fig. 107.2 the bandwidth is the difference in the two cutoff frequencies.

$$BW = \omega_{C2} - \omega_{C1} \quad (107.1)$$

This equation applies to the low-pass response with the lower cutoff frequency  $\omega_{C1}$  set to zero. In other words, the bandwidth of a low-pass circuit is equal to its cutoff frequency ( $BW = \omega_C$ ). The bandwidth of a high-pass characteristic is infinite since the upper cutoff frequency  $\omega_{C1}$  is infinity. For the band-stop case, Eq. (107.1) defines the bandwidth of the stopband rather than the passbands.

Frequency-response plots are usually made using logarithmic scales for the frequency variable because the frequency ranges of interest often span several orders of magnitude. A logarithmic frequency scale compresses the data range and highlights important features in the gain and phase responses. The use of a logarithmic frequency scale involves some special terminology. A frequency range whose end points have a 2:1 ratio is called an *octave* and one with a 10:1 ratio is called a *decade*.

In frequency-response plots the gain  $|T(j\omega)|$  is often expressed in *decibels* (dB), defined as

$$|T(j\omega)|_{dB} = 20 \log_{10} |T(j\omega)| \quad (107.2)$$

Gains expressed in decibels can be either positive, negative, or zero. A gain of zero dB means that  $|T(j\omega)| = 1$  —that is, the input and output amplitudes are equal. A positive dB gain means the output amplitude exceeds the input since  $|T(j\omega)| > 1$ , whereas a negative dB gain means the output amplitude is smaller than the input since  $|T(j\omega)| < 1$ . A cutoff frequency usually occurs when the gain is reduced from its maximum passband value by a factor  $1/\sqrt{2}$  or 3 dB.

Figure 107.3 shows the asymptotic gain characteristics of ideal and real low-pass filters. The gain of the *ideal filter* is unity (0 dB) throughout the passband and zero ( $-\infty$  dB) in the stopband. It also has an infinitely narrow transition band. The asymptotic gain responses of real low-pass filters show that we can only approximate the ideal response. As the order of the filter or number of poles  $n$  increases, the approximation improves since the asymptotic slope in the stopband is  $-20 \times n$  dB/decade. On the other hand, adding poles requires additional stages in a cascade realization, so there is a trade-off between (1) filter complexity and cost and (2) how closely the filter gain approximates the ideal response.

**Figure 107.3** The effect of increasing the order  $n$  of a filter relative to an ideal filter.

Figure 107.4 shows how low-pass filter requirements are often specified. To meet the specification, the gain response must lie within the unshaded region in the figure, as illustrated by the two responses shown in Fig. 107.4. The parameter  $T_{\max}$  is the *passband gain*. In the passband the gain must be within 3 dB of  $T_{\max}$  and must equal  $T_{\max}/\sqrt{2}$  at the cutoff frequency  $\omega_C$ . In the stopband the gain must decrease and remain below a gain of  $T_{\min}$  for all  $\omega \geq \omega_{\min}$ . A low-pass filter design requirement is usually defined by specifying values for these four parameters. The

parameters  $T_{\max}$  and  $\omega_C$  define the passband response, whereas  $T_{\min}$  and  $\omega_{\min}$  specify how rapidly the stopband response must decrease.

**Figure 107.4** Parameters for specifying low-pass filter requirements.

## 107.2 Applications

### Simple RL and RC Filters

A first-order LP filter has the following transfer function:

$$T(s) = \frac{K}{s + \alpha} \quad (107.3)$$

where for a passive filter  $K \leq \alpha$  and  $\alpha = \omega_C$ . This transfer function can be realized using either of the two circuits shown in Fig. 107.5. For sinusoidal response the respective transfer functions are

$$T(j\omega)_{RL} = \frac{R/L}{j\omega + (R/L)}; \quad T(j\omega)_{RC} = \frac{1/RC}{j\omega + (1/RC)} \quad (107.4)$$

For these filters the passband gain is one and the cutoff frequency is determined by  $R/L$  for the RL filter and  $1/RC$  for the RC filter. The gain  $|T(j\omega)|$  and phase  $\angle T(j\omega)$  plots of these circuits are shown in Fig. 107.1.

**Figure 107.5** Single-pole LP filter realizations: (a) RL, (b) RC.

A first-order HP filter is given by the following transfer function:

$$T(s) = \frac{Ks}{s + \alpha} \quad (107.5)$$

where, for a passive filter,  $K \leq 1$  and  $\alpha$  is the cutoff frequency. This transfer function can be realized using either of the two circuits shown in Fig. 107.6. For sinusoidal response the respective transfer functions are

$$T(j\omega)_{RL} = \frac{j\omega}{j\omega + (R/L)}; \quad T(j\omega)_{RC} = \frac{j\omega}{j\omega + (1/RC)} \quad (107.6)$$

For the LP filters the passband gain is one and the cutoff frequency is determined by  $R/L$  for the RL filter and  $1/RC$  for the RC filter. The gain  $|T(j\omega)|$  and phase  $\angle T(j\omega)$  plots of these circuits are shown in Fig. 107.7.

**Figure 107.6** Single-pole HP filter realizations: (a) RL, (b) RC.

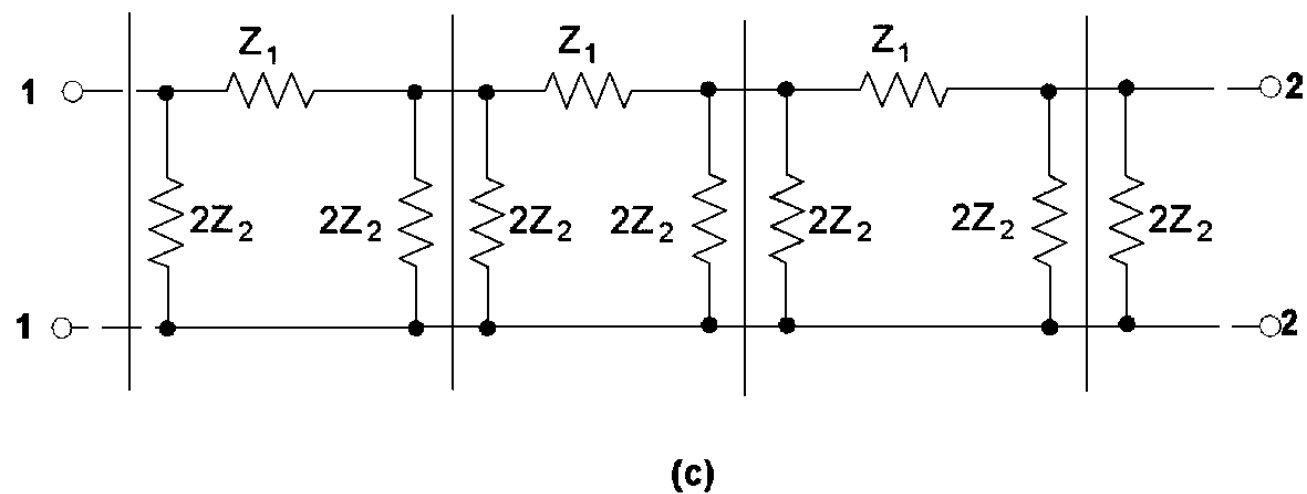

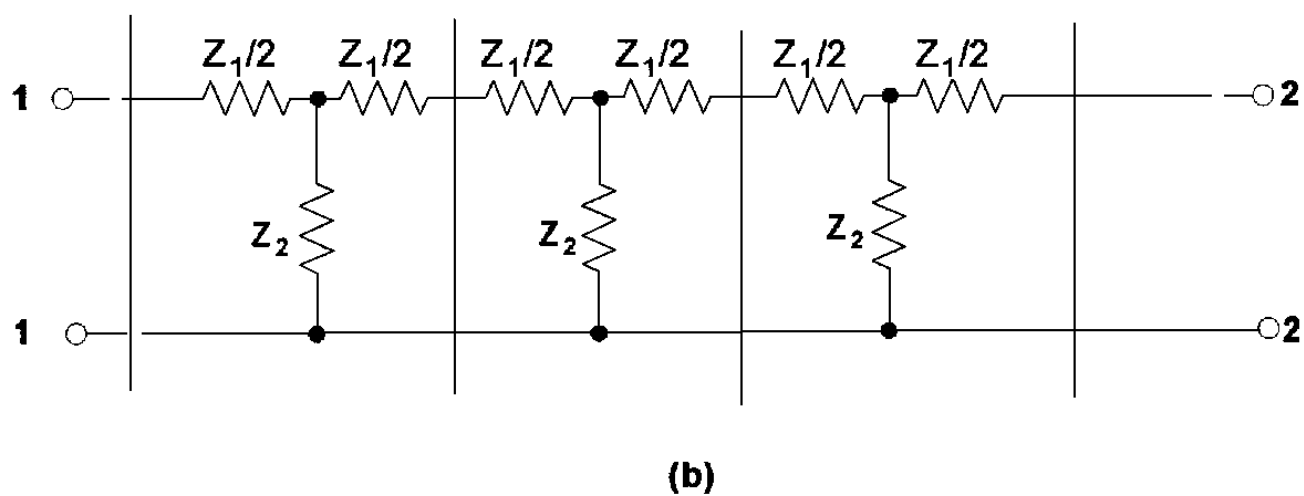

## Compound Filters

Compound filters are higher-order filters obtained by cascading lower-order designs. *Ladder circuits* are an important class of compound filters. Two of the more common passive ladder circuits are the *constant-k* and the *m-derived* filter (either of which can be configured using a *T-section*,  $\pi$ -*section*, *L-section*, or combinations thereof), the **bridge-T network** and **parallel-T network**, and the **Butterworth** and **Chebyshev** realizations. Only the first two will be discussed in this section. Figure 107.8(a) shows a standard ladder network consisting of two impedances,  $Z_1$  and  $Z_2$ , organized as an L-section filter. Figures 107.8(b) and (c) show how the circuit can be redrawn to represent a T-section or  $\Pi$ -section filter, respectively.

**Figure 107.7** High-pass filter characteristics showing passband, stopband, and the cutoff frequency,  $\omega_c$ .

**Figure 107.8** Ladder networks: (a) standard L-section, (b) T-section, (c)  $\Pi$ -section.

T- and  $\Pi$ -section filters are usually designed to be symmetrical so that either can have its input and output reversed without changing its behavior. The L-section is unsymmetrical and orientation is important. Since cascaded sections "load" each other, the choice of termination impedance is important. The *image impedance*,  $Z_i$ , of a symmetrical filter is the impedance with which the filter must be terminated in order to "see" the same impedance at its input terminals. The image impedance of a filter can be found from

$$Z_i = \sqrt{Z_{1O} Z_{1S}} \quad (107.7)$$

where  $Z_{1O}$  is the input impedance of the filter with the output terminals open circuited, and  $Z_{1S}$  is its input impedance with the output terminals short circuited. For symmetrical filters the output and input can be reversed without any change in its image impedance—that is,

$$\begin{aligned} Z_{1i} &= \sqrt{Z_{1O} Z_{1S}} \quad \text{and} \quad Z_{2i} = \sqrt{Z_{2O} Z_{2S}} \\ Z_{1i} &= Z_{2i} = Z_i \end{aligned} \quad (107.8)$$

The concept of matching filter sections and terminations to a common image impedance permits the development of symmetrical filter designs.

The image impedances of T- and  $\Pi$ -section filters are given as

$$\begin{aligned} Z_{iT} &= \sqrt{Z_{1O} Z_{1S}} = \sqrt{\frac{1}{4} Z_1^2 + Z_1 Z_2} \quad \text{and} \\ Z_{i\Pi} &= \sqrt{Z_{1O} Z_{1S}} = \frac{Z_1 Z_2}{\sqrt{(1/4) Z_1^2 + Z_1 Z_2}} \end{aligned} \quad (107.9)$$

The image impedance of an L-section filter, being unsymmetrical, depends on the terminal pair being calculated. For the L-section shown in [Fig. 107.8\(a\)](#) image impedances are

$$\begin{aligned} Z_{1iL} &= \sqrt{\frac{1}{4} Z_1^2 + Z_1 Z_2} = Z_{iT} \quad \text{and} \\ Z_{2iL} &= \frac{Z_1 Z_2}{\sqrt{(1/4) Z_1^2 + Z_1 Z_2}} = Z_{i\Pi} \end{aligned} \quad (107.10)$$

These equations show that the image impedance of an L-section at its input is equal to the image impedance of a T-section, whereas the image impedance of an L-section at its output is equal to the image impedance of a  $\Pi$ -section. This relationship is important in achieving an optimum termination when cascading L-sections with T- and/or  $\Pi$ -sections to form a composite filter.

Since  $Z_1$  and  $Z_2$  vary significantly with frequency, the image impedances of T- and  $\Pi$ -sections will also change. This condition does not present any particular problem in combining any number of equivalent filter sections together, since their impedances vary equally at all frequencies.

To develop the theory of constant- $k$  and  $m$ -derived filters, consider the circuit of [Fig. 107.9](#). The

current transfer function in the sinusoidal steady state is given by

$$T(j\omega) = |T(j\omega)| \angle T(j\omega) = I_2/I_1 \quad :$$

$$\begin{aligned} T(j\omega) &= |T(j\omega)| \angle T(j\omega) \\ &= \frac{I_2(j\omega)}{I_1(j\omega)} = e^{-\alpha} e^{-j\beta} = e^{-\gamma} \end{aligned} \quad (107.11)$$

where  $\alpha$  is the attenuation in dB,  $\beta$  is the phase shift in radians, and  $\gamma$  is the image transfer function. For the circuit shown in Fig. 107.9 the following relationship can be derived:

$$\tanh \gamma = \sqrt{Z_{1S}/Z_{1O}} \quad (107.12)$$

This relationship and those in Eq. (107.8) will be used to develop the constant- $k$  and  $m$ -derived filters.

**Figure 107.9** Circuit for determining the transfer function of a T-section filter.

## Constant- $k$ Filters

O. Zobel developed an important class of symmetrical filters called *constant- $k$  filters* with the conditions that  $Z_1$  and  $Z_2$  are purely reactive—that is,  $\pm X(j\omega)$  and

$$Z_1 Z_2 = k^2 = R^2 \quad (107.13)$$

Note that the units of  $k$  are ohms; in modern references the  $k$  is replaced by an  $R$ . The advantage of this type of filter is that the image impedance in the passband is a pure resistance, whereas in the stopband it is purely reactive. Hence if the termination is a pure resistance and equal to the image impedance, all the power will be transferred to the load since the filter itself is purely reactive. Unfortunately, the value of the image impedance varies significantly with frequency, and any termination used will result in a mismatch except at one frequency.

In LC constant- $k$  filters,  $Z_1$  and  $Z_2$  have opposite signs, so that  $Z_1 Z_2 = \pm jX_1 \mp jX_2 = +X_1 X_2 = R^2$ . The image impedances become

$$Z_{iT} = R\sqrt{1 - (-Z_1/4Z_2)} \quad \text{and} \quad Z_{i\Pi} = \frac{R}{\sqrt{1 - (-Z_1/4Z_2)}} \quad (107.14)$$

Therefore, in the stopband and passband, we have the following relations for standard T- or  $\Pi$ -sections, where  $n$  represents the number of identical sections:

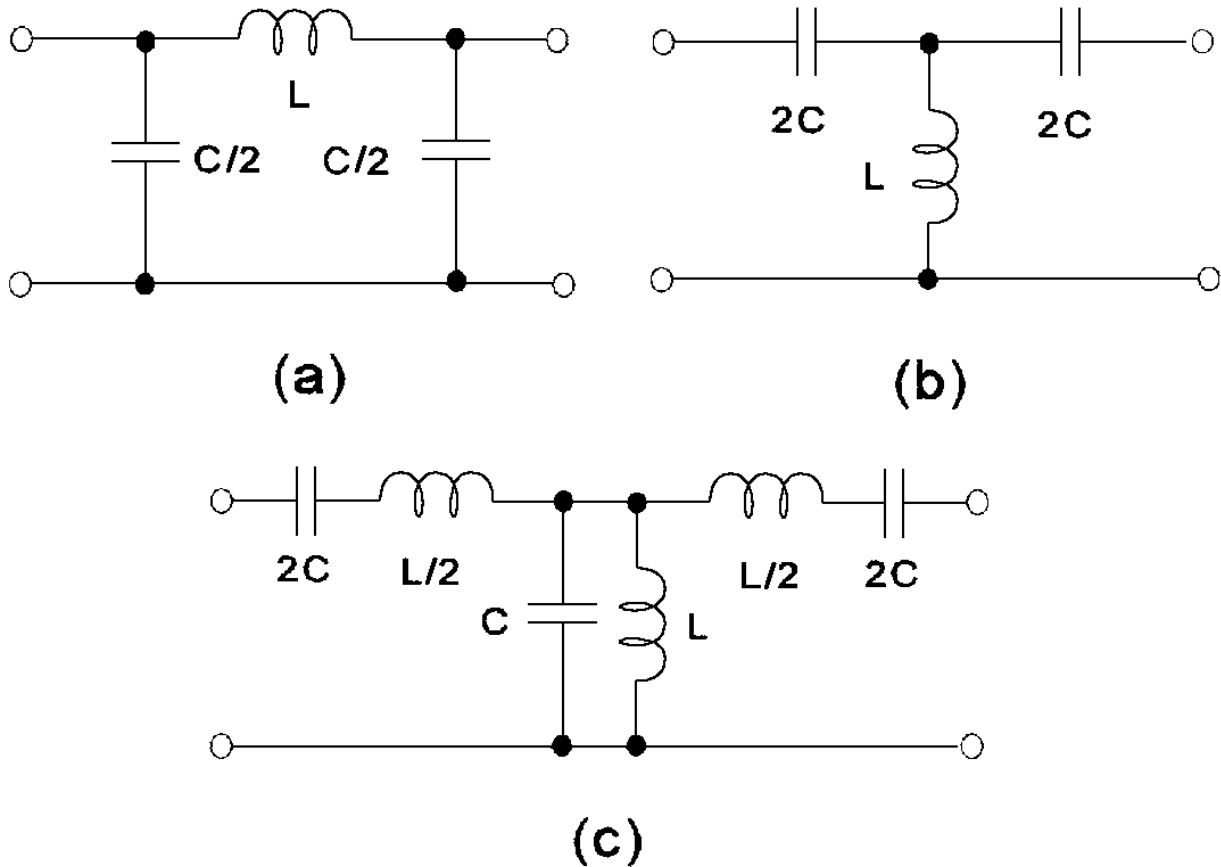

$$\begin{aligned} &\text{Stopband} \\ &\alpha = 2n \cosh^{-1} \sqrt{-Z_1/4Z_2} \\ &\beta = \pm n\pi, \pm 3n\pi, \dots \\ &\text{Passband} \\ &\alpha = 0 \\ &\beta = 2n \sin^{-1} \sqrt{-Z_1/4Z_2} \end{aligned} \quad (107.15)$$

Figure 107.10 shows normalized plots of  $\alpha$  and  $\beta$  versus  $\sqrt{-Z_1/4Z_2}$ . These curves are generalized and apply to low-pass, high-pass, band-pass, or band-reject filters. Figure 107.11 shows examples of a typical LP  $\Pi$ -section, an HP T-section, and a BP T-section.

**Figure 107.10** Normalized plots of attenuation and phase angle for various numbers of sections  $n$ .

**Figure 107.11** Typical sections: (a) LP  $\Pi$ -section, (b) HP T-section, (c) BP T-section.

## ***m*-Derived Filters**

The need to develop a filter section that could provide high attenuation in the stopband near the cutoff frequency prompted the development of the *m*-derived filter. O. Zobel developed a class of filters that had the same image impedance as the constant-*k* but had a higher attenuation near the cutoff frequency. The impedances in the *m*-derived filter were related to those in the constant-*k* as

$$Z_{1m} = mZ_{1k} \quad \text{and} \quad Z_{2m} = \left( \frac{1 - m^2}{4m} \right) Z_{1k} + \frac{1}{m} Z_{2k} \quad (107.16)$$

where *m* is a positive constant  $\leq 1$ . If *m* = 1 then the impedances reduce to those of the constant-*k*. [Figure 107.12](#) shows generalized *m*-derived T- and  $\Pi$ -sections.

**Figure 107.12**  $m$ -derived filters:(a) T-section, (b)  $\Pi$ -section.

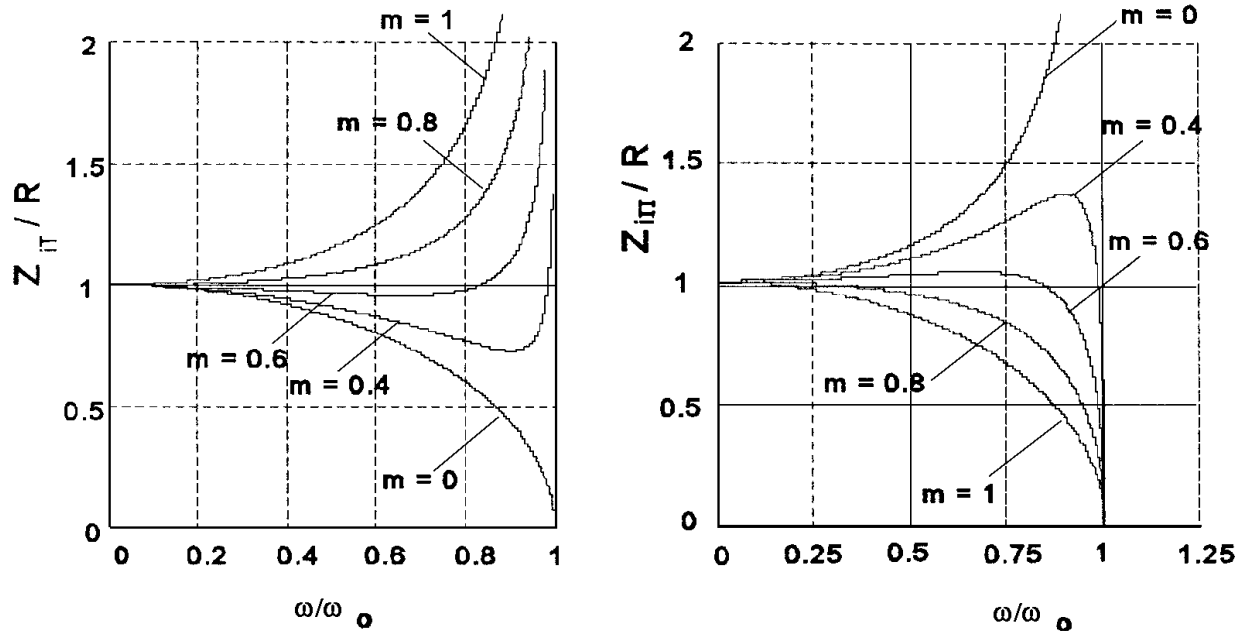

The advantage of the  $m$ -derived filter is that it gives rise to infinite attenuation at a selectable frequency just beyond cutoff. This singularity gives rise to a more rapid attenuation in the stopband than can be obtained using constant- $k$  filters. Figure 107.13 shows the attenuation curve for a single  $m$ -derived LP stage for two values of  $m$ . The smaller  $m$  becomes, the steeper the attenuation near the cutoff, but also the lesser the attenuation at higher frequencies.

**Figure 107.13** Attenuation curves for a single-stage filter with  $m = 0.6$  and  $m = 0.9$ .

Constant- $k$  filters have an image impedance in the passband that is always real but that varies with frequency, making the choice of an optimum termination difficult. The impedance of an  $m$ -derived filter also varies, but how it varies depends on  $m$ . Figure 107.14 shows how the impedance varies with frequency (both normalized) and  $m$ . In most applications,  $m$  is chosen to be 0.6, keeping the image impedance nearly constant over about 80% of the passband.

**Figure 107.14**  $Z_{iT}/R$  and  $Z_{i\Pi}/R$  versus normalized frequency for various values of  $m$ .

## Defining Terms

**Bridge-T network:** A two-port network that consists of a basic T-section and another element connected so as to "bridge across" the two arms. Such networks find applications as band rejection filters, calibration bridges, and feedback networks.

**Butterworth filters:** Ladder networks that enjoy a unique passband frequency response characteristic that remains very constant until near the cutoff, hence the designation "maximally flat." This filter has its critical frequency remain fixed regardless of the number of stages employed. It obtains this characteristic by realizing a transfer function built around a Butterworth polynomial.

**Chebyshev filters:** A variant of the Butterworth design that achieves a significantly steeper transition band for the same number of poles. Although the Chebyshev filter also maintains the integrity of its critical frequency regarding the number of poles, it trades the steeper roll-off for a fixed ripple—usually specified as 1 dB or 3 dB—in the passband. Chebyshev filters are also called *equal-ripple* or *stagger-tuned* filters. They are designed by realizing a transfer function using a Chebyshev polynomial.

**Parallel-T networks:** A two-port network that consists of two separate T-sections in parallel with only the ends of the arms and the stem connected. Parallel-T networks have applications similar to those of the bridge-T but can produce narrower attenuation bandwidths.

The function of power distribution is to deliver to consumers economic, reliable, and safe electrical energy in a manner that conforms to regulatory standards. Power distribution systems receive electric energy from high-voltage transmission systems and deliver energy to consumer service-entrance equipment. Systems typically supply alternating current at voltage levels ranging from 120 V to 46 kV.

Figure 108.1 illustrates aspects of a distribution system. Energy is delivered to the distribution substation (shown inside the dashed line) by three-phase transmission lines. A transformer in the substation steps the voltage down to the distribution primary system voltage—in this case, 12.47 kV. Primary distribution lines leave the substation carrying energy to the consumers. The substation contains a breaker that may be opened to disconnect the substation from the primary distribution lines. If the breaker is opened, outside the substation there is a normally open supervisory switch that may be closed in order to provide an alternate source of power for the customers normally served by the substation. The substation also contains a capacitor bank used for either voltage or power factor control.

**Figure 108.1** Distribution system schematic.

Four types of customers, along with representative distribution equipment, are shown in [Fig. 108.1](#). A set of loads requiring high reliability of service is shown being fed from an underground three-phase secondary network cable grid. A single fault does not result in an interruption to this set of loads. A residential customer is shown being supplied from a two-wire, one-phase overhead lateral. Commercial and industrial customers are shown being supplied from the three-phase, four-wire, overhead primary feeder. At the industrial site a capacitor bank is used to control power factor. Except for the industrial customer, all customers shown have 240/120 V service. The industrial customer has 480Y/277 V service.

For typical electric utilities in the U.S., investment in distribution ranges from 35 to 60% of total capital investment.

## 108.1 Equipment

---

[Figure 108.1](#) illustrates a typical arrangement of some of the most common equipment. Equipment may be placed into the general categories of transmission, protection, and control.

Arresters protect distribution system equipment from transient overvoltages due to lightning or switching operations. In overvoltage situations the arrester provides a low-resistance path to ground for currents to follow.

Capacitor banks are energy storage devices primarily used to control voltage and power factor. System losses are reduced by the application of capacitors.

Conductors are used to transmit energy and may be either bare or insulated. Bare conductors have better thermal properties and are generally used in overhead construction where contact is unlikely. Insulated cables are used in underground/conduit construction. Concentric neutral and tape-shielded cables provide both a phase conductor and a return path conductor in one unit.

Distribution lines are made up of conductors and are classified according to primary voltage, the number of **phases**, number of conductors, and return path. The three-phase, four-wire, multigrounded system is the most common primary system, where one conductor is installed for each of the three phases and the fourth conductor is a neutral that provides a **return current path**. *Multigrounded* means that the neutral is grounded at many points, so that the earth provides a parallel path to the neutral for return current. Three-phase, three-wire primary systems, or *delta-connected systems*, are rarely used because faults therein are more difficult to detect. A lateral is a branch of the system that is shorter in length, more lightly loaded, or has a smaller conductor size than the primary feeder.

Distribution transformers step the voltage down from the primary circuit value to the customer utilization level, thus controlling voltage magnitude. Sizes range from 10 to 2500 kVA. Distribution transformers are installed on poles, ground-level pads, or in underground vaults. A specification of 12470Y/7200 V for the high-voltage winding of a single-phase transformer means the transformer may be connected in a line-to-neutral "wye" connection for a system with a line-to-line voltage of 12470 V. A specification of 240/120 V for the low-voltage winding means the transformer may be used for a three-wire connection with 120 V midtap voltage and 240 V full-winding voltage. A specification of 480Y/277 V for the low voltage winding means the winding may be wye-connected for a three-phase, four-wire service to deliver 480 V line-to-line

and 277 V line-to-neutral.

Distribution substations consist of one or more step-down power transformers configured with switch gear, protective devices, and voltage regulation equipment for the purpose of supplying, controlling, switching, and protecting the primary feeder circuits. The voltage is stepped down for safety and flexibility of handling in congested consumer areas. Overcurrent protective devices open and interrupt current flow in order to protect people and equipment from **fault** current. Switches are used for control to interrupt or redirect power flow. Switches may be operated either manually or remotely with supervisory control. Switches are usually rated to interrupt load current and may be either pad or pole mounted.

Power transformers are used to control and change voltage level. Power transformers equipped with **tap-changing mechanisms** can control secondary voltage over a typical range of plus or minus 10%.

Voltage regulators are autotransformers with tap-changing mechanisms that may be used throughout the system for voltage control. If the voltage at a remote point is to be controlled, then the regulator can be equipped with a line drop compensator that may be set to regulate the voltage at the remote point based upon local voltage and current measurements.

## 108.2 System Divisions and Types

---

Distribution transformers separate the primary system from the secondary. Primary circuits transmit energy from the distribution substation to customer distribution transformers. Three-phase distribution lines that originate at the substation are referred to as *primary feeders* or *primary circuits*. Primary feeders are illustrated in [Fig. 108.1](#). Secondary circuits transmit energy from the distribution transformer to the customer's service entrance. Line-to-line voltages range from 208 to 600 V.

Radial distribution systems provide a single path of power flow from the substation to each individual customer. This is the least costly system to build and operate, and thus the most widely used.

Primary networks contain at least one loop that generally may receive power from two distinct sources. This design results in better continuity of service. A primary network is more expensive than the radial system design because more protective devices, switches, and conductors are required.

Secondary networks are normally underground cable grids providing multiple paths of power flow to each customer. A secondary network generally covers a number of blocks in a downtown area. Power is supplied to the network at a number of points via network units, consisting of a network transformer in series with a network protector. A network protector is a circuit breaker connected between the secondary winding of the network transformer and the secondary network itself. When the network is operating properly, energy flows into the network. The network protector opens when reverse energy flow is detected, such as may be caused by a fault in the primary system.

## 108.3 Electrical Analysis, Planning, and Design

---

The distribution system is planned, designed, constructed, and operated based on the results of electrical analysis. Generally, computer-aided analysis is used.

Line impedances are needed by most analysis applications. Distribution lines are electrically unbalanced due to loads, unequal distances between phases, dissimilar phase conductors, and single-phase or two-phase laterals. Currents flow in return paths due to the imbalance in the system. Three-phase, four-wire, multigrounded lines have two return paths—the neutral conductor and earth. Three-phase, multigrounded concentric neutral cable systems have four return paths. The most accurate modeling of distribution system impedance is based upon Carson's equations. With this approach a  $5 \times 5$  impedance matrix is derived for a system with two return paths, and a  $7 \times 7$  impedance matrix is derived for a system with four return paths. For analysis, these matrices are reduced to  $3 \times 3$  matrices that relate phase voltage drops (i.e.,  $\Delta V_A, \Delta V_B, \Delta V_C$ ) to phase currents (i.e.,  $I_A, I_B, I_C$ ), as indicated by

$$\begin{bmatrix} \Delta V_A \\ \Delta V_B \\ \Delta V_C \end{bmatrix} = \begin{bmatrix} Z_{AA} & Z_{AB} & Z_{AC} \\ Z_{BA} & Z_{BB} & Z_{BC} \\ Z_{CA} & Z_{CB} & Z_{CC} \end{bmatrix} \begin{bmatrix} I_A \\ I_B \\ I_C \end{bmatrix}$$

Load analysis forms the foundation of system analysis. Load characteristics are time varying and depend on many parameters, including connected consumer types and weather conditions. The load demand for a given customer or group of customers is the load averaged over an interval of time, say 15 minutes. The peak demand is the largest of all demands. The peak demand is of particular interest since it represents the load that the system must be designed to serve. Diversity relates to multiple loads having different time patterns of energy use. Due to diversity, the peak demand of a group of loads is less than the sum of the peak demands of the individual loads. For a group of loads,

$$\text{Diversity factor} = \frac{\text{Sum of individual load peaks}}{\text{Group peak}}$$

Loads may be modeled as either lumped parameter or distributed. Lumped parameter load models include constant power, constant impedance, constant current, voltage-dependent, and combinations thereof. Generally, equivalent lumped parameter load models are used to model distributed loads. Consider the line section of length  $L$  shown in [Fig. 108.2\(a\)](#), with a uniformly distributed load current that varies along the length of the line as given by

$$i(x) = \frac{I_2 - I_1}{L}x + I_1$$

The total load current drawn by the line section is thus

$$I_L = I_2 - I_1$$

An equivalent lumped parameter model for the uniformly distributed current load is shown in [Fig.](#)

108.2(b).

**Figure 108.2** (a) Line section model with distributed load current; (b) lumped parameter equivalent model.

Load forecasting is concerned with determining load magnitudes during future years from customer growth projections. Short-range forecasts generally have time horizons of approximately five years, whereas long-range forecasts project to around twenty years.

Power flow analysis determines system voltages, currents, and power flows. Power flow results are checked to ensure that voltages fall within allowable limits, that equipment overloads do not exist, and that phase imbalances are within acceptable limits. For primary and secondary networks, power flow methods used in transmission system analysis are applied. For radially operated systems, the ladder method is used. The actual implementation of the ladder method may vary with the type of load models used. All ladder load flow methods assume the substation bus voltage is known. An algorithm for the ladder method is as follows:

*Step 1.* Assume a value for all node voltages throughout the circuit. Generally, assumed voltages are set equal to the substation voltage.

*Step 2.* At each load in the circuit, calculate the current from the known load value and assumed voltage.

*Step 3.* Starting at the ending nodes, sum load currents to obtain line section current estimates, performing summation until the substation is reached.

*Step 4.* Having estimates of all line section currents, start at the substation and calculate line section voltage drops and new estimates of node voltages.

*Step 5.* Compare new node voltages with estimates of previous iteration values. The algorithm has converged if the change in voltage is sufficiently small. If the algorithm has not converged, return to step 2.

Dynamic load analysis includes such studies as motor-starting studies. Rapid changes in large loads can result in large currents, with a resultant drop in system voltage. If the dip in voltage is too large or too frequent, then other loads are adversely affected, such as in an annoying flicker of lights. This study generally employs a power flow calculation that is run at a number of points along the dynamic characteristic of the load.

Fault analysis provides the basis for protection system design. Generally, superposition is used to add load currents obtained from power flow analysis to fault currents. Thus, in the model used to calculate fault currents, load currents are neglected. Sources of fault current are the substation bus, cogenerators, and large synchronous motors on the feeder or neighboring feeders. A variety of fault conditions are considered at each line section, including three-phase-to-ground, single-phase-to-ground, and separate phases contacting one another. In performing the calculations, both bolted (i.e., zero-impedance) faults and faults with an impedance in the fault path are considered. Of interest are the maximum and minimum phase and return path fault currents, as well as the fault types that result in these currents.

Reliability analysis involves determining indices that relate to continuity of service to the customer. Reliability is a function of tree conditions, lightning incidence, equipment failure rates, equipment repair times, and circuit design. The reliability of a circuit generally varies from point to point due to protection system design, placement of switches, and availability of alternative feeds. There are many indices used in evaluating system reliability. Common ones include system average interruption frequency index (SAIFI), system average interruption duration index (SAIDI), and customer average interruption frequency index (CAIFI), as defined by

$$\text{SAIFI} = \frac{\text{Total number of customer interruptions}}{\text{Total number of customers served}}$$

$$\text{SAIDI} = \frac{\text{Sum of customer interruption durations}}{\text{Total number of customers}}$$

$$\text{CAIFI} = \frac{\text{Total number of customer interruptions}}{\text{Total number of customers affected}}$$

Phase balancing is used to balance the current or power flows on the different phases of a line section. This results in improved efficiency and primary voltage level balance. The average current in the three phases is defined as

$$I_{\text{avg}} = \frac{I_A + I_B + I_C}{3}$$

The maximum deviation from  $I_{\text{avg}}$  is given by

$$\Delta I_{\text{dev}} = \text{maximum of } \{|I_{\text{avg}} - I_A|, |I_{\text{avg}} - I_B|, |I_{\text{avg}} - I_C|\}$$

Phase imbalance is defined as

$$\text{Phase imbalance} = \frac{\Delta I_{\text{dev}}}{I_{\text{avg}}}$$

Planning involves using load forecasting and other analysis calculations to evaluate voltage level, substation locations, feeder routes, transformer/conductor sizes, voltage/power factor control, and restoration operations. Decisions are based upon considerations of efficiency, reliability, peak demand, and life cycle cost.

Overcurrent protection is the most common protection applied to the distribution system. With overcurrent protection, the protective device trips when a large current is detected. The time to trip is a function of the magnitude of the fault current. The larger the fault current is, the quicker the operation. Various types of equipment are used. A circuit breaker is a switch designed to interrupt fault current, the operation of which is controlled by relays. An overcurrent relay, upon detecting fault current, sends a signal to the breaker to open. A recloser is a switch that opens and then recloses a number of times before finally locking open. A fuse is a device with a fusible member, referred to as a *fuse link*, which in the presence of an overcurrent melts, thus opening up the circuit.

Breakers may be connected to reclosing relays, which may be programmed for a number of opening and reclosing cycles. With a recloser or a reclosing breaker, if the fault is momentary, then the power interruption is also momentary. If the fault is permanent, then after a specified number of attempts at reclosing the device locks open. Breakers are generally more expensive than comparable reclosers. Breakers are used to provide more sophisticated protection, which is available via choice of relays. Fuses are generally used in the protection of laterals.

Protective equipment sizing and other characteristics are determined from the results of fault analysis. Moving away from the substation in a radial circuit, both load current and available fault current decrease. Protective devices are selected based on this current grading. Protective devices are also selected to have different trip delay times for the same fault current. With this time grading, protective devices are coordinated to work together such that the device closest to a permanent fault clears the fault. Thus reclosers can be coordinated to protect load-side fuses from damage due to momentary faults.

## 108.4 System Control

---

Voltage control is required for proper operation of customer equipment. For instance, in the U.S., "voltage range A" for single-phase residential users specifies that the voltage may vary at the service entrance from 114/228 V to 126/252 V. Regulators, tap-changing under load transformers,

and switched capacitor banks are used in voltage control.

Power factor control is used to improve system efficiency. Due to the typical load being inductive, power factor control is generally achieved with fixed and/or switched capacitor banks.

Power flow control is achieved with switching operations. Such switching operations are referred to as *system reconfiguration*. Reconfiguration may be used to balance a load among interconnected distribution substations. Such switching operations reduce losses while maintaining proper system voltage.

Load control may be achieved with voltage control and also by remotely operated switches that disconnect load from the system. Generally, load characteristics are such that if the voltage magnitude is reduced, then the power drawn by the load will decrease for some period of time. Load control with remotely operated switches is also referred to as *load management*.

## 108.5 Operations

---

The operations function includes system maintenance, construction, and service restoration. Maintenance, such as trimming trees to prevent contact with overhead lines, is important to ensure a safe and reliable system. Interruptions may be classified as *momentary* or *permanent*. A momentary interruption is one that disappears very quickly—for instance, a recloser operation due to a fault from a tree limb briefly touching an overhead conductor. Power restoration operations are required to repair damage caused by permanent interruptions.

While damaged equipment is being repaired, power restoration operations often involve reconfiguration in order to restore power to interrupted areas. With reconfiguration, power flow calculations may be required to ensure that equipment overloads are not created from the switching operations.

# SYSTEM OF ELECTRIC LIGHTING

*William Stanley, Jr.*

*Patented January 5, 1886*

*#333,564*

This invention described a system for wiring lamps in series/parallel combinations to maintain a constant load in the cross circuits even when individual lights were switched in and out.

An excerpt:

My invention consists in arranging and connecting the wires constituting each cross-circuit in the manner hereinafter shown, and connecting with the wires and lamps switches and resistances in such a way that the resistance in each cross-circuit shall remain constant so long as any lamp therein is lighted, and so that each cross-circuit shall be interrupted and no current pass through it when no lamp in it is lighted.

Stanley obtained 130 patents in his lifetime and was instrumental in the development of AC electric power distribution for Westinghouse and others. He developed practical transformers, a self-starting motor, a two-phase AC generator and an electric meter with magnetic suspension instead of jeweled bearings. (©1994, DewRay Products, Inc. Used with permission.)

## Defining Terms

**Current return path:** The path that current follows from the load back to the distribution substation. This path may consist of either a conductor (referred to as the *neutral*) or earth, or the parallel combination of a neutral conductor and the earth.

**Fault:** A conductor or equipment failure or unintended contact between conductors or between conductors and grounded objects. If not interrupted quickly, fault current can severely damage conductors and equipment.

**Phase:** Relates to the relative angular displacement of the three sinusoidally varying voltages produced by the three windings of a generator. For instance, if phase A voltage is  $120\angle 0^\circ$  V, phase B voltage  $120\angle -120^\circ$  V, and phase C voltage  $120\angle 120^\circ$  V, the phase rotation is referred to as ABC. Sections of the system corresponding to the phase rotation of the voltage carried are commonly referred to as phase A, B, or C.

**Tap-changing mechanism:** A control device that varies the voltage transformation ratio between the primary and secondary sides of a transformer. The taps may only be changed by discrete amounts, say 0.625%.

### William G. Duff

*Computer Sciences Corporation*

Grounding and shielding are two very important factors that must be considered during the design of electronic circuits. Current trends in the electronics industry (such as increases in the number of electronic equipments, reliance on electronic devices in critical applications, higher clock frequencies of computing devices, higher power levels, lower sensitivities, increased packaging densities, use of plastics, etc.) will tend to create more electromagnetic interference (EMI) problems. To avoid problems, EMI control measures must be incorporated into circuit design.

## 109.1 Grounding

---

The material on grounding was adapted from Duff [1989] courtesy of Interference Control Technologies.

Grounding is one of the least understood and most significant factors in many EMI problems. The primary purposes for grounding circuits, cables, equipments, and systems are to prevent a shock hazard; to protect circuits and equipments; and to reduce EMI due to electromagnetic field, common ground impedance, or other forms of interference coupling. The EMI part of the problem is emphasized in this section.

### Characteristics of Ground Conductors

Ideally, a ground conductor should provide a zero-impedance path to all signals for which it serves as a reference. If this were the situation, signal currents from different circuits would return to their respective sources without creating unwanted coupling between circuits. Many interference problems occur because designers treat the ground as ideal and fail to give proper attention to the actual characteristics of the ground conductor.

A commonly encountered situation is that of a ground conductor running along in the proximity of a ground plane as illustrated in Fig. 109.1. The ground conductor and ground plane may be

represented as a short-circuited transmission line. At low frequencies the resistance of the ground conductor will predominate. At higher frequencies the series inductance and the shunt capacitance to ground will become significant and the ground conductor will exhibit alternating parallel and series resonances as illustrated in Fig. 109.2. To provide a low impedance to ground, it is necessary to keep the length of the grounding conductor short relative to wavelength (i.e., less than 1/20 of the wavelength).

**Figure 109.1** Idealized equipment grounding.

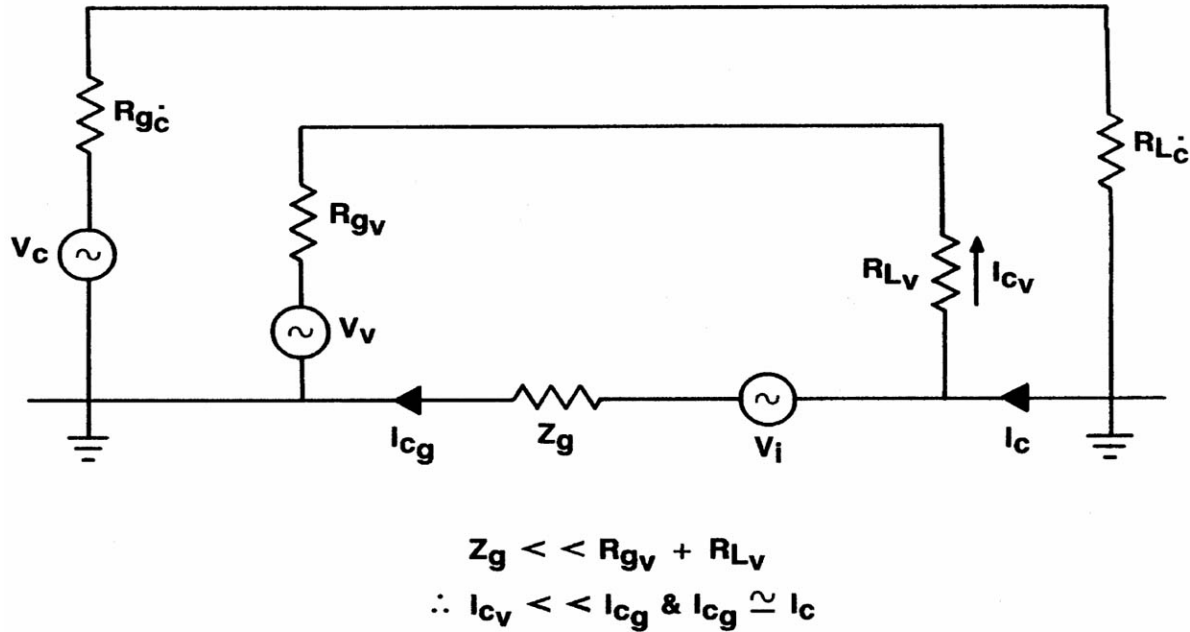

**Figure 109.2** Typical impedance versus frequency behavior of a grounding conductor.

## Ground-Related EMI Coupling

Ground-related EMI involves one of two basic coupling mechanisms. The first mechanism results from circuits sharing the ground with other circuits. [Figure 109.3](#) illustrates EMI coupling between culprit and victim circuits via the common-ground impedance. In this case, the interference current ( $I_{cg}$ ) flowing through the common-ground impedance ( $Z_g$ ) will produce an interfering signal voltage ( $V_i$ ) in the victim circuit. This effect can be reduced by minimizing or eliminating the common-ground impedance.

**Figure 109.3** Common-ground impedance coupling between circuits.

The second EMI coupling mechanism involving ground is a radiated mechanism whereby the ground loop, as shown in [Fig. 109.4](#), acts as a receiving or transmitting antenna. For this EMI coupling mechanism the induced EMI voltage (for the susceptibility case) or the emitted EMI field (for the emission case) is a function of the EMI driving function (field strength, voltage or current), the geometry and dimensions of the ground loop, and the frequency of the EMI signal. Radiated effects can be minimized by routing conductors close to ground and minimizing the ground-loop area.

**Figure 109.4** Common-mode radiation into and from ground loops.

It should be noted that both the conducted and radiated EMI coupling mechanisms identified earlier involve a "ground loop." It is important to recognize that ground loop EMI problems can exist without a physical connection to ground. In particular, at RF frequencies, capacitance-to-ground can create a ground loop condition even though circuits or equipments are floated with respect to ground.

## Grounding Configurations

A typical electronic equipment may have a number of different types of functional signals as shown in [Fig. 109.5](#). To mitigate interference due to common-ground impedance coupling, as many separate grounds as possible should be used.

**Figure 109.5** Grounding hierarchy.

The grounding scheme for a collection of circuits within an equipment can assume any one of several configurations. Each of these configurations tends to be optimum under certain conditions and may contribute to EMI problems under other conditions. In general, the ground configurations are a floating ground, a single-point ground, a multiple-point ground, or some hybrid combination.

A floating ground configuration is illustrated in [Fig. 109.6](#). The signal ground is electrically isolated from the equipment ground and other conductive objects. Hence, equipment noise currents present in the equipment and power ground will not be conductively coupled to the signal circuits.

**Figure 109.6** Floating signal ground.

The effectiveness of floating ground configurations depends upon their true isolation from other nearby conductors; that is, to be effective, floating ground systems must really float. It is often difficult to achieve and maintain an effective floating system. A floating ground configuration is most practical if only a few circuits are involved and power is supplied from either batteries or DC-to-DC converters.

A single-point ground configuration is illustrated in [Fig. 109.7](#). An important advantage of the single-point configuration is that it helps control conductively coupled interference. As illustrated in [Fig. 109.7](#), EMI currents or voltages in the equipment ground are not conductively coupled into the signal circuits via the signal ground. Therefore, the single-point signal ground network minimizes the effects of any EMI currents that may be flowing in the equipment ground.

**Figure 109.7** Single-point signal ground.

The multiple-point ground illustrated in [Fig. 109.8](#) is the third configuration frequently used for signal grounding. With this configuration, circuits have multiple connections to ground. Thus, in an equipment, numerous parallel paths exist between any two points in the multiple-point ground network. Multipoint grounding is more economical and practical for printed circuits and integrated circuits. Interconnection of these components through wafer risers, mother boards, and so forth should use a hybrid grounding approach in which single-point grounding is used to avoid low-frequency ground loops and/or common-ground impedance coupling; multipoint grounding is used otherwise.

**Figure 109.8** Multiple-point ground configuration.

## Summary of Grounding Considerations

A properly designed ground configuration is one of the most important engineering elements in protecting against the effects of EMI. The ground configuration should provide effective isolation between power, digital, high-level analog, and low-level analog signals. In designing the ground it is essential to consider the circuit, signal characteristics, equipment, cost, maintenance, and so forth. In general, either floating or single-point grounding is optimum for low-frequency situations and multiple-point grounding is optimum for high-frequency situations. In many practical applications a hybrid ground approach is employed to achieve the single-point configuration for low frequencies and the multiple-point configuration for high frequencies.

## 109.2 Shielding

The material on shielding was adapted from Duff [1991] courtesy of Interference Control Technologies.

Shielding is one of the most effective methods for controlling radiated EMI effects at the component, circuit, equipment, subsystem, and system levels. The performance of shields is a function of the characteristics of the incident electromagnetic fields. Therefore, shielding considerations in the near-field region of an EMI source may be significantly different from shielding considerations in the far-field region.

### Shielding Theory

If a metallic barrier is placed in the path of an electromagnetic field as illustrated in Fig. 109.9, only a portion of the electromagnetic field may be transmitted through the barrier. There are several effects that may occur when the incident wave encounters the barrier. First, a portion of the incident wave may be reflected by the barrier. Second, the portion of the incident wave that is not reflected will penetrate the barrier interface and may experience absorption loss while traversing the barrier. Third, additional reflection may occur at the second barrier interface, where the electromagnetic field exits the barrier. Usually this second reflection is insignificant relative to the other effects that occur and may be neglected.

**Figure 109.9** Shielding of plane waves.

The shielding effectiveness of the barrier may be defined in terms of the ratio of the impinging field intensity to the exiting field intensity. For high-impedance electromagnetic fields or plane waves, the shielding effectiveness is given by

$$SE_{dB} = 20 \log \left( \frac{E_1}{E_2} \right) \quad (109.1)$$

where  $E_1$  is the impinging field intensity in volts per meter and  $E_2$  is the exiting field intensity in

The shielding effectiveness of the barrier may be defined in terms of the ratio of the impinging field intensity to the exiting field intensity. For high-impedance electromagnetic fields or plane waves, the shielding effectiveness is given by

$$SE_{dB} = 20 \log \left( \frac{E_1}{E_2} \right) \quad (109.1)$$

where  $E_1$  is the impinging field intensity in volts per meter and  $E_2$  is the exiting field intensity in volts per meter. For low-impedance magnetic fields, the shielding effectiveness is defined in terms of the ratio of the magnetic field strengths.

The total shielding effectiveness of a barrier results from the combined effects of reflection loss and absorption loss. Thus, the shielding effectiveness,  $S$ , in dB is given by

$$S_{dB} = R_{dB} + A_{dB} + B_{dB} \quad (109.2)$$

where  $R_{dB}$  is the reflection loss,  $A_{dB}$  is the absorption loss, and  $B_{dB}$  is the internal reflection loss. Characteristics of the reflection and absorption loss are discussed in the following sections.

## Reflection Loss

When an electromagnetic wave encounters a barrier, a portion of the wave may be reflected. The reflection occurs as a result of a mismatch between the wave impedance and the barrier impedance. The resulting reflection loss,  $R$ , is given by

$$\begin{aligned} R_{dB} &= 20 \log_{10} \frac{(K + 1)^2}{4K}, \quad K = \frac{Z_w}{Z_b} \\ &\simeq 20 \log_{10} \left( \frac{Z_w}{4Z_b} \right), \quad K \geq 10 \end{aligned} \quad (109.3)$$

where  $Z_w$  is the wave impedance  $= E/H$ , and  $Z_b$  is the barrier impedance.

## Absorption Loss

When an electromagnetic wave encounters a barrier, a portion of the wave penetrates the barrier. As the wave traverses the barrier, the wave may be reduced as a result of the absorption loss that occurs in the barrier. This absorption loss,  $A$ , is independent of the wave impedance and may be expressed as follows:

$$A_{dB} = 8.68t/\delta = 131t\sqrt{f_{MHz}\mu_r\sigma_r} \quad (109.4)$$

where  $t$  is the thickness in mm,  $f_{\text{MHz}}$  is the frequency in MHz,  $\mu_r$  is the permeability relative to copper, and  $\sigma_r$  is the conductivity relative to copper.

## Total Shielding Effectiveness

The total shielding effectiveness resulting from the combined effects of reflection and absorption loss are plotted in Fig. 109.10 for copper and iron materials having thicknesses of 0.025 mm and 0.8 mm, having electric and magnetic fields and plane-wave sources, and having source-to-barrier distances of 2.54 cm and 1 meter.

**Figure 109.10** Total shielding effectiveness.

## Shielding Materials

As shown in Fig. 109.10, good shielding efficiency for plane waves or electric (high-impedance) fields is obtained by using materials of high conductivity such as copper and aluminum. However, low-frequency magnetic fields are more difficult to shield because both the reflection and absorption loss of nonmagnetic materials, such as aluminum, may be insignificant. Consequently, to shield against low-frequency magnetic fields, it may be necessary to use magnetic materials.

## Conductive Coatings

Conductive coatings applied to nonconductive materials such as plastics will provide some degree of EMI shielding. The principal techniques for metalizing plastic are the following:

- Conductive paints
- Plating (electrolytic)
- Electroless plating
- Flame spray
- Arc spray
- Ion (plasma torch) spray

- Vacuum deposition

Because the typical conductive coatings provide only a thin film of conductive material, the shielding results from reflection losses that are determined by the ratio of the wave impedance to the conductive barrier impedance. The surface resistance (in ohms per square) will determine shielding effectiveness. Figure 109.11 shows comparative data for shielding effectiveness for various conductive coatings. The most severe situation (i.e., a low-impedance magnetic field source) has been assumed.

**Figure 109.11** Shielding of conductive coatings. (By standard. 30 cm distance test. Near field attenuation is given against H field.) For paints, thickness is typically 2 mil. = .05 mm.

## Aperture Leakages

Various shielding materials are capable of providing a high degree of shielding effectiveness under somewhat idealized conditions. However, when these materials are used to construct a shielded housing, the resulting enclosure will typically have holes and seams that may severely compromise

the overall shielding effectiveness.

Figure 109.12 shows a rectangular aperture in a metal (or metalized) panel. A vertically polarized incident electric field will induce currents in the surface of the conductive panel. If the aperture dimensions are much less than a half wavelength, the path around the slot will provide a low impedance to the induced currents and, as a result, the aperture leakage will be small. On the other hand, as the aperture dimensions approach a half wavelength, the path around the slot will provide a high impedance to the induced currents and the aperture leakage will be significant. An aperture with dimensions equal to or greater than a half wavelength will provide almost no shielding (i.e., the incident field will propagate through the aperture with very little loss). In general, the shielding effectiveness of a conductive panel with an aperture may be approximated by the following equation:

$$SE_{dB} \cong 100 - 20 \log L_{mm} \times F_{MHz} + 20 \log \left( 1 + \ln \frac{L}{S} \right) \quad (109.5)$$

**Figure 109.12** Slot and aperture leakage.

To maintain shielding integrity for an equipment enclosure, it may be necessary to provide EMI

protection for the apertures.

## Summary of Shielding Considerations

Shielding can provide an effective means of controlling radiated EMI effects. To ensure that shielding effectiveness requirements are met, it is necessary to

- Select a material that is capable of providing the required shielding
- Minimize the size of openings to control aperture leakages
- Subdivide large openings into a number of smaller ones
- Protect leaky apertures (e.g., cover with wire screen)
- Use EMI gaskets on leaky seams
- Filter conductors at points where they enter or exit a shielded compartment

## Defining Terms

**Ground:** Any reference conductor that is used for a common return.

**Near-field/far-field transition distance:** For electrically small radiators (i.e., dimensions  $\ll$  wavelength ), the near-field/far-field transition occurs at a distance equal to approximately one sixth of a wavelength from the radiating source.

**Plane wave:** Far-field electromagnetic wave with an impedance of 377 ohms in air.

**Reference:** Some object whose potential (often 0 volts with respect to earth or a power supply) is the one to which analog and logic circuits, equipments, and systems can be related or benchmarked.

**Return:** The low (reference) voltage side of a wire pair (e.g., neutral), outer jacket of a coax, or conductor providing a path for intentional current to get back to the source.

**Wavelength:** The distance corresponding to a period for the electromagnetic wave spatial variation. Wavelength (meters) = 300 /frequency (MHz).

THE TERM *ELECTRONICS* IS USED in the field of electrical engineering to distinguish devices and phenomena that depend on the motion of charge carriers in a semiconductor, vacuum, or gas, from those that depend on the motion of charge carriers in a metal. The latter is where electrical engineering began, with motors, generators, light bulbs, telegraphy, and so on, but today electronics is by far the dominant area of interest and activity. Perhaps more than any other area of technology, it is advances in electronics that have provided the foundation on which our modern world is built. From personal computers to computer-controlled automobiles to advanced medical technology to fly-by-wire aircraft to space technology to high-bandwidth communications to a vast array of consumer products, it is the devices and fundamental circuits of electronics that form the essential foundation on which the technology is built.

This section will consider the most important building blocks of electronics. Although historically these building blocks have been discrete electronic devices (first vacuum tubes and later semiconductor diodes and transistors of various types), today the building blocks may be more complex and be themselves built up from several simpler electronic devices. One of the most important examples is the operational amplifier, or op amp, and this section begins with this device and also introduces the important approach of treating building blocks with considerable internal complexity as simple electronic devices. The section continues by considering an important op amp application—active filters—which may themselves be considered as individual electronic building blocks for application in more complex systems.

It is this hierarchical approach of assembling electronic devices into building blocks, which then may themselves be considered as the "devices" for constructing more complicated blocks, that makes it possible to manage the incredible complexity of modern electronic systems. This theme is continued by a chapter that discusses diodes and transistors (the most fundamental electronic device building blocks), followed by a chapter that describes how these devices are used in general to form analog integrated circuits (of which the op amp is just one example). Next, less familiar, but no less important, opto-electronic and power electronic devices are discussed, followed by a chapter that describes how electronics is used to make the link between the analog and digital worlds. Finally, a chapter on superconductivity is included to give insight into another important aspect of the continually broadening field of electronics.

- 110.1 The Ideal Op Amp
- 110.2 Feedback Circuit Analysis
- 110.3 Input and Output Impedances
- 110.4 Practical Limitations and Considerations

**Paul J. Hurst**

*University of California, Davis*

The operational amplifier (op amp) is one of the most versatile building blocks for analog circuit design. The earliest op amps were constructed of discrete devices—first vacuum tubes and later transistors. Today, an op amp is constructed of numerous transistors along with a few resistors and capacitors, all fabricated on a single piece of silicon. Parts are sold with one, two, or four op amps in a small integrated circuit package.

Op amps are popular because they are small, versatile, easy to use, and inexpensive. Despite their low cost, modern op amps offer superb performance. An op amp provides high voltage gain, high input impedance, and low output impedance. Many op amps are commercially available, and they differ in specifications such as input noise, bandwidth, gain, offset voltage, output swing, and supply voltage.

Op amps are used as high-gain amplifiers in negative feedback circuits. An advantage of such circuits is that design and analysis is relatively simple, with the overall gain depending only on external passive components that provide the feedback around the op amp. In the following sections, analysis and design of op-amp feedback circuits are covered.

---

## 110.1 The Ideal Op Amp

---

The schematic symbol for an op amp is shown in [Fig. 110.1\(a\)](#). The op amp has two inputs,  $v_+$  and  $v_-$ , and a single output. The voltages  $v_+$ ,  $v_-$ , and  $v_{\text{OUT}}$  are measured with respect to ground. The op amp amplifies the voltage difference  $v_+ - v_-$  to produce the output voltage  $v_{\text{OUT}}$ . A simple model for the op amp that is valid when the op amp is operating in its linear high-gain region is shown in [Fig. 110.1\(b\)](#). The model consists of an input impedance  $Z_i$ , output impedance  $Z_o$ , and voltage gain  $a$ . Here, the voltage difference  $v_+ - v_-$  is called  $v_E$ . If  $Z_i$ ,  $Z_o$ , and  $a$  are known, this model can be used to analyze an op-amp circuit if the op amp is biased in the linear region, which is usually the case when the op amp is in a negative feedback loop. A typical op amp has large  $Z_i$ , small  $Z_o$ , and large  $a$ . As a result, the op-amp model is often further simplified by setting  $Z_i = \infty$  and  $Z_o = 0$ , as shown in [Fig. 110.1\(c\)](#).

**Figure 110.1** (a) The schematic symbol for an op amp; (b) a simple three-element model for the op amp; (c) the model in (b) simplified further by setting  $Z_i = \infty$  and  $Z_o = 0$ .

(a)

(b)

(c)

For an example of an op-amp feedback circuit, consider the inverting gain amplifier shown in Fig. 110.2. Using the model of Fig. 110.1(c) in Fig. 110.2, the gain can be found by summing currents at the  $v_-$  input of the op amp. Since the current into the op amp is zero (due to  $Z_i = \infty$ ),  $i_1 = i_2$ ; therefore,

$$\frac{v_{\text{IN}} - (-v_E)}{R_1} = i_1 = i_2 = \frac{-v_E - v_{\text{OUT}}}{R_2} \quad (110.1)$$

Using the relationship  $v_E = v_{\text{OUT}}/a$ , Eq. (110.1) yields

$$\frac{v_{\text{OUT}}}{v_{\text{IN}}} = -\frac{R_2}{R_1} \frac{1}{1 + (R_1 + R_2)/aR_1} \quad (110.2)$$

Assuming that the op-amp gain is very large ( $a \rightarrow \infty$ ), Eq. (110.2) becomes

$$\frac{v_{\text{OUT}}}{v_{\text{IN}}} = -\frac{R_2}{R_1} \quad (110.3)$$

The gain depends on the ratio of resistors and is independent of the op-amp parameters.

**Figure 110.2** An inverting gain amplifier.

The above analysis can be made easier by assuming that the op amp is ideal ( $Z_i = \infty$ ,  $Z_o = 0$ , and  $a = \infty$ ) before beginning the analysis. This **ideal op-amp model** greatly simplifies analysis and gives results that are surprisingly accurate. The assumption  $Z_i = \infty$  ensures that the currents flowing into the op-amp input terminals are zero. With  $Z_o = 0$ , the controlled source directly controls the output, giving  $v_{\text{OUT}} = av_E$ . The final assumption  $a = \infty$  leads to  $v_E = v_{\text{OUT}}/a = 0$  if  $v_{\text{OUT}}$  is bounded, which is typically true in negative feedback circuits. The condition  $v_E = 0$  is referred to as a *virtual short circuit* because the op-amp input voltages are equal ( $v_+ = v_-$ ), even though these inputs are not actually connected together. Negative feedback forces  $v_E$  to be equal to zero.

To demonstrate the advantage of the ideal op-amp model, consider the circuit in [Fig. 110.3](#). If the op amp is ideal,  $v_+ = v_-$ , and therefore  $v_- = v_{\text{IN}}$  as a result of the virtual short circuit. Since no current flows into the op-amp input, the currents  $i_3$  flowing through resistor  $R_3$  and  $i_4$  through  $R_4$  must be equal:

$$\frac{0 - v_{\text{IN}}}{R_3} = i_3 = i_4 = \frac{v_{\text{IN}} - v_{\text{OUT}}}{R_4} \quad (110.4)$$

The resulting gain is positive, or noninverting, and is given by

$$\frac{v_{\text{OUT}}}{v_{\text{IN}}} = 1 + \frac{R_4}{R_3} \quad (110.5)$$

This example demonstrates how the ideal op-amp model can be used to quickly analyze op-amp feedback circuits.

**Figure 110.3** A noninverting gain amplifier.

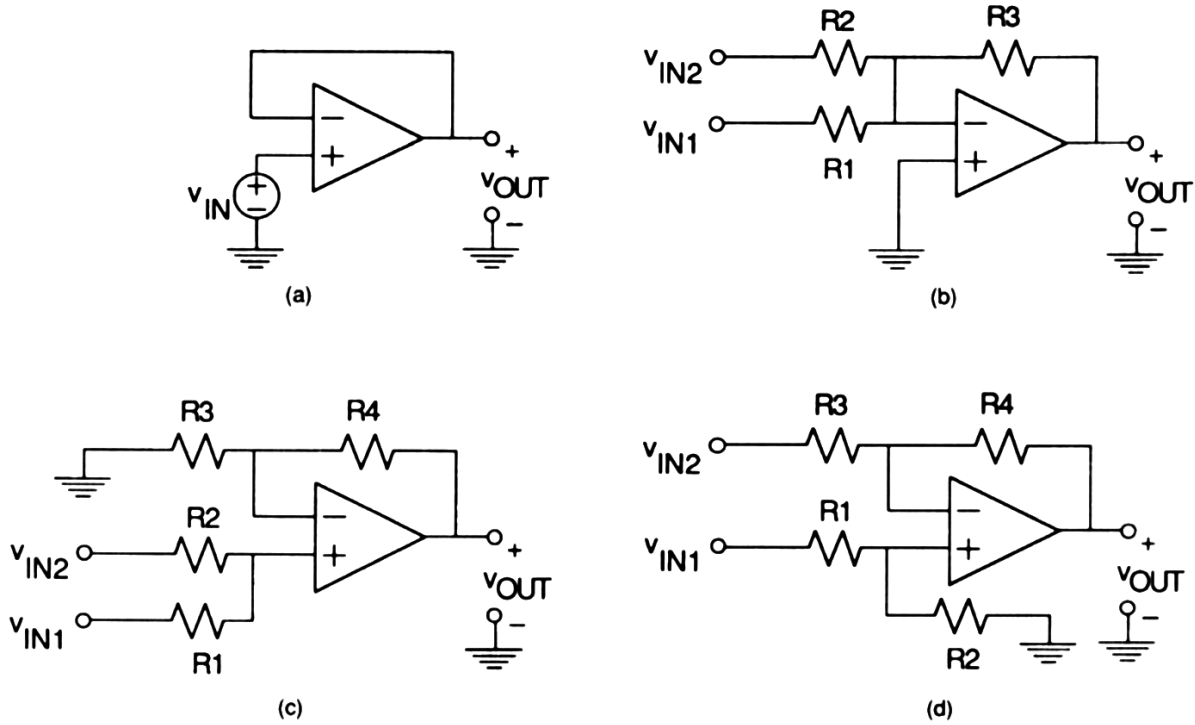

A number of interesting op-amp feedback circuits are shown in Fig. 110.4. The corresponding expressions for  $v_{OUT}$  are given in the caption for Fig. 110.4, assuming an ideal op amp. The simplest circuit is the voltage buffer of Fig. 110.4(a), which has a voltage gain of one. The circuits in Fig. 110.4(b–d) have multiple inputs. Figure 110.4(b) is an inverting, summing amplifier if  $R_1 = R_2$ . Figure 110.4(c) is a noninverting, summing amplifier if  $R_1 = R_2$ . If  $R_1/R_2 = R_3/R_4$  in Fig. 110.4(d), this circuit is a differencing amplifier with

$$v_{OUT} = \frac{R_4}{R_3}(v_{IN1} - v_{IN2}) \quad (110.6)$$

**Figure 110.4** (a) A voltage buffer,  $v_{OUT} = v_{IN}$ ; (b) a two-input inverting gain amplifier,  $v_{OUT} = -(R_3/R_1)v_{IN1} - (R_3/R_2)v_{IN2}$ ; (c) a two-input noninverting stage,  $v_{OUT} = \{[R_2/(R_1 + R_2)]v_{IN1} + [R_1/(R_1 + R_2)]v_{IN2}\}(R_3 + R_4)/R_3$ ; (d) a differencing amplifier,  $v_{OUT} = -(R_4/R_3)v_{IN2} + [R_2/(R_1 + R_2)][(R_3 + R_4)/(R_3)]v_{IN1}$ .

**Figure 110.4**

Op amps can be used to construct filters for signal conditioning. If  $R_1$  in Fig. 110.2 is replaced by a capacitor  $C_1$ , the circuit becomes a differentiator and its input and output are related by either of the following:

$$v_{OUT}(t) = -R_2 C_1 \frac{dv_{IN}(t)}{dt} \quad (110.7a)$$

$$V_{OUT}(s) = -s R_2 C_1 V_{IN}(s) \quad (110.7b)$$

where  $s$  is the Laplace operator and  $V(s)$  is the Laplace transform of  $v(t)$ .

Again, starting with Fig. 110.2, if  $R_2$  is replaced by a capacitor  $C_2$ , the circuit becomes an integrator. Its input and output are related by either of the following:

$$v_{OUT}(t) = -\frac{1}{R_1 C_2} \int_0^t v_{IN}(\tau) d\tau \quad (110.8a)$$

$$V_{OUT}(s) = -\frac{V_{IN}(s)}{s R_1 C_2} \quad (110.8b)$$

Here,  $v_{OUT}(t = 0) = 0$  is assumed. Since there is no DC feedback from the op-amp output to its input through capacitor  $C_2$ , an integrator will only work properly when used in an application that

provides DC feedback around the integrator for biasing. Integrators are often used inside feedback loops to construct filters or control loops.

Figure 110.5 is a one-pole, one-zero filter with transfer function

$$\frac{V_{\text{OUT}}(s)}{V_{\text{IN}}(s)} = -\frac{R_2}{R_1} \frac{1 + sR_1C_1}{1 + sR_2C_2} \quad (110.9)$$

Higher-order filters can be constructed using op amps [Jung, 1986].

**Figure 110.5** A one-pole, one-zero filter.

## 110.2 Feedback Circuit Analysis

The goal of every op-amp feedback circuit is an input/output relationship that is independent of the op amp itself. An exact formula for the closed-loop gain  $A$  of an op-amp feedback circuit (e.g., Fig. 110.2) is given by Rosenstark [1986]:

$$A = \frac{v_{\text{OUT}}}{v_{\text{IN}}} = A_{\infty} \frac{\text{RR}}{1 + \text{RR}} + \frac{d}{1 + \text{RR}} \quad (110.10)$$

Here,  $A_{\infty}$  is the gain when the op-amp gain  $a = \infty$ . The term  $d = v_{\text{OUT}}/v_{\text{IN}}|_{a=0}$  accounts for feed-forward directly from input to output; typically,  $d$  is zero or close to zero. RR is the return ratio for the controlled source  $a$ . From Eq. (110.10), it can be seen that gain  $A$  approaches the ideal value  $A_{\infty}$  as RR approaches infinity. The return ratio for the controlled source  $a$  can be found by (1) setting all independent sources to zero, (2) breaking the connection between the controlled source  $a$  and the rest of the circuit, (3) driving the circuit at the break with a voltage source with value  $v_t$ , and (4) finding the resulting voltage  $v_r$  across the dependent source. Then  $\text{RR} = -v_r/v_t$ . For negative feedback, RR is positive. Ideally, RR is large so that the gain  $A$  is close to  $A_{\infty}$ .

For example, consider Fig. 110.2. Using the op-amp model of Fig. 110.1(c), the return ratio for the dependent source  $a$  can be found using Fig. 110.6, and the result is

$$\text{RR} = -\frac{v_r}{v_t} = a \frac{R_1}{R_1 + R_2} \quad (110.11)$$

With this model,  $d$  is zero, since setting  $a$  equal to 0 forces  $v_{\text{OUT}}$  equal to 0. Therefore Eq. (110.10) simplifies to

$$A = \frac{v_{\text{OUT}}}{v_{\text{IN}}} = A_{\infty} \frac{\text{RR}}{1 + \text{RR}} \quad (110.12)$$

The RR in Eq. (110.11) can be used in Eq. (110.10) to determine  $A$  at DC or as a function of frequency if  $a(s)$  is known. Information on  $a(s = j\omega)$  is usually provided graphically on a data sheet.

**Figure 110.6** Figure 110.2 modified to allow calculation of the return ratio.

Since op-amp circuits use feedback, stability is a concern. In circuits with passive feedback and load elements, the terms  $A_\infty$ ,  $RR$ , and  $d$  in Eq. (110.10) are stable (all poles are in the left half of the  $s$  plane). Therefore, stability of the closed-loop transfer function  $A(s)$  is determined by the location of the zeroes of  $[1 + RR(s)]$ , which are poles of  $A(s)$ . The location of the zeroes of  $[1 + RR(s)]$  can be determined by examining the phase and gain margins of  $RR$  [Rosenstark, 1986]. The **phase margin** is  $180^\circ - [\text{the phase of } RR(s = j\omega_U)]$ , where  $\omega_U$  is the frequency where the magnitude of  $RR$  is unity. The **gain margin** is  $-20 \log_{10} |RR(s = j\omega_{180})|$ , where  $\omega_{180}$  is the frequency where the phase of  $RR$  is  $-180^\circ$ . The phase and gain margins are positive for a stable circuit. Using an accurate frequency-dependent model for the op amp, or using the frequency response plot of  $a(s = j\omega)$  on the data sheet, the gain and phase margins can be found. Roughly,  $A(s = j\omega) = A_\infty$  for frequencies below  $\omega_U$ , and  $A(s = j\omega)$  will deviate from  $A_\infty$  at frequencies near and above  $\omega_U$ .

Most op amps are designed to be unity-gain stable—that is, they are stable when connected as a buffer [see Fig. 110.4(a)]. In that configuration,  $RR(s) = a(s)Z_i/(Z_i + Z_o) \approx a(s)$  (the approximation follows from  $|Z_o| \ll |Z_i|$ ).

## 110.3 Input and Output Impedances

The input impedance of an op-amp circuit can be found by applying a test voltage source across the input port and measuring the current that flows into the port. The applied voltage divided by the resulting current is the input impedance. (When computing the output impedance, the input source(s) must be set to zero and then the same procedure is carried out on the output port.) Using the model in Fig. 110.1(b), the input impedance for the voltage buffer in Fig. 110.4(a) can be found by following these steps, and the result is

$$Z_{in}(\text{with feedback}) = (Z_i + Z_o) \cdot \left(1 + a \frac{Z_i}{Z_o + Z_i}\right) \approx aZ_i \quad (110.13)$$

where the approximation is valid since  $|Z_o| \ll |Z_i|$  and  $a \gg 1$ . The negative feedback increases the input impedance from  $Z_i$  to  $aZ_i$ . For the OP-07 op amp (see Table 110.1),  $Z_i = 60 \text{ M}\Omega$  and  $a = 500\,000$  at DC, giving a remarkably large  $Z_{in}(\text{with feedback}) = 3 \cdot 10^{13} \Omega$  at DC. Calculation of the output impedance in Fig. 110.4(a) gives

$$Z_{out}(\text{with feedback}) = \frac{Z_i \parallel Z_o}{1 + a(Z_i)/(Z_o + Z_i)} \approx \frac{Z_o}{a} \quad (110.14)$$

where  $x \parallel y = xy/(x + y)$ , and  $Z_i \parallel Z_o \approx Z_o$  because  $|Z_o| \ll |Z_i|$ . The feedback reduces the output impedance. Again, using values for the OP-07,  $Z_{out}(\text{with feedback}) = 0.1 \text{ m}\Omega$  at DC.

**Table 110.1** Typical Op-Amp Specifications

Part #	$a$ at DC	$R_i = Z_i$ (DC)	$R_o = Z_o$ (DC)	Output Swing	$ V_{os} $	$I_B$	Bandwidth for $A_{\infty} = 1$	Slew Rate
OP-07	$5 \cdot 10^5$	$60 \text{ M}\Omega$	$60 \Omega$	$\pm 14 \text{ V}$	$30 \mu\text{V}$	$1.8 \text{ nA}$	$0.6 \text{ MHz}$	$0.3 \text{ V}/\mu\text{s}$
LF411	$2 \cdot 10^5$	$10^{12} \Omega$	$40 \Omega$	$\pm 13.5 \text{ V}$	$0.8 \text{ mV}$	$50 \text{ pA}$	$4 \text{ MHz}$	$15 \text{ V}/\mu\text{s}$
OP-177F	$1.2 \cdot 10^7$	$45 \text{ M}\Omega$	$60 \Omega$	$\pm 12.5 \text{ V}$	$10 \mu\text{V}$	$1.2 \text{ nA}$	$0.6 \text{ MHz}$	$0.3 \text{ V}/\mu\text{s}$

Supply voltage =  $\pm 15 \text{ V}$ ; temperature =  $25^\circ \text{C}$

In some cases, the ideal op-amp model can be used to quickly determine the input impedance. For example, the input resistance in Fig. 110.2 is approximately  $R_1$  because feedback forces  $v_-$  to be close to 0. The output impedance of an ideal op-amp circuit is zero because  $Z_o = 0$ . The actual value can be found by using the model in Fig. 110.1(b) and carrying out the computation described earlier.

## 110.4 Practical Limitations and Considerations

The ideal op-amp model is easy to use, but practical limitations are not included in this simple model. Specifications for a few popular op amps are given in Table 110.1 [[Analog Devices, 1992](#); [National Semiconductor, 1993](#)]. The LF411 uses field-effect input transistors to give extremely high-input resistance and low-input bias current. The input bias current  $I_B$  is the DC current that flows into the op-amp inputs; this is bias current required by the input transistors in the op amp. (This current is not included in the simple models of Fig. 110.1, and it cannot be computed using  $Z_i$ .)

The output voltage swing over which the linear model is valid is limited by the power supply voltage(s) and the op-amp architecture. The peak output current is limited by internal bias currents and/or protection circuitry. The output slew rate, which is the maximum slope of the output signal before distortion occurs, is limited by op-amp internal currents and capacitances. The common-mode input voltage range is the range of the common-mode (or average) input voltage, which is  $(v_+ + v_-)/2$ , for which the linear op-amp model is valid. In Fig. 110.2, it is important

that ground be within this range since  $(v_+ + v_-)/2 \approx 0$  in this circuit. In Fig. 110.3,  $v_{IN}$  must stay in the common-mode input range since  $(v_+ + v_-)/2 \approx v_{IN}$ .

The **input offset voltage**  $V_{OS}$  is the DC op-amp input voltage that causes  $V_{OUT}$  to equal 0 V DC. The offset voltage varies from part to part; it is dependent on imbalances within the op amp. The input offset voltage can be included in the op-amp model, as shown in Fig. 110.7. When this model is used in Fig. 110.2, for example, the output voltage depends on the input voltage and the offset voltage:

$$v_{OUT} = -\frac{R_2}{R_1}v_{IN} + \left(1 + \frac{R_2}{R_1}\right)V_{OS} \quad (110.15)$$

For high gain ( $R_2 \gg R_1$ ), the amplification of  $V_{OS}$  can cause problems, in which case a capacitor can be added in series with  $R_1$ . This eliminates the amplification of  $V_{OS}$ , but it also causes the DC gain from  $v_{IN}$  to  $v_{OUT}$  to be zero.

**Figure 110.7** The op-amp model of Figure 110.1(c) with the addition of the input offset voltage  $V_{OS}$ .

These parameters and many more are specified on the data sheet and are incorporated into an op-amp macro model, which is an interconnection of circuit elements that model the linear and nonlinear behavior of the op amp. Most companies provide macro models for their op amps that can be used in a circuit simulation program such as **SPICE**.

## Defining Terms

**Ideal op-amp model:** Has  $Z_i = \infty$ ,  $Z_o = 0$ , and  $a = \infty$ , which leads to  $v_E = v_+ - v_- = 0$  (the virtual-short-circuit condition).

**Input offset voltage:** The op-amp DC input voltage,  $V_+ - V_-$ , that causes  $V_{OUT}$  to equal 0 V DC.

**Phase margin:** Is  $180^\circ - [\text{the phase of } RR(s = j\omega_U)]$ , where  $\omega_U$  is the frequency where the magnitude of  $RR$  is unity (i.e.,  $|RR(s = j\omega_U)| = 1$ ). Phase margin is measured in degrees.

**Gain margin:** Is  $-20 \log_{10} |\text{RR}(s = j\omega_{180})|$ , where  $\omega_{180}$  is the frequency where the phase of RR is  $-180^\circ$  (i.e., phase of  $\text{RR}(s = j\omega_{180}) = -180^\circ$ ). Gain margin is measured in decibels. Since RR is some factor times  $a(s)$  [e.g., see Eq. (110.11)], plots of the magnitude and phase of RR versus frequency can be generated from plots of  $a(s = j\omega)$ . The gain and phase margins can be found from magnitude and phase plots of  $\text{RR}(s = j\omega)$ .

**SPICE:** A computer program that can simulate circuits with linear and nonlinear elements. Many versions of SPICE are available.

### Michael A. Soderstrand

*University of California, Davis*

**Active RC filters** arose out of the need for filters that are compatible with modern integrated circuit (IC) technology. Attempts to implement **passive RLC filters** in IC technology have largely failed due to the difficulties in implementing inductors using IC technology. Circuit theorists, however, have shown that adding an active device (e.g., an operational amplifier) to resistors and capacitors makes it possible to implement any filter function that can be implemented using passive components (i.e., passive R, L, C filters). Since operational amplifiers (op-amps), resistors, and capacitors are all compatible with modern IC technology, active RC filters are very attractive.

While the primary motivation for active RC filters comes from the desire to implement **filter circuits** in IC technology, there are additional advantages over passive RLC filters:

1. Op-amps, resistors, and capacitors perform much more closely to their ideal characteristics than inductors, which typically exhibit large parasitic resistances and significant nonlinearities.
2. Passive RLC filters are not able to take advantage of the component tracking and very accurate matching of component ratios available in IC technologies. (Note: Filter characteristics depend on ratios of element values rather than the absolute value of the components.)
3. Passive RLC filters cannot realize power gain, only attenuation.

In their infancy, active filters often suffered from a tendency to oscillate. Early work in active filters eliminated these problems but led to filters with high sensitivity to component values. Finally, in the 1970s, active filters emerged that clearly outperformed passive filters in cost, power consumption, ease of tuning, sensitivity, and flexibility. While IC technology allows for active filters that take full advantage of the new active RC filter design techniques, even active RC filters

designed with discrete components will perform as well as, if not better than, their passive counterparts.

## 111.1 History of Active Filters

---

The first practical circuits for active RC filters emerged during World War II and were documented much later in a classic paper by Sallen and Key [1955]. With the advent of IC technology in the early 1960s, active filter research flourished with the emphasis on obtaining stable filters [Mitra, 1971]. During the early 1970s, research focused on reducing the sensitivity of active filters to their component values [Schaumann *et al.*, 1976]. By the end of the 1970s, active filters had been developed that were better than passive filters in virtually every aspect [Bowron and Stephenson, 1979; Ghausi and Laker, 1981; Schaumann *et al.*, 1990; Tsividis and Voorman, 1993].

Unfortunately, most active filter handbooks and books that concentrate on the practical design of active filters have used the old Sallen and Key approach to active filter design. In this chapter we will briefly discuss op-amp-based active RC filter design techniques. (Note: In VLSI applications transconductance-based active filters offer an excellent alternative, which we will not discuss [Tsividis and Voorman, 1993].) Then we will introduce a table-based design procedure for one of the modern op-amp techniques that yields active RC filters as good as or better than passive RLC filters.

## 111.2 Active Filter Design Techniques

---

In this section we define three categories of active RC filter design using very different approaches. Within each category, we will briefly describe several of the specific methods available.

### Cascaded Biquads

The simplest and most popular active RC filter design techniques are based on a **cascade** of second-order (biquadratic or **biquad**) sections. The numerator and denominator of the filter function  $H(s)$  (expressed in terms of the complex frequency variable  $s$ ) are factored into second-order factors (plus one first-order, in the case of an odd-order filter). Second-order transfer functions are then formed by combining appropriate numerator terms with each second-order denominator term such that the product of the second-order transfer functions is equal to the original  $H(s)$ . (Note: In the case of odd-order filters, there will also be one first-order section.) Active RC biquad circuits are then used to implement each second-order section. In the case of odd-order filters, a separate first-order RC section may be added or the real pole can be combined with one of the second-order sections to form a third-order section. The different cascade methods are defined based on which biquad circuits are used and whether the ordering of the biquads is considered as part of the design procedure.

The advantages of the cascade design lie in the ease of design and the fact that the biquads are isolated and thus can be separately tuned during the manufacturing process. The disadvantage of the cascade design also derives from the isolated sections, as it allows only for feedback around

individual second-order stages without overall feedback around the entire filter structure. Thus the cascade of second-order sections is essentially operated open-loop.

## Cascade of Sallen and Key Filters

This approach is the basis for most active RC filter handbooks and many practical texts on active RC filter design. The resulting filters have the advantage of being canonical (i.e., having the fewest possible components—two resistors, two capacitors, and one op-amp per second-order stage). The performance of these filters is generally acceptable but is not as good as passive RLC filters. The primary disadvantage of this approach lies in the fact that it is not possible to use matched op-amps to compensate for the nonideal properties of the operational amplifier, since the sections only use one op-amp. A complete description of the design of a cascade of Sallen and Key filters can be found in the text by Arthur Williams [1975]. Williams also describes a slightly improved design using state-variable-based second-order sections. However, one should use optimum biquads rather than state-variable biquads since the optimum biquads have the same number or fewer components and outperform the state-variable filters.

### Cascade of Optimum Biquads

Optimum biquads require at least two active elements in order to make use of matched op-amps to reduce the effects of the nonideal properties of the active elements. Optimum two-op-amp biquad circuits are based on the gyrator circuits introduced by Antoniou [1967] and modified by Hamilton and Sedra [1971]. The design of these circuits will be covered later in this chapter.

### Ordered Cascade of Optimum Biquads

In order to obtain the best performance possible using the cascade technique, it is not sufficient to use optimum biquads. The second-order sections must also be ordered in an optimum fashion. In this chapter we will show how to design using the optimum biquads, but we will not go into the details of ordering the biquads. For those who need the ultimate in performance, an excellent discussion of ordering is provided in chapter 10 of Sedra and Brackett [1978].

## Simulation of LC Ladders

This approach was originally designed simply to take advantage of the vast reservoir of knowledge on passive **LC ladder filter circuit** design in the design of active filters. The simplest approach uses a gyrator [Antoniou, 1967] and a capacitor to simulate an inductor and replaces the inductors in the passive RLC ladder with this simulation (chapter 11 of Sedra and Brackett [1978]). More sophisticated techniques simulate the voltage and current equations of the passive RLC ladder (chapter 12 of Sedra and Brackett [1978]) or the scattering parameters [Haritantis *et al.*, 1976]. The latter techniques have resulted in the best filter circuits ever constructed.

At first it may seem that simulating passive RLC filters would at best yield filters equal to, but not better than, passive filters. However, the poor quality of passive inductors coupled with the ability of active RC filters to be constructed in IC technology, where very accurate ratios of components can be obtained, gives a huge advantage to active RC filters compared with passive

RLC filters. Even for filters realized with discrete components (i.e., not using IC technology), the advantage of not using an inductor and the use of dual matched op-amps yields circuits superior to those available with passive RLC filters.

### Component Simulation of LC Ladders

The primary attraction of this technique is the ease of design. You simply replace the inductors in a passive RLC filter obtained from any passive RLC design handbook [Hansell, 1969; Zverev, 1967] with active RC simulated inductors. Unfortunately, the floating inductors (inductors which do not have one terminal grounded) required for most passive RLC filters are one of the poorer-performing active RC components. However, modifications of this approach using *frequency-dependent negative resistors* (FDNRs) proposed by Bruton *et al.* [1972] have largely eliminated these problems. For details on the component simulation of LC ladders, see chapter 11 of Sedra and Brackett [1978].

### Operational Simulation of LC Ladders

In this approach active RC components are used as an *analog computer* to simulate the differential equations of Kirchhoff's current and voltage laws at each node in a passive RLC circuit. This approach has resulted in some of the best filter circuits ever designed. For details, see chapter 12 of Sedra and Brackett [1978] (see also [Ghausi and Laker, 1981; Schaumann *et al.*, 1990]).

### Wave Analog Filters

This approach is similar in concept to the operational simulation of RLC ladders except that scattering matrices of the passive RLC filter are simulated rather than Kirchhoff's current and voltage laws. This approach has become very popular in Europe, yielding filters every bit as good as those designed using the operational simulation of RLC ladders. For details see either Schaumann *et al.* [1990] or Haritantis *et al.* [1976].

## Coupled Biquads

The *coupled biquad* approach uses the same optimum biquads that we will use in the cascade approach later in this chapter, but provides feedback around the biquad sections. The advantage of this approach is that this additional feedback makes it possible to obtain filter performance equivalent to the filters realized by simulating RLC ladders, but using the modular, easily tuned biquad sections. However, the coupling of the biquads makes it much more difficult to tune the structure than in the case of cascaded biquads. For an excellent discussion of the coupled biquad design approach, see chapter 5 of Ghausi and Laker [1981] (see also chapter 10 of Sedra and Brackett [1978] and chapter 5 of Schaumann *et al.* [1990]).

## 111.3 Filter Specifications and Approximations

---

Low-pass filters are specified by four parameters: (1)  $\alpha_p$ , the **passband** ripple; (2)  $\omega_p$ , the passband frequency; (3)  $\alpha_s$ , the **stopband** attenuation; and (4)  $\omega_s$ , the stopband frequency. Figure 111.1 illustrates these parameters. A filter meeting these specifications must have  $|H(s)|$  lie between 0

dB and  $\alpha_p$  from DC to frequency  $\omega_p$ , and below  $\alpha_s$  for frequencies above  $\omega_s$ . For passive filters and odd-order active filters,  $\alpha_p$  is always negative. For active even-order filters,  $\alpha_p$  is positive and these filters exhibit power gain. Note that the gain for all active filter designs is normalized to 0 dB at DC (normalization is different for even-order passive filters). In practice, active RC filters are capable of providing an overall gain  $K$ , which multiplies the system function  $H(s)$  with the effect of scaling the vertical axis in Fig. 111.1.

**Figure 111.1** Magnitude specifications for a low-pass filter.

The specifications of Fig. 111.1 are only half the story, however. In addition to the magnitude characteristics, filters have group delay characteristics related to the phase response of the filter. Figure 111.2 shows a typical group delay specification where (1)  $\tau_0$  is the nominal group delay, (2)  $\Delta\tau$  is the passband group delay tolerance, and (3)  $\omega_g$  is the frequency at which the group delay has decayed to 50% of  $\tau_0$ . Unfortunately, magnitude characteristics cannot be specified independent of group delay characteristics. Thus designers must make a choice between which set of specifications they wish to implement and must settle for whatever they get with the other specifications. Filter approximations are specific techniques for achieving one or the other set of

specifications. Each approximation offers a different compromise between meeting the magnitude specification and meeting the group delay specification.

**Figure 111.2** Delay specifications for a low-pass filter.

Filters can be classified into two broad classes: (1) all-pole filters and (2) filters with finite zeros. [Figure 111.3](#) shows the basic asymptotic response for all-pole filters in the left column and the basic asymptotic response for filters with finite zeros in the right column. In each column the response of the three basic filters, low-pass, high-pass, and band-pass, are shown. A fourth filter type, called a notch filter or band-elimination filter, is not shown because this type of filter exhibits an asymptotic response that is 0 dB at all frequencies, with a notch (area of high attenuation) around the corner frequency  $\omega_c$ . Most filter design procedures concentrate on designing low-pass filters and use standard transformations to convert these low-pass filters to high-pass, band-pass, or notch filters (a good explanation of how to do this can be found in chapter 6 of Sedra and Brackett [1978]).

**Figure 111.3** Asymptotic response of filters.

**Low-Pass All-Pole Filter**

**Low-Pass Finite Zero Filter**

**Band-Pass All-Pole Filter**

**Band-Pass Finite Zero Filter**

**High-Pass All-Pole Filter**

**High-Pass Finite Zero Filter**

All passive RLC and active RC filters, regardless of the filter approximation or the method of implementation, have the same asymptotes for the same-order filter (*order* refers to the number of effective reactive elements—inductors and capacitors in a passive RLC filter, and capacitors in an active RC filter). The various filter approximations that we are about to introduce primarily affect how the filter performs in the **transition band** between frequencies  $\omega_p$  and  $\omega_s$ . In general, the wider the transition band, the better the group delay performance, but at the expense of significant deviation from the asymptotic response in the transition band. Note that the corner frequency  $\omega_c$  is an important parameter for all-pole filters because the asymptotic response is defined by this corner frequency along with the order of the filter  $N$  and the filter gain  $K$ .

## Bessel-Thompson Filters

The focus of the **Bessel-Thompson filters** is on meeting the group delay specification. The group delay is fixed at  $\tau_0$  for DC, and as many derivatives of the group delay function as possible are set to zero at DC. This yields what is called a *maximally flat* delay response. Mathematically it can be shown that this will obtain the closest possible match to the ideal "brick wall" delay response without any delay in excess of the prescribed group delay  $\tau_0$ . These filters were originally developed by Thompson and make use of Bessel functions—hence the name Bessel-Thompson filters. Bessel-Thompson filters exhibit the low-pass all-pole asymptotic response of [Fig. 111.3](#).

Although Bessel-Thompson filters offer the best possible group delay response, they do this at the expense of very poor magnitude response in the transition band. Furthermore, for a given order of filter, the transition band is much larger than for the other filter approximations. Other group delay approximations such as the equal-ripple group delay approximation provide only slightly better magnitude performance.

It is often very useful to calculate the required order of a Bessel-Thompson filter from the specifications for that filter. Since Bessel-Thompson filters are primarily dependent on the group delay specifications, the exact formula does not involve the standard magnitude specifications. However, the following approximate formula estimates the order of a Bessel-Thompson filter:

$$N \approx \frac{\alpha_s}{20 \log_{10}(\omega_s/\omega_c)} \quad (111.1)$$

with  $\alpha_s$  in dB and  $\omega_c$  and  $\omega_s$  in radians (or hertz).

## Butterworth Filters

**Butterworth filters** provide a maximally flat passband response for the magnitude of the transfer function at the expense of some peaking in the group delay response around the passband frequency  $\omega_p$ . In most cases the large improvement in magnitude response compared with Bessel-Thompson filters more than compensates for the peaking of the group delay response. Butterworth filters exhibit the low-pass all-pole asymptotic response of [Fig. 111.3](#) with exactly 3 dB of attenuation at the corner frequency  $\omega_c$ . This is less droop (i.e., attenuation at the corner frequency) than Bessel-Thompson filters, but more than the other filter approximations we will

discuss.

It is often very useful to calculate the required order of a Butterworth filter from the specifications. The following formula gives this relationship:

$$N \geq \frac{\log_{10}(K_\alpha)}{\log_{10}(K_\omega)} \quad (111.2)$$

where

$$K_\alpha = \sqrt{\frac{10^{\alpha_s/10} - 1}{10^{\alpha_p/10} - 1}} \quad (111.3)$$

$$K_\omega = \omega_s / \omega_p \quad (111.4)$$

with  $\alpha_p$  and  $\alpha_s$  in dB and  $\omega_p$  and  $\omega_s$  in radians (or hertz).

## Chebyshev Filters

**Chebyshev filters** provide an equal-ripple response in the passband (i.e., the magnitude of  $H(s)$  oscillates or ripples between zero and  $\alpha_p$  in the passband). Chebyshev filters are all-pole filters that can be shown to provide the narrowest transition band for a given filter order  $N$  of any of the all-pole filters. This narrow transition band, however, comes at the expense of significant and often unacceptable peaking and oscillation in the group delay response.

It is often very useful to calculate the required order of a Chebyshev filter from the specifications for that filter. The following formula gives this relationship:

$$N \geq \frac{\cosh^{-1}(K_\alpha)}{\cosh^{-1}(K_\omega)} \quad (111.5)$$

or

$$N \geq \frac{\log_{10} \left( K_\alpha + \sqrt{K_\alpha^2 - 1} \right)}{\log_{10} \left( K_\omega + \sqrt{K_\omega^2 - 1} \right)} \quad (111.6)$$

where  $K_\alpha$  and  $K_\omega$  are as defined in Eqs. (111.3) and (111.4), respectively.

## Inverse Chebyshev Filters

**Inverse Chebyshev filters** provide the same maximally flat magnitude response of Butterworth filters, including the slight, but usually acceptable, peaking in the group delay response, with a transition band exactly the same as for the Chebyshev filters. However, the inverse Chebyshev

filters exhibit the low-pass finite-zero asymptotic response of Fig. 111.3 with equal ripple in the stopband.

It is often very useful to calculate the required order of an inverse Chebyshev filter from the specifications. Since the inverse Chebyshev filter has the same order as the Chebyshev filter, Eqs. (111.5) or (111.6) can also be used to calculate the order of inverse Chebyshev filters.

## Elliptical-Cauer Filters

The **elliptical-Cauer filters** exhibit the low-pass finite-zero asymptotic response of Fig. 111.3 with equal ripple in both the passband (like Chebyshev filters) and the stopband (like inverse Chebyshev filters). While the group delay of these filters is poor, like that of the Chebyshev filters, elliptical-Cauer filters can be shown to have the narrowest transition band of any of the filter approximations.

It is often very useful to calculate the required order of an elliptical-Cauer filter. The following formula gives this relationship:

$$N \geq \frac{CEI(1/K_\omega)CEI\left(\sqrt{1-1/K_\alpha^2}\right)}{CEI(1/K_\alpha)CEI\left(\sqrt{1-1/K_\omega^2}\right)} \quad (111.7)$$

where  $CEI$  is the *complete elliptic integral* function.■

The  $CEI$  function is denoted by  $K$  or  $q$  in most textbooks, but we have chosen  $CEI$  so as not to be confused with other filter parameters.

Although the  $CEI$  function is not typically provided on calculators or in computer mathematics libraries, computer programs are readily available for calculating the  $CEI$  function.■

For example, MATLAB has the algorithm *ellipord* for calculating the order of both digital and analog elliptic filters. Also, Daniels [1974] contains a computer algorithm for calculating  $CEI$  (p. 79), and Lindquist [1977] contains an approximate formula for  $N$ .

$K_\alpha$  and  $K_\omega$  are as defined in Eqs. (111.3) and (111.4), respectively.

## 111.4 Filter Design

---

Figure 111.4 represents a biquad circuit that can be used for low-pass all-pole filters, and Fig. 111.5 shows a biquad that can be used for low-pass finite-zero filters. Both biquads exhibit optimum performance with regard to both passive and active sensitivities [Sedra and Brackett, 1978]. The element values for the circuit of Fig. 111.4 are given by

$$R = Q \quad C = 1/\omega_0 \quad (111.8)$$

where  $\omega_0$  and  $Q$  are the normalized **pole frequency** and **Q** of the second-order filter section. Practical element values are obtained by impedance scaling to practical impedance levels (i.e., multiply each resistor by the desired impedance level and divide each capacitor by the desired impedance level) and frequency scaling to the desired  $\omega_p$  (i.e., divide each capacitor by the desired

**Figure 111.5** Biquad circuit for finite-zero low-pass filters.

Figure 111.5 is used for the filters with finite zeros. The element values for the circuit of Fig. 111.5 are given by

$$\begin{aligned} R_a &= \frac{Q^2 \omega_n^2}{Q^2 \omega_n^2 + \omega_0^2} & R_b &= \frac{Q \omega_n^2}{\omega_0^2} & R_c &= \frac{\omega_n^2}{\omega_0^2} \\ R &= Q & C &= 1/\omega_0 \end{aligned} \quad (111.9)$$

where  $\omega_0$  and  $Q$  are the normalized resonant frequency and  $Q$  for the second-order filter section and  $\omega_n$  is the normalized frequency of the finite zero. As for the all-pole filter section, our tables have been normalized to  $\omega_p = 1$ . Practical resistor and capacitor values are obtained by impedance scaling to the desired impedance level and frequency scaling to the desired  $\omega_p$ .

In order to determine what the resonant frequencies,  $Q$ 's, and zero frequencies are for various types of filters, one may either use a computer program or a table. Many commercial computer programs are available for this purpose and should be used if a significant number of filters are going to be designed. For the casual filter designer, public domain software is available. The programs *filter* [Wilamowski, 1994] and *ladder* [Koller and Wilamowski, 1994] can be obtained by anonymous FTP to PLAINS.UWYO.EDU in directory "electrical." Copy files FILTERxx.ZIP and LADDERyy.ZIP (where xx and yy are the version numbers; currently xx = 35 and yy = 31) in *binary* mode, as these are in "zip" format. (Note: You must use an "unzip" program to expand them.) or the tables included with this chapter may be used. In what follows, we will make use of the tables to do a design example.

## Low-Pass All-Pole Filter Design Example

Table 111.1 applies to the circuit of Fig. 111.4 and is used for the design of the all-pole filters: Bessel-Thompson, Butterworth, and Chebyshev. Consider the design of an all-pole filter with the specifications

$$\alpha_p = 1 \text{ dB}, \quad \omega_p = 1 \text{ kHz}, \quad \alpha_s = 40 \text{ dB}, \quad \text{and} \quad \omega_s = 3 \text{ kHz}$$

Plugging these values into Eqs. (111.3) and (111.4), we obtain  $K_\alpha = 197$  and  $K_\omega = 3$ . Using Eqs. (111.2) and (111.5), we see that the order of filter necessary to meet these specifications is  $N_B = 5$  for a Butterworth filter and  $N_C = 4$  for a Chebyshev filter. Note that these specifications are too restrictive to be met by a Bessel-Thompson filter. (From Table 111.1 we see that  $\omega_c \approx 3$  for a sixth-order Bessel-Thompson filter and  $\omega_c > 3$  for higher-order Bessel-Thompson filters. From Eq. (111.1) for the order of a Bessel-Thompson filter, we see that  $\omega_s = 3 > \omega_c$  to obtain a practical value for  $N$ .)

	1	0.5324	0.5817		0.5550	1.0000		1.9829	2.2127					
	2	0.6608	0.5479		0.8019	1.0000		5.0214	1.2626					
	3	1.1263	0.4872		2.2470	1.0000		17.4645	1.0172					

From Table 111.1 we obtain the following values for the Butterworth fifth-order and Chebyshev fourth-order filters that meet the specifications

*Butterworth fifth-order* ( $\alpha_p = 1.00$  dB):

Stage 0	$R_0 = 1.0000$	$C_0 = 0.8736$
Stage 1	$R_1 = 0.6180$	$C_1 = 0.8736$
Stage 2	$R_2 = 1.6180$	$C_2 = 0.8736$

*Chebyshev fourth-order* ( $\alpha_p = 1.00$  dB):

Stage 1	$R_1 = 0.7845$	$C_1 = 1.8919$
Stage 2	$R_2 = 3.5590$	$C_2 = 1.0068$

To obtain practical values, we must denormalize by impedance scaling to a practical impedance level (we have chosen 10 k $\Omega$ ) and frequency scaling to  $\omega_p = 1$  kHz. Thus we multiply all resistors by  $10^4$  and divide all capacitors by  $10^4$  to impedance-scale, and we then divide all capacitors by  $2\pi \times 10^3$  to frequency-scale. For active filter implementation, we recommend *metal film* resistors and *polystyrene* capacitors. *Mica* capacitors are slightly superior to polystyrene capacitors but have a more restricted range of values. *Polycarbonate* capacitors have a larger range of values but a poorer "retrace" property. *Mylar* capacitors provide large capacitance values in a small package, but at the expense of a much poorer temperature coefficient. The practical values for the resistors and the capacitors of our example after scaling are as follows:

*Butterworth fifth-order* ( $\alpha_p = 1.00$  dB):

Stage 0	$R_0 = 10.0$ k- $\Omega$	$C_0 = 13.9$ nF
Stage 1	$R_1 = 6.18$ k- $\Omega$	$C_1 = 13.9$ nF
Stage 2	$R_2 = 16.2$ k- $\Omega$	$C_2 = 13.9$ nF

*Chebyshev fourth-order* ( $\alpha_p = 1.00$  dB):

Stage 1	$R_1 = 7.85$ k- $\Omega$	$C_1 = 30.1$ nF
Stage 2	$R_2 = 35.6$ k- $\Omega$	$C_2 = 16.0$ nF

Note: All resistors labeled 1 - in Fig. 111.4 become 10 k $\Omega$ , and the two resistors labeled 2 - become 20 k $\Omega$ . These values are well suited for metal film resistors and polystyrene capacitors.

## Low-Pass Finite-Zero Filter Design Example

Table 111.2 applies to the circuit of Fig. 111.5 and is used for the design of the finite-zero filters: inverse Chebyshev and elliptical-Cauer. Consider the design of a finite-zero filter with the same specifications as in the first example:

$$\alpha_p = 1 \text{ dB}, \quad \omega_p = 1 \text{ kHz}, \quad \alpha_s = 40 \text{ dB}, \quad \text{and} \quad \omega_s = 3 \text{ kHz}$$

Plugging these values into Eqs. (111.3) and (111.4), we obtain  $K_\alpha = 197$  and  $K_\omega = 3$ . Using Eqs. (111.6) and (111.7), respectively, we see that the order of filter necessary to meet these specifications is  $N_{IC} = 4$  for an inverse Chebyshev filter and  $N_{EC} = 3$  for an elliptical-Cauer filter. From Table 111.2 we obtain the following values for the inverse Chebyshev fourth-order and elliptical-Cauer third-order filters that meet the specifications:

*Inverse Chebyshev fourth-order* ( $\alpha_s = 40 \text{ dB}$  and  $\alpha_p = 1.00 \text{ dB}$ ):

$$\text{Stage 1} \quad Q_1 = 0.5540 \quad \omega_1 = 1.3074 \quad \omega_{n1} = 2.5312$$

$$\text{Stage 2} \quad Q_2 = 1.4780 \quad \omega_2 = 1.1832 \quad \omega_{n2} = 6.1109$$

*Elliptical-Cauer third-order* ( $\alpha_s = 40 \text{ dB}$  and  $\alpha_p = 1.00 \text{ dB}$ ):

$$\text{Stage 0} \quad \omega_0 = 0.5237$$

$$\text{Stage 1} \quad Q_1 = 2.2060 \quad \omega_1 = 1.0027 \quad \omega_{n1} = 2.7584$$

With Table 111.2, an extra step is required in order to find the normalized element values for the circuit of Fig. 111.5. We must use Eq. (111.9) to find the element values for each stage from the values found in the table for  $Q$  ( $Q_1, Q_2, \dots$ ),  $\omega_0$  ( $\omega_1, \omega_2, \dots$ ), and  $\omega_n$  ( $\omega_{n1}, \omega_{n2}, \dots$ ). For odd-order filters, we must also add a first-order RC low-pass filter to the cascade with normalized values  $R = 1.0$  and  $C = \omega_0$ . To obtain practical values, we then denormalize by impedance scaling to a practical impedance level (we have chosen 10 k $\Omega$ ) and frequency scaling to  $\omega_p = 1$  kHz. Thus we multiply all resistors by  $10^4$  and divide all capacitors by  $10^4$  to impedance-scale, and we then divide all capacitors by  $2\pi \times 10^3$  to frequency-scale. The practical values for the resistors and the capacitors become:

*Inverse Chebyshev fourth-order* ( $\alpha_p = 1.00$  dB):

Stage 1	$R_a = 5.35 \text{ k}\Omega$	$R_b = 20.8 \text{ k}\Omega$	$R_c = 37.5 \text{ k}\Omega$
	$R = 5.54 \text{ k}\Omega$	$C = 12.2 \text{ nF}$	
Stage 2	$R_a = 9.83 \text{ k}\Omega$	$R_b = 394 \text{ k}\Omega$	$R_c = 267 \text{ k}\Omega$
	$R = 14.8 \text{ k}\Omega$	$C = 13.5 \text{ nF}$	

*Elliptical-Cauer third-order* ( $\alpha_p = 1.00$  dB)

Stage 0	$R_0 = 10.0 \text{ k}\Omega$	$C_0 = 30.4 \text{ nF}$	
Stage 1	$R_a = 9.74 \text{ k}\Omega$	$R_b = 167 \text{ k}\Omega$	$R_c = 75.7 \text{ k}\Omega$
	$R = 22.1 \text{ k}\Omega$	$C = 15.9 \text{ nF}$	

Note: All resistors labeled 1 - in Fig. 111.5 become 10 k $\Omega$ .

## Defining Terms

**Active RC filter:** A filter circuit that uses an active device (FET, transistor, op-amp, transconductance amp, etc.) with resistors and capacitors without the need for inductors. Active RC filters are particularly suited for integrated circuit applications.

**Bessel-Thompson filter:** A mathematical approximation to an ideal filter in which the group delay of the transfer function in the frequency domain is maximally flat. Bessel-Thompson filters are optimum in the sense that they offer the least droop without overshoot in the group delay.

**Biquad:** A filter circuit that implements a second-order filter function. High-order filters are often built from a cascade of second-order blocks. Each of these second-order blocks is referred to as a biquad because in the  $s$  domain these filters are characterized by a quadratic function of  $s$  in both the numerator and denominator.

**Butterworth filter:** A mathematical approximation to an ideal filter in which the magnitude of the transfer function in the frequency domain is maximally flat. Butterworth filters are optimum in the sense that they provide the least droop without overshoot in the magnitude response.

**Cascade:** A circuit topology in which a series of simple circuits (often biquads) are connected with the output of the first to the input of the second, the output of the second to the input of the third, and so forth. Using this configuration, a complex filter can be constructed from a "cascade" of simpler circuits.

**Chebyshev filter:** A mathematical approximation to an ideal filter in which the magnitude of the transfer function has a series of ripples in the passband that are of equal amplitude. Chebyshev filters are optimum in the sense that they offer the sharpest transition band for a given filter order for an all-pole filter.

**Elliptical-Cauer filter:** A mathematical approximation of an ideal filter in which the magnitude of the transfer function has a series of ripples in both the passband and stopband that are of equal amplitude. Elliptical-Cauer filters are optimum in the sense that they provide the sharpest possible transition band for a given filter order.

**Filter circuit:** An electronic circuit that passes some frequencies and rejects others so as to separate signals according to their frequency content. Common filter types are low-pass, band-pass, and high-pass, which refer to whether they pass low, middle, or high frequencies, respectively.

**Inverse Chebyshev filters:** A mathematical approximation to an ideal filter exhibiting a Butterworth magnitude response in the passband and an elliptical-Cauer magnitude response in the stopband.

**LC ladder filter circuits:** A planar circuit topology resembling a ladder in which the rungs of the ladder (referred to as the *parallel circuit elements*) consist of inductors or capacitors, one rail of the ladder is the ground plane, and the other rail (referred to as the *series circuit elements*) consists of a series connection of inductors and capacitors.

**Passband:** The frequencies for which a filter passes the signal from the input to the output without significant attenuation.

**Passive RLC filter:** A filter circuit that uses only passive devices, resistors, capacitors, inductors, and mutual inductors.

**Pole frequency ( $\omega_0$ ):** A parameter of a biquad filter used along with  $Q$  to define the location of the complex second-order pole pair in the  $s$  domain. The pole frequency  $\omega_0$  is the distance of the second-order pole pair from the origin in the  $s$  plane. This frequency is approximately equal to the cutoff frequency for low-pass and high-pass filters and to the resonant frequency for band-pass filters (see  $Q$ ).

**$Q$ :** A parameter of a biquad circuit used along with  $\omega_0$  to define the location of the complex second-order pole pair in the  $s$  plane. The real part of the pole pair is located in the  $s$  plane at  $\omega_0/2Q$ . The two poles are at a distance  $\omega_0$  from the origin in the  $s$  plane.

**Stopband:** The frequencies for which a filter provides significant attenuation for signals between the input and the output.

**Transition band:** The frequencies between a passband and stopband for which there are no filter specifications that must be met. Transition bands are necessary to allow for practical filter circuits, but it is desirable to keep transition bands as narrow as possible (i.e., a sharp

transition band).

Transistors form the basis of all modern electronic devices and systems, including the integrated circuits used in systems ranging from radio and TVs to computers. Transistors are solid-state electron devices made out of a category of materials called *semiconductors*. The most widely used semiconductor for transistors, by far, is silicon, although gallium arsenide, which is a compound semiconductor, is used for some very-high-speed applications. We will start off with a very brief discussion of semiconductors. Then there will be a short discussion of PN junctions and diodes, followed by a section on the three major types of transistors, the bipolar junction transistor (BJT), the junction field-effect transistor (JFET), and the metal-oxide silicon field-effect transistor (MOSFET).

## 112.1 Semiconductors

---

Semiconductors are a category of materials with an electrical conductivity that is intermediate between that of the good conductors and the insulators. The good conductors, which are all metals, have electrical resistivities down in the range of  $10^{-6}$ – $\cdot\text{cm}$ . The insulators have electrical resistivities that are up in the range of  $10^6$  to as much as about  $10^{12}$ – $\cdot\text{cm}$ . Semiconductors have resistivities that are generally in the range of  $10^{-4}$  to  $10^4$ – $\cdot\text{cm}$ . The resistivity of a semiconductor is strongly influenced by impurities, called **dopants**, that are purposely added to the material to change the electronic characteristics.

We will first consider the case of the pure, or **intrinsic**, semiconductor. As a result of the thermal energy present in the material, electrons can break loose from covalent bonds and become free electrons able to move through the solid and contribute to the electrical conductivity. The covalent bonds left behind have an electron vacancy called a **hole**. Electrons from neighboring covalent bonds can easily move into an adjacent bond with an electron vacancy, or hole, and thus the hole can move from one covalent bond to an adjacent bond. As this process continues, we can say that

the hole is moving through the material. These holes act as if they have a positive charge equal in magnitude to the electron charge, and they can also contribute to the electrical conductivity. Thus, in a semiconductor there are two types of mobile electrical charge carriers that can contribute to the electrical conductivity: the free electrons and the holes. Since the electrons and holes are generated in equal numbers and recombine in equal numbers, the free electron and hole populations are equal.

In the **extrinsic** or **doped semiconductor**, impurities are purposely added to modify the electronic characteristics. In the case of silicon, every silicon atom shares its four valence electrons with each of its four nearest neighbors in covalent bonds. If an impurity or "dopant" atom with a valency of five, such as phosphorus, is substituted for silicon, four of the five valence electrons of the dopant atom will be held in covalent bonds. The extra, or fifth, electron will not be in a covalent bond and is loosely held. At room temperature, almost all of these extra electrons will have broken loose from their parent atoms and become free electrons. These pentavalent dopants thus donate free electrons to the semiconductor and are called **donors**. These donated electrons upset the balance between the electron and hole populations, so there are now more electrons than holes. This is now called an **N-type semiconductor**, in which the electrons are the **majority carriers** and holes are the **minority carriers**. In an N-type semiconductor the free electron concentration is generally many orders of magnitude larger than the hole concentration.

If an impurity or dopant atom with a valency of three, such as boron, is substituted for silicon, three of the four valence electrons of the dopant atom will be held in covalent bonds. One of the covalent bonds will be missing an electron. An electron from a neighboring silicon-to-silicon covalent bond, however, can easily jump into this electron vacancy, thereby creating a vacancy, or hole, in the silicon-to-silicon covalent bond. These trivalent dopants thus accept free electrons, thereby generating holes, and are called **acceptors**. These additional holes upset the balance between the electron and hole populations, so there are now more holes than electrons. This is now called a **P-type semiconductor**, in which the holes are the majority carriers and the electrons are the minority carriers. In a P-type semiconductor the hole concentration is generally many orders of magnitude larger than the electron concentration.

Figure 112.1 shows a single crystal chip of silicon that is doped with acceptors to make it a P-type on one side and doped with donors to make it N-type on the other side. The transition between the two sides is called the *PN junction*. As a result of the concentration difference of the free electrons and holes there will be an initial flow of these charge carriers across the junction, which will result in the N-type side attaining a net positive charge with respect to the P-type side. This results in the formation of an electric potential "hill" or barrier at the junction. Under equilibrium conditions the height of this potential hill, called the **contact potential**, is such that the flow of the majority carrier holes from the P-type side up the hill to the N-type side is reduced to the extent that it becomes equal to the flow of the minority carrier holes from the N-type side down the hill to the P-type side. Similarly, the flow of the majority carrier free electrons from the N-type side is reduced to the extent that it becomes equal to the flow of the minority carrier electrons from the P-type side. Thus the net current flow across the junction under equilibrium conditions is zero.

**Figure 112.1** PN junction.

In Fig. 112.2 the silicon chip is connected as a *diode*, or two-terminal electrode device. The situation in which a bias voltage is applied is shown. In Fig. 112.2(a) the bias voltage is a **forward bias**, which produces a reduction in the height of the potential hill at the junction. This allows for a large increase in the flow of electrons and holes across the junction. As the forward bias voltage increases, the **forward current** will increase at approximately an exponential rate and can become very large.

**Figure 112.2** Diode.

In Fig. 112.2(b) the bias voltage is a **reverse bias**, which produces an increase in the height of the potential hill at the junction. This essentially chokes off the flow of (1) electrons from the N-type side to the P-type side, and (2) holes from the P-type side to the N-type side. The only thing left is the very small trickle of electrons from the P-type side and holes from the N-type side. Thus the **reverse current** of the diode will be very small.

In Fig. 112.3 the circuit schematic symbol for the diode is shown, and in Fig. 112.4 a graph of the current versus voltage curve for the diode is presented. The P-type side of the diode is called the **anode**, and the N-type side is the **cathode** of the diode. The forward current of diodes can be very large—in the case of large power diodes, up into the range of 10 to 100 A. The reverse current is generally very small, often down in the low nanoampere or even picoampere range.

**Figure 112.3** Diode symbol.

**Figure 112.4** Current versus voltage curve.

The diode is basically a one-way voltage-controlled current switch. It allows current to flow in the forward direction when a forward bias voltage is applied, but when a reverse bias is applied the current flow becomes extremely small. Diodes are used extensively in electronic circuits. Applications include rectifiers to convert AC to DC, waveshaping circuits, peak detectors, DC level shifting circuits, and signal transmission gates. Diodes are also used for the demodulation of amplitude-modulated (AM) signals.

## 112.2 Bipolar Junction Transistors

---

A basic diagram of the bipolar junction transistor, or BJT, is shown in [Fig. 112.5](#). Whereas the diode has one PN junction, the BJT has two PN junctions. The three regions of the BJT are the emitter, base, and collector. The middle, or base, region is very thin, generally less than 1 micrometer wide. This middle electrode, or base, can be considered as the control electrode that controls the current flow through the device between emitter and collector. A small voltage applied to the base (i.e., between base and emitter) can produce a large change in the current flow through the BJT.

**Figure 112.5** Bipolar junction transistor.

BJTs are often used for the amplification of electrical signals. In these applications the emitter-base PN junction is turned "on" (forward biased) and the collector-base PN junction is "off" (reverse biased). For the NPN BJT shown in Fig. 112.5, the emitter will emit electrons into the base region. Since the P-type base region is so very thin, most of these electrons will survive the trip across the base and reach the collector-base junction. When the electrons reach the collector-base junction they will "roll downhill" into the collector and thus be collected by the collector to become the collector current,  $I_C$ . The emitter and collector currents will be approximately equal, so  $I_C \cong I_E$ . There will be a small base current,  $I_B$ , resulting from the emission of holes from the base across the emitter-base junction into the emitter. There will also be a small component of the base current due to the recombination of electrons and holes in the base. The ratio of collector current to base current, given by the parameter  $\beta$  or  $h_{FE}$ , is  $\beta = I_C/I_B$ , which will be very large, generally up in the range of 50 to 300 for most BJTs.

In Fig. 112.6(a) the circuit schematic symbol for the NPN transistor is shown, and in Fig. 112.6(b) the corresponding symbol for the PNP transistor is given. The basic operation of the PNP transistor is similar to that of the NPN, except for a reversal of the polarity of the algebraic signs of all DC currents and voltages.

**Figure 112.6** BJT schematic symbols.

In Fig. 112.7 the operation of a BJT as an amplifier is shown. When the BJT is operated as an amplifier the emitter-base PN junction is turned "on" (forward biased) and the collector-base PN junction is "off" (reverse biased). An AC input voltage applied between base and emitter,  $v_{in} = v_{be}$ , can produce an AC component,  $i_c$ , of the collector current. Since  $i_c$  flows through a load resistor,  $R_L$ , an AC voltage,  $v_o = v_{ce} = -i_c \cdot R_L$ , will be produced at the collector. The AC small-signal voltage gain is  $A_V = v_o/v_{in} = v_{ce}/v_{be}$ .

**Figure 112.7** BJT amplifier.

The collector current,  $I_C$ , of a BJT when operated as an amplifier is related to the base-to-emitter voltage,  $V_{BE}$ , by the exponential relationship  $I_C = I_{CO} \cdot \exp(V_{BE}/V_T)$ , where  $I_{CO}$  is a constant and  $V_T = \text{thermal voltage} = 25 \text{ mV}$ . The rate of change of  $I_C$  with respect to  $V_{BE}$  is given by the **transfer conductance**,  $g_m \geq dI_C/dV_{BE} = I_C/V_T$ . If the net load driven by the collector of the transistor is  $R_L$ , the AC small-signal voltage gain is  $A_V = v_{ce}/v_{be} = -g_m \cdot R_L$ . The negative sign indicates that the output voltage will be an amplified but inverted replica of the input signal. If, for example, the transistor is biased at a DC collector current level of  $I_C = 1 \text{ mA}$  and drives a net load of  $R_L = 10 \text{ k}\Omega$ , then  $g_m = I_C/V_T = 1 \text{ mA}/25 \text{ mV} = 40 \text{ mS}$ , and  $A_V = v_{ce}/v_{be} = -g_m \cdot R_L = -40 \text{ mS} \cdot 10 \text{ k}\Omega = -400$ . Thus we see that the voltage gain of a single BJT amplifier stage can be very large, often up in the range of 100 or more.

The BJT is a three-electrode or *triode* electron device. When connected in a circuit it is usually operated as a two-port, or two-terminal, pair device, as shown in Fig. 112.8. Therefore, one of the three electrodes of the BJT must be common to both the input and output ports. Thus there are three basic BJT configurations: common-emitter (CE), common-base (CB), and common-collector (CC). The most often used configuration, especially for amplifiers, is the common-emitter (CE), although the other two configurations are used in some applications.

**Figure 112.8** The BJT as a two-port device.

The BJT is often used as a switching device, especially in digital circuits, and in high-power applications. When used as a switching device, the transistor is switched between the *cutoff region*, in which both junctions are off, and the *saturation region*, in which both junctions are on. In the cutoff region the collector current is reduced to a very small value, down in the low nanoampere range, so the transistor looks essentially like an open circuit. In the saturation region the voltage drop between collector and emitter becomes very small, usually less than 0.1 volts, and the transistor looks like a very small resistance.

## 112.3 Junction Field-Effect Transistors

A *junction field-effect transistor* (JFET) is a type of transistor in which the current flow through the device between the drain and source electrodes is controlled by the voltage applied to the gate electrode. A simple physical model of the JFET is shown in Fig. 112.9. In this JFET an N-type conducting channel exists between drain and source. The gate is a heavily doped P-type region (designated as P<sup>+</sup> that surrounds the N-type channel. The gate-to-channel PN junction is normally kept reverse biased. As the reverse bias voltage between gate and channel increases, the depletion region width increases, as shown in Fig. 112.10. The depletion region extends mostly into the N-type channel because of the heavy doping on the P<sup>+</sup> side. The depletion region is depleted of mobile charge carriers and thus cannot contribute to the conduction of current between drain and source. Thus, as the gate voltage increases, the cross-sectional area of the N-type channel available for current flow decreases. This reduces the current flow between drain and source. As the gate voltage increases, the channel gets further constricted and the current flow gets smaller. Finally when the depletion regions meet in the middle of the channel, as shown in Fig. 112.11, the channel is pinched off in its entirety, all of the way between the source and the drain. At this point the current flow between drain and source is reduced to essentially zero. This voltage is called the **pinch-off voltage,  $V_p$** . The pinch-off voltage is also represented as  $V_{GS}(\text{off})$ , as being the gate-to-source voltage that turns the drain-to-source current,  $I_{DS}$ , off.

**Figure 112.9** JFET model.

**Figure 112.10** JFET with increased gate voltage.

**Figure 112.11** JFET with pinched-off channel.

We have been considering here an N-channel JFET. The complementary device is the P-channel JFET, which has a heavily doped N-type P<sup>+</sup> gate region surrounding a P-type channel. The operation of a P-channel JFET is the same as for an N-channel device, except the algebraic signs of all DC voltages and currents are reversed.

We have been considering the case for  $V_{DS}$  small compared to the pinch-off voltage, such that the channel is essentially uniform from drain to source, as shown in Fig. 112.12(a). Now let's see what happens as  $V_{DS}$  increases. As an example, let's assume an N-channel JFET with a pinch-off voltage of  $V_P = -4$  V. We will see what happens for the case of  $V_{GS} = 0$  as  $V_{DS}$  increases. In Fig. 112.12(a) the situation is shown for the case of  $V_{DS} = 0$  in which the JFET is fully on and there is a uniform channel from source to drain. This is at point A on the  $I_{DS}$  versus  $V_{DS}$  curve of Fig. 112.13. The drain-to-source conductance is at its maximum value of  $g_{ds}(on)$ , and the drain-to-source resistance is correspondingly at its minimum value of  $r_{ds}(on)$ . Now let's consider the case of  $V_{DS} = +1$  V, as shown in Fig. 112.12(b). The gate-to-channel bias voltage at the source end is still  $V_{GS} = 0$ . The gate-to-channel bias voltage at the drain end is  $V_{GD} = V_{GS} - V_{DS} = -1$  V, so the depletion region will be wider at the drain end of the channel than at the source end. The channel will thus be narrower at the drain end than at the source end and this will result in a decrease in the channel conductance,  $g_{ds}$ , and correspondingly, an increase in the channel resistance,  $r_{ds}$ . So the slope of  $I_{DS}$  versus  $V_{DS}$  curve that corresponds to the channel conductance will be smaller at  $V_{DS} = 1$  V than it was at  $V_{DS} = 0$ , as shown at point B on the  $I_{DS}$  versus  $V_{DS}$  curve of Fig. 112.13.

**Figure 112.12** N-type channel.

**Figure 112.13**  $I_{DS}$  versus  $V_{DS}$  curve.

In Fig. 112.12(c) the situation for  $V_{DS} = +2$  V is shown. The gate-to-channel bias voltage at the source end is still  $V_{GS} = 0$ , but the gate-to-channel bias voltage at the drain end is now  $V_{GD} = V_{GS} - V_{DS} = -2$  V, so the depletion region will now be substantially wider at the drain end of the channel than at the source end. This leads to a further constriction of the channel at the drain end and this will again result in a decrease in the channel conductance,  $g_{ds}$ , and correspondingly, as increase in the channel resistance,  $r_{ds}$ . So, the slope of the  $I_{DS}$  versus  $V_{DS}$  curve will be smaller at  $V_{DS} = 2$  V than it was at  $V_{DS} = 1$  V, as shown at point C on the  $I_{DS}$  versus  $V_{DS}$  curve of Fig. 112.13.

**Figure 112.14** JFET drain characteristics.

In Fig. 112.12(d) the situation for  $V_{DS} = +3 \text{ V}$  is shown, and this corresponds to point D on the  $I_{DS}$  versus  $V_{DS}$  curve of Fig. 112.13.

When  $V_{DS} = +4 \text{ V}$  the gate-to-channel bias voltage will be  $V_{GD} = V_{GS} - V_{DS} = 0 - 4 \text{ V} = -4 \text{ V} = V_P$ . As a result the channel is now pinched off at the drain end, but it is still wide open at the source end since  $V_{GS} = 0$ , as shown in Fig. 112.12(e). It is very important to note that the channel is pinched off just for a very short distance at the drain end, so that the drain-to-source current,  $I_{DS}$ , can still continue to flow. This is not at all the same situation as for the case of  $V_{GS} = V_P$ , wherein the channel is pinched off in its entirety, all of the way from source to drain. When this happens, it is like having a big block of insulator the entire distance between source and drain, and  $I_{DS}$  is reduced to essentially zero. The situation for  $V_{DS} = +4 \text{ V} = -V_P$  is shown at point E on the  $I_{DS}$  versus  $V_{DS}$  curve of Fig. 112.13.

The region below the active region where  $V_{DS} < +4 \text{ V} = -V_P$  has several names. It is called the **nonsaturated region**, the **triode region**, and the **ohmic region**. The term *triode region* apparently originates from the similarity of the shape of the curves to that of the vacuum tube triode. The term *ohmic region* is due to the variation of  $I_{DS}$  with  $V_{DS}$  as in Ohm's law, although this variation is nonlinear except for the region where  $V_{DS}$  is small compared to the pinch-off voltage, where  $I_{DS}$  will have an approximately linear variation with  $V_{DS}$ .

So far we have looked at the  $I_{DS}$  versus  $V_{DS}$  curve only for the case of  $V_{GS} = 0$ . In Fig. 112.14 a family of curves  $I_{DS}$  versus  $V_{DS}$  for various constant values of  $V_{GS}$  is presented. These are called the *drain characteristics*, also known as the **output characteristics**, since the output side of the JFET is usually the drain side. In the active region where  $I_{DS}$  is relatively independent of  $V_{DS}$ , there is a simple approximate equation relating  $I_{DS}$  to  $V_{GS}$ . This is the "square law" **transfer equation** as given by  $I_{DS} = I_{DSS} [1 - (V_{GS}/V_P)]^2$ . In Fig. 12.15 a graph of the  $I_{DS}$  versus  $V_{GS}$  *transfer characteristics* for the JFET is presented. When  $V_{GS} = 0$ ,  $I_{DS} = I_{DSS}$  as expected, and as  $V_{GS} \rightarrow V_P$ ,  $I_{DS} \rightarrow 0$ . The lower boundary of the active region is controlled by the condition that the channel be pinched off at the drain end. To meet this condition the basic requirement is that the gate-to-channel bias voltage at the drain end of the channel,  $V_{GD}$ , be greater than the pinch-off voltage  $V_P$ . For the example under consideration with  $V_P = -4 \text{ V}$ , this means that  $V_{GD} = V_{GS} - V_{DS}$  be more negative than  $-4 \text{ V}$ . Therefore,  $V_{DS} - V_{GS} \geq +4 \text{ V}$ . Thus, for  $V_{GS} = 0$ , the active region will begin at  $V_{DS} = +4 \text{ V}$ . When  $V_{GS} = -1 \text{ V}$ , the active region will begin at  $V_{DS} = +3 \text{ V}$ , for now  $V_{GD} = -4 \text{ V}$ . When  $V_{GS} = -2 \text{ V}$ , the active region begins at  $V_{DS} = +2 \text{ V}$ , and when  $V_{GS} = -3 \text{ V}$ , the active region begins at  $V_{DS} = +1 \text{ V}$ . The dotted line in Fig. 112.14 marks the boundary between the nonsaturated and active regions.

**Figure 112.15** JFET transfer characteristics.

In the nonsaturated region  $I_{DS}$  is a function of both  $V_{GS}$  and  $I_{DS}$ , and in the lower portion of the nonsaturated region where  $V_{DS}$  is small compared to  $V_P$ ,  $I_{DS}$  becomes an approximately linear function of  $V_{DS}$ . This linear portion of the nonsaturated is called the *voltage-variable resistance* (VVR) region, for in this region the JFET acts like a linear resistance element between source and drain. The resistance is variable in that it is controlled by the gate voltage.

### THREE-ELECTRODE CIRCUIT ELEMENT UTILIZING SEMICONDUCTIVE MATERIALS

John Bardeen and

Walter H. Brattain

Patented October 3, 1950

#2,524,035

An excerpt:

The principal object of the invention is to amplify or otherwise translate electric signals or variations by use of compact, simple, and rugged apparatus of novel type.

Another object is to provide a circuit element for use as an amplifier or the like which does not require a heated thermionic cathode for its operation, and which therefore is immediately operative when turned on. A related object is to provide such a circuit element which requires no evacuated

or gas-filled envelope.

What Bardeen, Brattain, and Shockley invented at Bell Laboratories was the Transistor; the fundamental element in our modern electronic world. It soon replaced vacuum tubes in applications calling for amplifiers, oscillators and even relays in digital switching. (©1992, DewRay Products, Inc. Used with permission.)

This Schottky-collector Resonant Tunneling Diode (RTD) is believed to be the fastest active semiconductor-based device. Microwave and DC measurements indicate that it has a maximum frequency of oscillation ( $f_{\max}$ ) of 2.2 THz ( $2.2 \times 10^{12}$  Hz). Devices capable of such fast oscillation are potentially useful for extremely compact, high-frequency radiometers, radar systems, or space-based communications systems.

The semiconductor material consists of heavily doped n-type InGaAs beneath an AlAs/InGaAs quantum well structure. The T-shaped, air-bridged anode is in contact with a very thin top layer of fully depleted InGaAs. The novel top contact, together with its very small size of approximately

0.1 micron, results in much lower resistance than other, similar devices. This low resistance is responsible for the extremely high  $f_{\max}$  of the RTD.

The semiconductor layer structure was grown on an InP substrate by MBE (Molecular Beam Epitaxy). The T-anode was fabricated using an electron-beam lithography system and a multi-layer resist.

This device was developed by M. Reddy, M. J. Mondry, and M. J. W. Rodwell, U.C.S.B.; S. C. Martin, R. E. Muller, and R. P. Smith, CSMT, JPL/Caltech; and D. H. Chow and J. N. Schulman, Hughes Research Laboratories. (Photo courtesy of Madhukar Reddy.)

The work at U.C.S.B. was supported by ONR under contract #N00014-93-1-0378, NSF/PYI, and a JPL President's Fund. The work at JPL was performed by the Center for Space Microelectronics Technology, Jet Propulsion Laboratory, California Institute of Technology, and was sponsored by the National Aeronautics and Space Administration, Office of Advanced Concepts and Technology, and by the Innovative Science and Technology Office of BMDO through an agreement with NASA.

## JFET as an Amplifier - Small-Signal AC Voltage Gain

Let's consider the common-source amplifier of Fig. 112.16. The input AC signal is applied between gate and source, and the output AC voltage between is taken between drain and source. Thus the source electrode of this triode device is common to input and output, hence the designation of this JFET configuration as a common-source (CS) amplifier.

**Figure 112.16** Common source amplifier.

A good choice of the DC operating point or quiescent point ("Q-point") for an amplifier is in the middle of the active region at  $I_{DS} = I_{DSS} / 2$ . This allows for the maximum symmetrical drain current swing, from the quiescent level of  $I_{DSQ} = I_{DSS} / 2$ , down to a minimum of  $I_{DS} \cong 0$ , and up to a maximum of  $I_{DS} = I_{DSS}$ . This choice for the Q-point is also a good one from the standpoint of allowing for an adequate safety margin for the location of the actual Q-point due to the inevitable variations in device and component characteristics and values. This safety margin should keep the Q-point well away from the extreme limits of the active region, and thus ensure operation of the JFET in the active region under most conditions. If  $I_{DSS} = +10$  mA, then a good choice for the Q-point would thus be around +5 mA. The AC component of the drain current,  $i_{ds}$ , is related to the AC component of the gate voltage,  $v_{gs}$  by  $i_{ds} = g_m \cdot v_{gs}$  where  $g_m$  is the **dynamic transfer conductance** and is given by  $g_m = 2\sqrt{I_{DS} \cdot I_{DSS}} / (-V_P)$ . If  $V_P = -4$  V, then  $g_m = \sqrt{5 \text{ mA} \cdot 10 \text{ mA}} / 4 \text{ V} = 3.54 \text{ mA/V} = 3.54 \text{ mS}$ . If a small AC signal voltage,  $v_{gs}$ , is superimposed on the quiescent DS gate bias voltage  $V_{GSQ} = V_{GG}$  only a small segment of the transfer characteristic adjacent to the Q-point will be traversed, as shown in Fig. 112.17. This small segment will be close to a straight line, and as a result the AC drain current,  $i_{ds}$ , will have a waveform close to that of the AC voltage applied to the gate. The ratio of  $i_{ds}$  to  $v_{gs}$  will be the slope of the transfer curve as given by  $i_{ds}/v_{gs} \cong dI_{DS}/dV_{GS} = g_m$ . Thus  $i_{ds} \cong g_m \cdot v_{gs}$ . If the net load driven by the drain of the JFET is the drain load resistor,  $R_D$ , as shown in Fig. 112.16, then the AC drain current  $i_{ds}$  will produce an AC drain voltage of  $v_{ds} = -i_{ds} \cdot R_D$ . Since  $i_{ds} = g_m \cdot v_{gs}$ , this becomes  $v_{ds} = -g_m v_{GS} \cdot R_D$ . The AC small-signal voltage gain from gate to drain thus becomes  $A_V = v_O/v_{IN} = v_{ds}/v_{gs} = -g_m \cdot R_D$ . The negative sign indicates signal inversion as is the case for a common-source amplifier.

**Figure 112.17** JFET transfer characteristic.

If the DC drain supply voltage is  $V_{DD} = +20$  V, a quiescent drain-to-source voltage of  $V_{DSQ} = V_{DD} / 2 = 10$  V will result in the JFET being biased in the middle of the active region. Since  $I_{DSQ} = 5$  mA in the example under consideration, the voltage drop across the drain load resistor,  $R_D$ , is 10 V. Thus  $R_D = 10 \text{ V} / 5 \text{ mA} = 2 \text{ k}\Omega$ . The AC small-signal voltage gain,  $A_V$ , thus becomes  $A_V = -g_m \cdot R_D = -3.54 \text{ mS} \cdot 2 \text{ k}\Omega = -7.07$ . Note that the voltage gain is relatively modest compared to the much larger voltage gains that can be obtained in a

bipolar-junction transistor (BJT) common-emitter amplifier. This is due to the lower transfer conductance of both JFETs and MOSFETs compared to BJTs. For a BJT the transfer conductance is given by  $g_m = I_C/V_T$ , where  $I_C$  is the quiescent collector current and  $V_T = kT/q \cong 25$  mV is the "thermal voltage." At  $I_C = 5$  mA,  $g_m = 5$  mA / 25 mV = 200 mS for the BJT, as compared to only 3.5 mS for the JFET in this example. With a net load of 2 k $\Omega$ , the BJT voltage gain will be  $-400$  as compared to the JFET voltage gain of only 7.1. Thus FETs have the disadvantage of a much lower transfer conductance and therefore lower voltage gain than BJTs operating under similar quiescent current levels, but they do have the major advantage of a much higher input impedance and a much lower input current. In the case of a JFET the input signal is applied to the reverse-biased gate-to-channel PN junction and thus sees a very high impedance. In the case of a common-emitter BJT amplifier the input signal is applied to the forward-biased base-emitter junction and the input impedance is given approximately by  $r_{IN} = r_{BE} \cong 1.5 \cdot \beta \cdot V_T/I_C$ . If  $I_C = 5$  mA and  $\beta = 200$ , for example, then  $r_{IN} \cong 1500\Omega$ . This moderate input resistance value of 1.5 k $\Omega$  is certainly no problem if the signal source resistance is less than around 100 $\Omega$ . However, if the source resistance is above 1 k $\Omega$ , then there will be a substantial signal loss in the coupling of the signal from the signal source to the base of the transistor. If the source resistance is in the range of above 100 k $\Omega$ , and certainly if it is above 1 M $\Omega$ , there will be severe signal attenuation due to the BJT input impedance, and a FET amplifier will probably offer a greater overall voltage gain. Indeed, when high impedance signal sources are encountered, a multistage amplifier with a FET input stage, followed by cascaded BJT stages, is often used.

## 112.4 Metal-Oxide Silicon Field-Effect Transistors

A **metal-oxide silicon field-effect transistor** (MOSFET) is similar to a JFET, in that it is a type of transistor in which the current flow through the device between the drain and source electrodes is controlled by the voltage applied to the gate electrode. A simple physical model of the MOSFET is shown in Fig. 112.18. The gate electrode is electrically insulated from the rest of the device by a thin layer of silicon dioxide (SiO<sub>2</sub>). In the absence of any gate voltage there is no conducting channel between source and drain, so the device is off and  $I_{DS} \cong 0$ . If now a positive voltage is applied to the gate, electrons will be drawn into the silicon surface region immediately underneath the gate oxide. If the gate voltage is above the **threshold voltage**,  $V_T$ , there will be enough electrons drawn into this silicon surface region to make the electron population greater than the hole population. This surface region under the oxide will thus become N-type; this region will be called an *N-type surface inversion layer*. This N-type surface inversion layer will now constitute an N-type conducting channel between source and drain, as shown in Fig. 112.19, so that now current can flow and  $I_{DS} > 0$ . Further increases in the gate voltage,  $V_{GS}$ , above the threshold voltage,  $V_T$ , will cause more electrons to be drawn into the channel. The increase in the electron population in the channel will result in an increase in the conductance of the channel and thus an increase in  $I_{DS}$ .

**Figure 112.18** MOSFET physical model.

**Figure 112.19**  $V_{GS} > V_T$ .

At small values of the drain-to-source voltage,  $V_{DS}$ , the drain current,  $I_{DS}$ , will increase linearly with  $V_{DS}$ , but as  $V_{DS}$  increases the channel will become constricted at the drain end and the curve of  $I_{DS}$  versus  $V_{DS}$  will start to bend over. Finally, if  $V_{DS}$  is large enough such that  $V_{GS} - V_{DS} < V_T$ , the channel becomes pinched off at the drain end and the curve of  $I_{DS}$  versus  $V_{DS}$  will become almost horizontal, as shown in Fig. 112.20. This region where  $I_{DS}$  becomes relatively independent of  $V_{DS}$  is called the *active region*. When the MOSFET is used as an amplifier it should be operated in the active region.

**Figure 112.20**  $I_{DS}$  versus  $V_{DS}$  curve.

In the active region  $I_{DS}$  is relatively independent of  $V_{DS}$  but is a strong function  $V_{GS}$ . The transfer relationship between  $I_{DS}$  and  $V_{GS}$  in the active region is given approximately by the square law equation  $I_{DS} = K(V_{GS} - V_T)^2$ , where  $K$  is a constant. In Fig. 112.21, a graph of the  $I_{DS}$  versus  $V_{GS}$  transfer characteristics of an N-channel MOSFET is shown.

**Figure 112.21** Transfer characteristic.

In the active region, under small-signal conditions, the AC component of the drain current is related to the AC component of the gate voltage by  $i_{ds} = g_m \cdot v_{gs}$  where  $g_m$  is the *dynamic transfer conductance*. We have that  $g_m = dI_{DS}/dV_{GS} = 2K(V_{GS} - V_T)$  Since  $K = I_{DS}/(V_{GS} - V_T)^2$  this can be expressed as  $g_m = 2I_{DS}/(V_{GS} - V_T)$  Since  $(V_{GS} - V_T) = \sqrt{I_{DS}/K}$  this can also be rewritten as  $g_m = 2\sqrt{K \cdot I_{DS}}$

## MOSFET as an Amplifier - Small-Signal AC Voltage Gain

In Fig. 112.22 some MOSFET symbols are shown for both N-channel and P-channel devices.

**Figure 112.22** MOSFET symbols.

Let's consider the MOSFET common-source amplifier circuit of Fig. 112.23. The input AC signal is applied between the gate and the source as  $v_{gs}$ , and the output AC voltage is taken between the drain and the source as  $v_{ds}$ . Thus the source electrode of this triode device is common to input and output—hence the designation of this MOSFET configuration as common-source (CS) amplifier.

**Figure 112.23** Common source amplifier.

Let us assume a quiescent current level of  $I_{DSQ} = 10 \text{ mA}$  and  $V_{GS} - V_T = 1 \text{ V}$ . The AC component of the drain current,  $i_{ds}$ , is related to the AC component of the gate voltage,  $v_{gs}$ , by  $i_{ds} = g_m \cdot v_{gs} \Omega$ , where  $g_m$  is the *dynamic transfer conductance*, and is given by  $g_m = 2K(V_{GS} - V_T) = 2I_{DS}/(V_{GS} - V_T) = 2 \cdot 10 \text{ mA} / 1 \text{ V} = 20 \text{ mS}$ . If a small AC signal voltage,  $v_{gs}$ , is superimposed on the DC gate bias voltage  $V_{GS}$ , only a small segment of the transfer characteristic adjacent to the Q-point will be traversed, as shown in Fig. 112.24. This small segment will be close to a straight line, and as a result the AC drain current,  $i_{ds} \Omega$ , will have a waveform close to that of the AC voltage applied to the gate. The ratio of  $i_{ds}$  to  $v_{gs}$  will be the slope of the transfer curve, as given by  $i_{ds}/v_{gs} \cong dI_{DS}/dV_{GS} = g_m \Omega$ . Thus,  $i_{ds} \cong g_m \cdot v_{gs}$ . If the net load driven by the drain of the MOSFET is the drain load resistor,  $R_D$ , as shown in Fig. 112.23, then the AC drain current  $i_{ds}$  will produce an AC drain voltage of  $v_{ds} = -i_{ds} \cdot R_D \Omega$ . Since  $i_{ds} = g_m \cdot v_{gs}$ , this becomes  $v_{ds} = -g_m v_{gs} \cdot R_D \Omega$ . The AC small-signal voltage gain from gate to drain thus becomes  $A_V = v_o/v_{in} = v_{ds}/v_{gs} = -g_m \cdot R_D \Omega$ . The negative sign indicates signal inversion as is the case for a common-source amplifier.

**Figure 112.24** Transfer characteristic.

If the DC drain supply voltage is  $V_{DD} = +20 \text{ V}$ , a quiescent drain-to-source voltage of  $V_{DSQ} = V_{DD}/2 = +10 \text{ V}$  will result in the MOSFET being biased in the middle of the active region. Since  $I_{DSQ} = 10 \text{ mA}$  in the example under consideration and the voltage drop across the drain load resistor ( $R_D$ ) is  $10 \text{ V}$ , we obtain  $R_D = 10 \text{ V} / 10 \text{ mA} = 1 \text{ k}\Omega$ . The AC small-signal voltage gain,  $A_V$ , thus becomes  $A_V = -g_m \cdot R_D = -20 \text{ mS} \cdot 1 \text{ k}\Omega = -20$ . Note that the voltage gain is relatively modest, as compared to the much larger voltage gains that can be obtained in a bipolar-junction transistor (BJT) common-emitter amplifier. This is due to the lower transfer conductance of both JFETs and MOSFETs compared to BJTs. For a BJT the transfer conductance is given by  $g_m = I_C/V_T \Omega$ , where  $I_C$  is the quiescent collector current and  $V_T = kT/q \cong 25 \text{ mV}$  is the thermal voltage. At  $I_C = 10 \text{ mA}$ ,  $g_m = 10 \text{ mA} / 25 \text{ mV} = 400 \text{ mS}$ , compared to only  $20 \text{ mS}$  for the MOSFET in this example. With a net load of  $1 \text{ k}\Omega$  the BJT voltage gain will be  $-400 \Omega$  compared to the MOSFET voltage gain of only  $-20 \Omega$ . Thus FETs do have the disadvantage of a much lower transfer conductance and therefore lower voltage gain than BJTs operating under similar quiescent current levels, but they do have the major advantage of a much higher input impedance and a much lower input current. In the case of a MOSFET the input signal is applied to

the gate, which is insulated from the rest of the device by the thin  $\text{SiO}_2$  layer, and thus sees a very high impedance. In the case of a common-emitter BJT amplifier, the input signal is applied to the forward-biased base-emitter junction and the input impedance is given approximately by  $r_{\text{IN}} = r_{\text{BE}} \cong 1.5 \cdot \beta \cdot V_T / I_C$ , where  $V_T$  is the thermal voltage of about 25 mV. If  $I_C = 5$  mA and  $\beta = 200$ , for example, then  $r_{\text{IN}} \cong 1500 \Omega$ . This moderate input resistance value of 1.5 k $\Omega$  is certainly no problem if the signal source resistance is less than around 100  $\Omega$ . However, if the source resistance is above 1 k $\Omega$ , there will be a substantial signal loss in the coupling of the signal from the signal source to the base of the transistor. If the source resistance is in the range of above 100 k $\Omega$ , and certainly if it is above 1 M $\Omega$ , there will be severe signal attenuation due to the BJT input impedance, and an FET amplifier will probably offer a greater overall voltage gain. Indeed, when high-impedance signal sources are encountered, a multistage amplifier with an FET input stage followed by cascaded BJT stages is often used.

## MOSFETs for Digital Circuits

MOSFETs are used very extensively for digital applications. For high-density integrated circuits MOSFETs offer great advantages over BJTs and JFETs from the standpoint of a much smaller size and lower power consumption.

A very important MOSFET configuration is the *complementary symmetry MOSFET*, or **CMOS** circuit. In Fig. 112.25, a CMOS inverter circuit is shown, comprising an N-channel MOSFET (NMOS) and a P-channel MOSFET (PMOS). In Fig. 112.25(b), the situation is shown with the input signal in the high or "1" state. The NMOS is now on and exhibits a moderately low resistance, typically on the order of 100  $\Omega$ . The PMOS is off and acts as a very high resistance. This situation results in the output voltage  $V_O$ , going low, close to ground potential (0 V).

**Figure 112.25** CMOS circuit.

In Fig. 112.25(c), the situation is shown with the input signal in the low, or "0" state. The NMOS is off and acts as a very high resistance, and the PMOS is on and exhibits a moderately low resistance, typically on the order of  $100\ \Omega$ . This situation results in the output voltage,  $V_O$ , being pulled up high (the "1" state), close to the  $V_{DD}$  supply.

We note that under both input conditions one of the transistors will be off, and as a result the current flow through the two transistors will be extremely small. Thus the power dissipation will also be very small, and, indeed, the only significant amount of power dissipation in the CMOS pair occurs during the short switching interval when both transistors are simultaneously on.

## Defining Terms

**Active region:** The region of transistor operation in which the output current is relatively independent of the output voltage. For the BJT this corresponds to the condition that the emitter-base junction is on, and the collector-base junction is off. For the FETs this corresponds to the condition that the channel is on, or open, at the source end, and pinched off at the drain end.

**Acceptors:** Impurity atoms that, when added to a semiconductor, contribute holes. In the case of silicon, acceptors are atoms from the third column of the periodic table, such as boron.

**Anode:** The P-type side of a diode.

**Cathode:** The N-type side of a diode.

**CMOS:** The complementary-symmetry MOSFET configuration composed of an N-channel MOSFET and a P-channel MOSFET, operated such that when one transistor is on, the other is off.

**Contact potential:** The internal voltage that exists across a PN junction under thermal equilibrium conditions, when no external bias voltage is applied.

**Donors:** Impurity atoms that, when added to a semiconductor, contribute free electrons. In the case of silicon, donors are atoms from the fifth column of the periodic table, such as phosphorus, arsenic, and antimony.

**Dopants:** Impurity atoms that are added to a semiconductor to modify the electrical conduction characteristics.

**Doped semiconductor:** A semiconductor that has had impurity atoms added to modify the electrical conduction characteristics.

**Extrinsic semiconductor:** A semiconductor that has been doped with impurities to modify the electrical conduction characteristics.

**Forward bias:** A bias voltage applied to the PN junction of a diode or transistor that makes the P-type side positive with respect to the N-type side.

**Forward current:** The large current flow in a diode that results from the application of a forward bias voltage.

**Hole:** An electron vacancy in a covalent bond between two atoms in a semiconductor. Holes are mobile charge carriers with an effective charge that is opposite to the charge on an electron.

**Intrinsic semiconductor:** A semiconductor with a degree of purity such that the electrical characteristics are not significantly affected.

**Majority carriers:** In a semiconductor, the type of charge carrier with the larger population. For example, in an N-type semiconductor, electrons are the majority carriers.

**Minority carriers:** In a semiconductor, the type of charge carrier with the smaller population. For example, in an N-type semiconductor, holes are the minority carriers.

**N-type semiconductor:** A semiconductor that has been doped with donor impurities to produce the condition that the population of free electrons is greater than the population of holes.

**Ohmic, nonsaturated, or triode region:** These three terms all refer to the region of FET operation in which a conducting channel exists all of the way between source and drain. In this region the drain current varies with both the gate voltage and the drain voltage.

**Output characteristics:** The family of curves of output current versus output voltage. For the BJT output characteristics are curves of collector current versus collector voltage for various constant values of base current or voltage and are also called the *collector characteristics*. For FETs these will be curves of drain current versus drain voltage for various constant values of gate voltage and are also called the *drain characteristics*.

**P-type semiconductor:** A semiconductor that has been doped with acceptor impurities to produce the condition that the population of holes is greater than the population of free electrons.

**Pinch-off voltage,  $V_P$  :** The voltage that, when applied across the gate-to-channel PN junction, will cause the conducting channel between drain and source to become pinched off. This is also represented as  $V_{GS}$  (off).

**Reverse bias:** A bias voltage applied to the PN junction of a diode or transistor that makes the P-type side negative with respect to the N-type side.

**Reverse current:** The small current flow in a diode that results from the application of a reverse bias voltage.

**Thermal voltage:** The quantity  $kT/q$  where  $k$  is Boltzmann's constant,  $T$  is absolute temperature, and  $q$  is electron charge. The thermal voltage has units of volts and is a function only of temperature, being approximately 25 mV at room temperature.

**Threshold voltage:** The voltage required to produce a conducting channel between source and drain in a MOSFET.

**Transfer conductance:** The AC or dynamic parameter of a device that is the ratio of the AC output current to the AC input voltage. The transfer conductance is also called the *mutual transconductance* and is usually designated by the symbol  $g_m$ .

**Transfer equation:** The equation that relates the output current (collector or drain current) to the input voltage (base-to-emitter or gate-to-source voltage).

**Triode:** The three-terminal electron device, such as a bipolar junction transistor or a field-effect transistor.

An **integrated circuit** is an electronic device in which there is more than one circuit component in the same package. Most integrated circuits contain many transistors, together with diodes, resistors, and capacitors. Integrated circuits may contain tens, hundreds, or even many thousands of transistors. Indeed, some integrated circuits for computer and image-sensing applications may have millions of transistors or diodes on a single silicon chip.

A **monolithic integrated circuit** is one in which all of the components are contained on a single-crystal chip of silicon. This silicon chip typically measures from  $1 \times 1 \times 0.25$  mm thick for the smallest integrated circuits to  $10 \times 10 \times 0.5$  mm for the larger integrated circuits.

A **hybrid integrated circuit** has more than one chip in the package. The chips may be monolithic integrated circuits and separate or "discrete" devices such as transistor or diode chips. There can also be discrete passive components such as capacitor and resistor chips. The chips are usually mounted on an insulating ceramic substrate, usually alumina ( $\text{Al}_2\text{O}_3$ ), and are interconnected by a thin-film or thick-film conductor pattern that has been deposited on the ceramic substrate. Thin-film patterns are deposited by vacuum evaporation techniques and are usually about 1 micrometer in thickness, whereas thick-film patterns are pastes that are printed on the substrate through a screen and usually range in thickness from 10 to 30 micrometers.

Integrated circuits can be classified according to function, the two principal categories being *digital* and *analog* (also called *linear*) integrated circuits. A digital integrated circuit is one in

which all of the transistors operate in the switching mode, being either off (in the cutoff mode of operation) or on (in the saturation mode) to represent the high and low (1 and 0) digital logic levels. The transistors during the switching transient pass very rapidly through the active region. Virtually all digital integrated circuits are of the monolithic type and are composed almost entirely of transistors, usually of the MOSFET type. Some digital integrated circuits contain more than one million transistors on a single silicon chip.

Analog or linear integrated circuits operate on signal voltages and currents that are in analog or continuous form. The transistors operate mostly in the active (or linear) mode of operation. There are many different types of analog integrated circuits, such as operational amplifiers, voltage comparators, audio power amplifiers, voltage regulators, voltage references, video (wide-bandwidth) amplifiers, radio-frequency amplifiers, modulators and demodulators for AM and FM, logarithmic converters, function generators, voltage-controlled oscillators, phase-locked loops, digital-to-analog and analog-to-digital converters, and other devices. The majority of analog integrated circuits are of the monolithic type, although there are many hybrid integrated circuits of importance.

In addition to the two basic functional categories of analog and digital integrated circuits, there are many integrated circuits that have both analog and digital circuitry in the same integrated circuit package, or even on the same chip. Some of the analog integrated circuits mentioned previously, such as the digital-to-analog and analog-to-digital converters, contain both types of circuitry.

Almost all integrated circuits are fabricated from silicon. The principal exceptions are some very high-speed digital integrated circuits that use gallium arsenide (GaAs) to take advantage of the very high electron mobility in that material. Integrated circuits are fabricated using the same basic processes as for other semiconductor devices. In integrated circuits the vast majority of devices are transistors and diodes, with relatively few passive components such as resistors and capacitors. In many cases no capacitors at all are used, and in some cases there are no resistors either. The active devices contained in an integrated circuit are transistors, including bipolar junction transistors (BJTs), junction field-effect transistors (JFETs), and metal-oxide silicon field-effect transistors (MOSFETs). Digital integrated circuits are made up predominantly of MOSFETs, with generally very few other types of components. Some analog integrated circuits use mostly, or even exclusively, BJTs, although many integrated circuits use a mixture of BJTs and field-effect transistors (either JFETs or MOSFETs), and some are even exclusively FETs, with no BJTs at all.

The sections that follow give very brief descriptions of some of the analog integrated circuits.

## 113.1 Operational Amplifiers

---

An operational amplifier is an integrated circuit that produces an output voltage,  $V_O$ , that is an amplified replica of the difference between two input voltages, as given by the equation  $V_O = A_{OL}(V_1 - V_2)$ , where  $A_{OL}$  is called the open-loop gain. The basic symbol for the operational amplifier is shown in Fig. 113.1. Most operational amplifiers are of the monolithic type, and there are hundreds of different types of operational amplifiers available from dozens of different manufacturers.

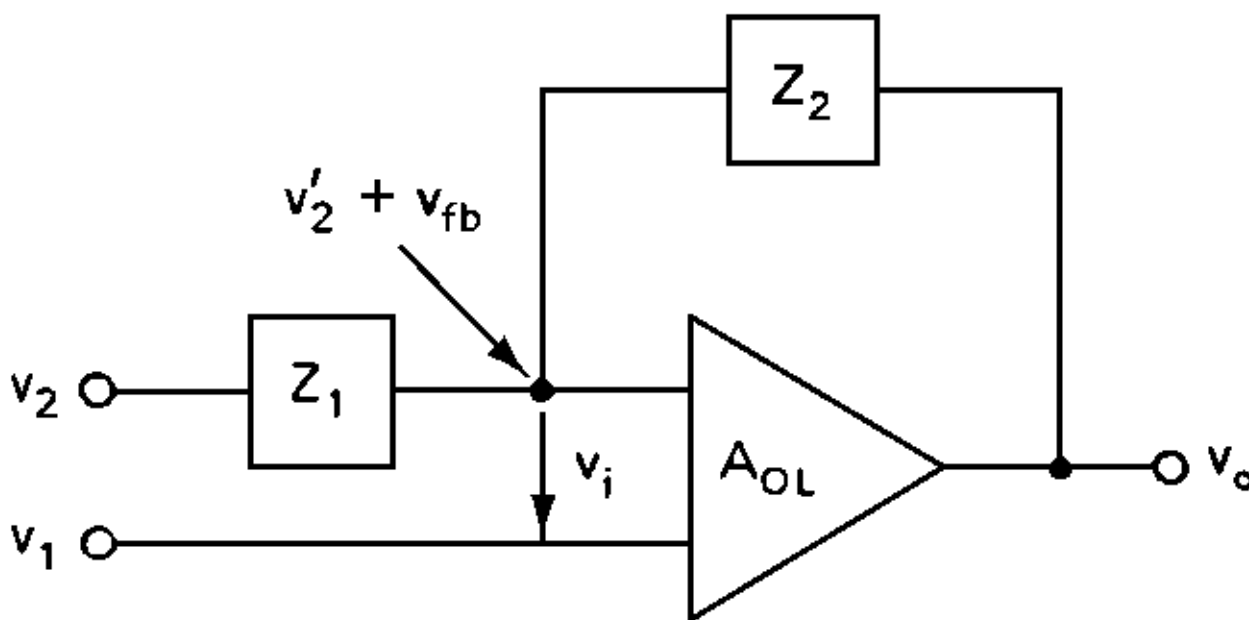

**Figure 113.1** Operational amplifier symbols: (a) basic operational amplifier symbol; (b) symbol with input polarities indicated explicitly; (c) symbol with input polarities indicated explicitly. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

The operational amplifier was one of the first types of analog integrated circuits developed; the term *operational amplifier* comes from one of the earliest uses of this type of circuit—in analog computers dating back to the early and middle 1960s. Operational amplifiers were used in conjunction with other circuit components, principally resistors and capacitors, to perform various mathematical operations, such as addition, subtraction, multiplication, integration, and differentiation—hence the name "operational amplifier." The range of applications of operational amplifiers has vastly expanded since these early beginnings; operational amplifiers are now used to perform a multitude of tasks through the entire field of electronics.

Operational amplifiers are usually used in a feedback, or closed-loop, configuration, as shown in Fig. 113.2. Under the assumption of a large open-loop gain,  $A_{OL}$ , the output voltage is given by  $V_o = V_1[1 + (Z_2/Z_1)] - V_2(Z_2/Z_1)$ .

**Figure 113.2** Closed-loop (negative feedback) operational-amplifier system. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

The following is a list of some important applications of operational amplifiers:

*Difference amplifier.* This produces an output voltage proportional to the difference of two input voltages.

*Summing amplifier.* This produces an output voltage that is a weighted summation of a number of input voltages.

*Current-to-voltage converter.* This produces an output voltage that is proportional to an input current.

*Voltage-to-current converter.* This produces an output current that is proportional to an input voltage but is independent of the load being driven.

*Active filters.* This is a very broad category of operational amplifier circuit that can be configured as low-pass, high-pass, band-pass, or band-stop filters.

*Precision rectifiers and clipping circuits.* This is a broad category of wave-shaping circuits that can be used to clip off or remove various portions of a waveform.

*Peak detectors.* This produces an output voltage proportional to the positive or negative peak value of an input voltage.

*Logarithmic converters.* This produces an output voltage proportional to the logarithm of an input voltage.

*Exponential or antilogarithmic converters.* This produces an output voltage that is an exponential function of an input voltage.

*Current integrator or charge amplifier.* This produces an output voltage proportional to net flow of charge in a circuit.

*Voltage regulators.* This produces an output voltage that is regulated to remain relatively constant with respect to changes in the input or supply voltage and with respect to changes in the output or load current.

*Constant current sources.* This produces an output current that is regulated to remain relatively constant with respect to changes in the input or supply voltage and with respect to changes in the output or load impedance or voltage.

*Amplifiers with electronic gain control.* These are amplifiers in which the gain can be controlled over a wide range by the application of an external voltage.

*Function generators.* These are circuits that can be used to generate various types of waveforms, including square waves and triangular waves.

*Clamping circuits.* These circuits produce an output voltage that has the same AC waveform as the input signal, but the DC level is shifted by an amount controlled by a fixed reference voltage.

*Analog signal multiplexer.* This circuit combines several input signals for transmission over a single communications link by means of *time-domain multiplexing*.

*Sample-and-hold circuit.* The input signal is sampled over a short period of time, and the sampled value is then held at that value until the next sample is taken.

*Analog multiplier.* This produces an output voltage proportional to the product of two input voltages.

## 113.2 Voltage Comparators

A voltage comparator is an integrated circuit as shown in Fig. 113.3 that is used to compare two input voltages and produce an output voltage that is in the high (or "1") stage if  $V_1 > V_2$  and in the low (or "0") stage if  $V_1 < V_2$ . It is essentially a one-bit analog-to-digital converter.

**Figure 113.3** Voltage comparator. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

In many respects, voltage comparators are similar to operational amplifiers, and, indeed, operational amplifiers can be used as voltage comparators. A voltage comparator is, however, designed specifically to be operated under open-loop conditions, basically as a switching device. An operational amplifier, on the other hand, is almost always used in a closed-loop configuration and is usually operated as a linear amplifier.

Being designed to be used in a closed-loop configuration, the frequency response characteristics of an operational amplifier are generally designed to ensure an adequate measure of stability against an oscillatory type of response. This results in a sacrifice being made in the bandwidth, rise time, and slewing rate of the device. In contrast, since a voltage comparator operates as an open-loop device, no sacrifices have to be made in the frequency response characteristics, so a very fast response time can be obtained.

An operational amplifier is designed to produce a zero output voltage when the difference between the two input signals is zero. A voltage comparator, in contrast, operates between two fixed output voltage levels, so the output voltage is either in the high or low states.

The output voltage of an operational amplifier will saturate at levels that are generally about 1 or 2 V away from the positive and negative power supply voltage levels. The voltage comparator output is often designed to provide some degree of flexibility in fixing the high- and low-state output voltage levels and for ease in interfacing with digital logic circuits.

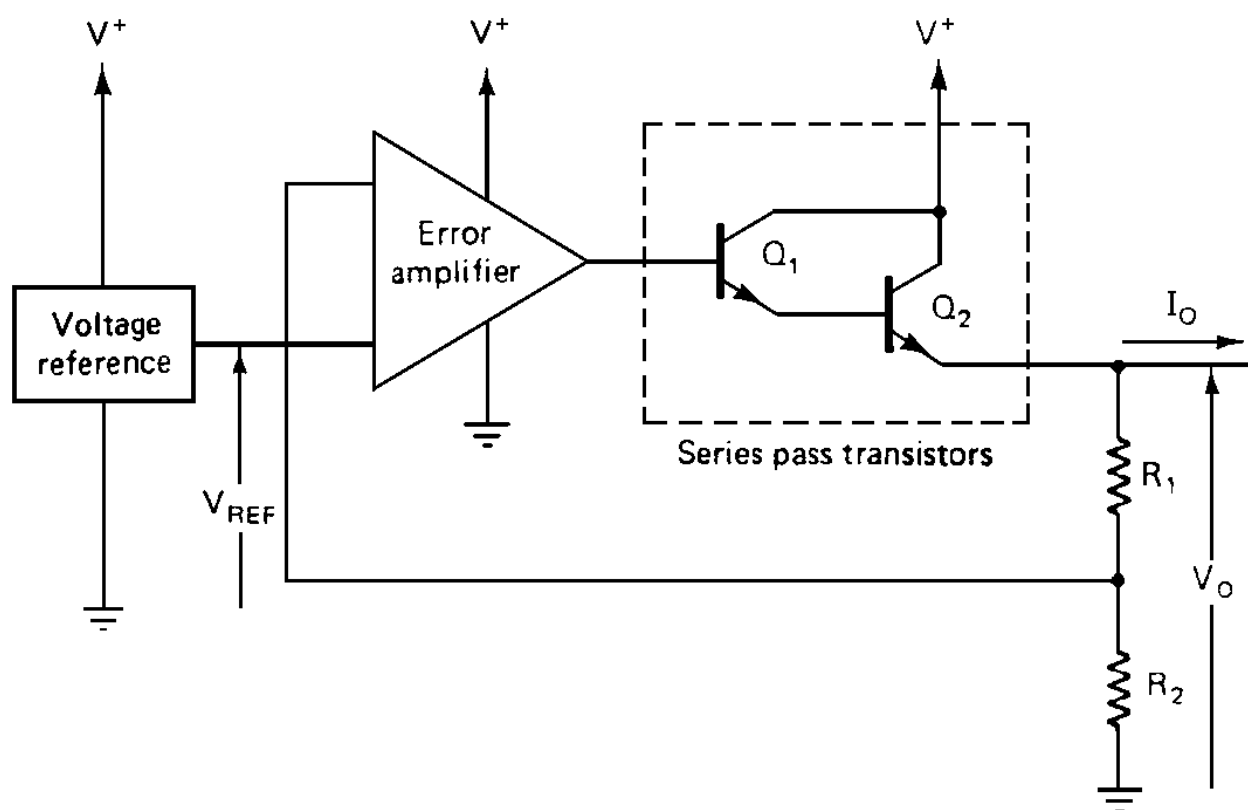

There are many applications of voltage comparators. These include pulse generators, square-wave and triangular-wave generators, pulse-width modulators, level and zero-crossing detectors, pulse regenerators, line receivers, limit comparators, voltage-controlled oscillators, analog-to-digital converters, and time-delay generators.

## 113.3 Voltage Regulators

A voltage regulator is an electronic device that supplies a constant voltage to a circuit or load. The output voltage of the voltage regulator is regulated by the internal circuitry of the device to be relatively independent of the current drawn by the load, the supply or line voltage, and the ambient temperature. A voltage regulator may be part of some larger electronic circuit but is often a separate unit or module, usually in the form of an integrated circuit. A voltage regulator, as shown in Fig. 113.4, is composed of three basic parts:

1. A voltage reference circuit that produces a reference voltage that is independent of the temperature and supply voltage
2. An amplifier to compare the reference voltage with the fraction of the output that is fed back from the voltage regulator output to the inverting input terminal of the amplifier
3. A series-pass transistor or combination of transistors to provide an adequate level of output current to the load being driven

**Figure 113.4** Voltage regulator: basic block diagram. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

Voltage regulators usually include protection circuitry such as current limiting and thermal limiting to protect the integrated circuit against overheating and possible damage.

An important type of voltage regulator is the *switching-mode regulator*, in which the series-pass transistors are not on continuously but, rather, are rapidly switched from being completely on to completely off. The output voltage level is controlled by the fraction of time that the series-pass transistors are on (i.e., the duty cycle). Switching-mode regulators are characterized by having very high efficiencies, often above 90%.

## 113.4 Power Amplifiers

---

Although most integrated circuit amplifiers can deliver only small amounts of power to a load, generally well under 1 watt, there are integrated circuits that are capable of supplying much larger amounts of power, up in the range of several watts, or even several tens of watts. There are a variety of integrated circuit audio power amplifiers available that are used in the range of frequencies up to about 10 or 20 kHz for amplification of audio signal for delivery to loudspeakers. These integrated circuit audio power amplifiers also are used for other applications, such as relay drivers and motor controllers.

There are also available a variety of power operational amplifiers. The maximum current available from most operational amplifiers is generally in the range of about 20 to 25 mA. The maximum supply voltage rating is usually around 36 V with a single supply or +18 V and −18 V when a split supply is used. For an operational amplifier with a 36 V total supply voltage, the maximum peak-to-peak output voltage swing available will be around 30 V. With a maximum output current rating of 20 mA, the maximum AC power that can be delivered to a load is  $P_L = 30 \text{ V} \times 20 \text{ mA} / 4 = 150 \text{ mW}$ . Although this level of output power is satisfactory for many applications, a considerably larger power output is required for some applications.

Larger AC power outputs from operational amplifiers can be obtained by adding external *current boost* power transistors that are driven by the operational amplifier to the circuit. There are also available *power operational amplifiers* that are capable of operation with supply voltages as high as 200 V, and with peak output current swings as large as 20 A. With the proper heat sinking for efficient transfer of heat from the integrated circuit to the ambient, the power operational amplifiers can deliver output power up in the range of tens of watts to a load.

### HOW A CHIP IS MADE

Semiconductor chips are made from silicon, an element found in ordinary beach sand. Silicon's conductive properties allow for the creation of on/off switches that equal a one or zero in a computer's binary language.

Through hundreds of complex processing steps, the switches are built and connected into circuits, millions of which can be placed on a single chip.

The exact nature and number of steps needed to manufacture a semiconductor chip varies with its design and complexity, but the basic process remains the same.

Ultra-pure silicon is processed into cylinders that are sliced into thin, 5- to 8-inch diameter wafers on which hundreds of individual computer chips can be made. The wafers are cleaned, inspected, and placed in high temperature furnaces where they are coated with a non-conducting oxide film.

A thin layer of light-sensitive plastic, called photoresist, is applied over the oxide. A glass "mask," containing the chip's circuit pattern, is placed over the wafer and precisely aligned. In a process called photolithography, which is similar to developing a photograph from a negative, light or an X-ray beam is projected through the mask to print each chip's circuit pattern on the wafer surface.

The unexposed photoresist is washed away in solvent baths, etching the protective oxide layer with the shape of the circuit pattern. Holes are also etched in the protective oxide layer.

The wafer is then bombarded with ions, or charged particles, that penetrate the holes etched in the oxide surface. The depth and concentration of these materials determine the specific electrical characteristics of the chip. The process of oxidation, photolithography, etching, and ion implanting are repeated to build transistors and other electronic circuitry that make up each chip.

Once the electronic components have been implanted in the silicon, interconnecting wiring is added to the chip by placing the wafer in a vacuum chamber and coating it with copper mixed with aluminum or other metals. The aluminum is etched away, leaving the desired wiring.

A thin layer of material is added to protect the wafer. The wafers are then cut into individual chips by diamond-bladed saws and mounted in metal or plastic packages, called modules. These modules are tested and plugged into printed circuit boards, which are eventually built into finished computers.

## 113.5 Wide-Bandwidth (Video) Amplifiers

Video, or wide-bandwidth, amplifiers are designed to give a relatively flat gain versus frequency response characteristic over the frequency range that is generally required to transmit video information. This frequency range is from low frequencies, generally around 30 Hz, up to several megahertz. For standard television reception, the bandwidth required is around 4 MHz, but for other video display applications the bandwidth requirement may be as high as 20 MHz, and for some applications up in the range of 50 MHz.

In contrast, the bandwidths required for audio applications extend only over the frequency range corresponding to the range of the human ear—around 50 Hz to 15 kHz.

The principal technique that is used to obtain the large bandwidths that are required for video amplifiers is the trading off of reduced gain in each amplifier stage for increased bandwidth. This trade-off is accomplished by the use of reduced load resistances for the various gain stages of the amplifier and by the use of negative feedback. In many video amplifiers both techniques are employed. The reduction in the gain of the individual stages can be compensated for by adding additional gain stages.

Included in the category of video amplifiers are the very wide-bandwidth operational amplifiers. Most operational amplifiers are limited to a bandwidth of around 1 to 10 MHz, but there are wide-bandwidth operational amplifiers available that can be used up in the range of 100 to 200 MHz.

## 113.6 Modulators, Demodulators, and Phase Detectors

---

This is a category of integrated circuit that can be used to produce amplitude-modulated (AM) and frequency-modulated (FM) signals. These same integrated circuits can also be used for the demodulation, or detection, of AM and FM signals. In the AM case these integrated circuits can be used to generate and to demodulate *double-sideband/suppressed carrier* (DSB/SC) and *single-sideband/suppressed carrier* (SSB/SC) signals. Another application of this type of integrated circuit is as a *phase detector*, in which an output voltage proportional to the phase difference of two input signals is produced.

## 113.7 Voltage-Controlled Oscillators

---

A voltage-controlled oscillator (VCO) is an oscillator circuit in which the frequency of oscillation can be controlled by an externally applied voltage. VCOs are generally designed to operate over a wide frequency range, often with a frequency ratio of 100:1. One important feature that is often required for VCOs is a linear relationship between the oscillation frequency and the control voltage. Many VCOs have a maximum frequency of operation of around 1 MHz, but there are some emitter-coupled VCOs that can operate up to 50 MHz.

## 113.8 Waveform Generators

---

A waveform generator is an integrated circuit that generates the following three types of voltage waveforms: square waves, triangular waves, and sinusoidal waves. The square and triangular waves can be generated by the same type of circuits as used for VCOs.

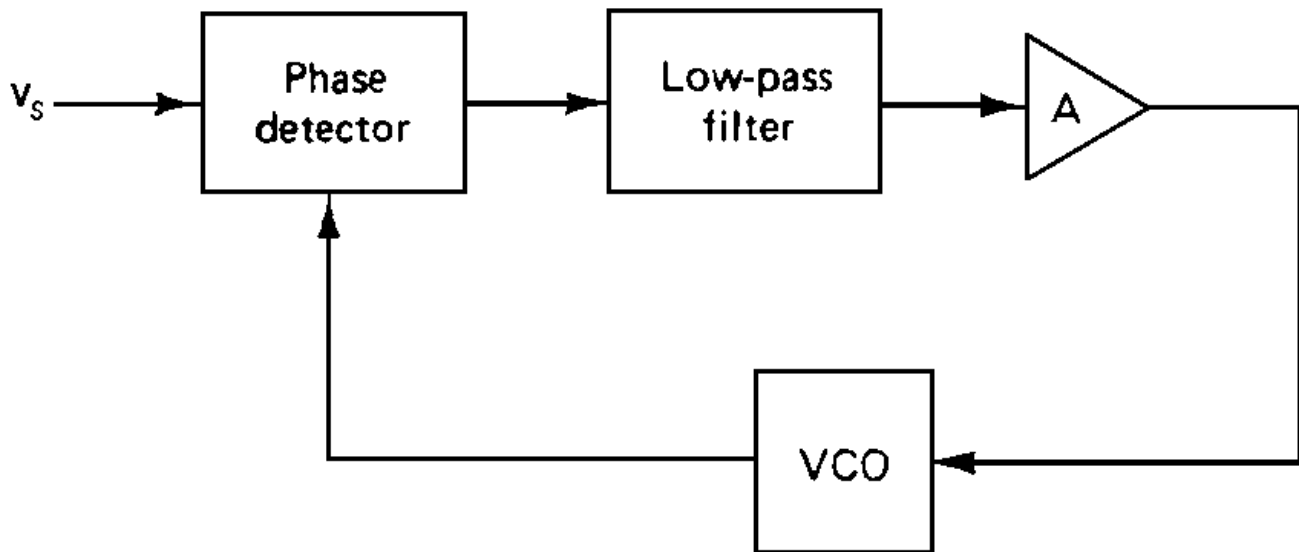

For the generation of a sinusoidal waveform a feedback amplifier using an LC tuned circuit or an RC phase shift network in the feedback loop can be used. These feedback oscillators can produce a very low-distortion sine wave, but it is difficult to modulate the oscillation frequency over a very wide range by means of a control voltage. The VCO, on the other hand, is capable of a frequency sweep ratio as large as 100:1, with very good linearity between the frequency and the control voltage. A sinusoidal waveform can be obtained from a VCO by using a waveshaping network to convert the triangular wave output to a sine wave.

## 113.9 Phase-Locked Loops

---

A phase-locked loop (PLL) is a feedback loop comprising a phase detector, low-pass filter, and a voltage-controlled oscillator (VCO) as shown in [Fig. 113.5](#). When the PLL has locked in on a signal, the frequency of the VCO will exactly follow the signal frequency.

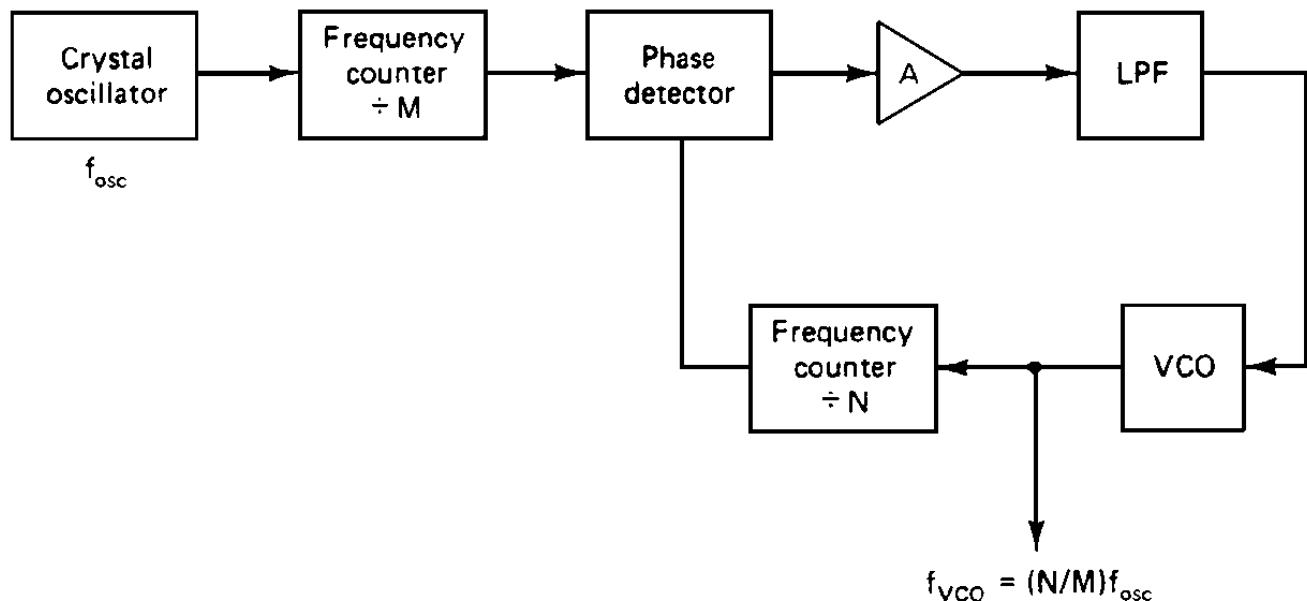

**Figure 113.5** Phase-locked loop. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

The PLL can be used as an FM demodulator or detector. In this case the VCO control voltage is proportional to the frequency deviation of the FM signal and represents the demodulated output voltage. Another closely related application is the demodulation of frequency-shift keying (FSK) signals, a process that is similar to FM except that the signal frequency is shifted between just two values.

One important application of PLLs is in frequency synthesis, in which a precise series of frequencies is produced, all derived from a stable crystal-controlled oscillator. In Fig. 113.6, a PLL frequency synthesizer circuit is shown.

**Figure 113.6** PLL frequency synthesizer. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

## **113.10 Digital-to-Analog and Analog-to-Digital Converters**

---

A digital-to-analog converter (D/A or DAC) is an integrated circuit that converts a digital input signal to an analog output voltage (or current) that is proportional to the digital signal. DACs vary in resolution from 4 to 16 bits.

An analog-to-digital converter (A/D or ADC) is an integrated circuit that converts an analog input signal to a digital output. ADCs vary in resolution from a simple voltage comparator used as a 1-bit ADC to 16-bit ADCs.

For some applications, such as storing entire frames of video information in one-thirtieth of a second, very high conversion rates are required. For these applications parallel comparator (or "flash") ADCs are used with conversion rates as high as 500 MHz for an 8-bit ADC.

## **113.11 Radio-Frequency Amplifiers**

---

There are radio-frequency (R-F) integrated circuits that use tuned circuits and operate as band-pass amplifiers. These are used in communications circuits, such as AM and FM radio, and in television for signal amplification and mixing.

## **113.12 Integrated Circuit Transducers**

---

This is a broad category of integrated circuits that are used for the conversion of various physical inputs to an electrical signal. These circuits include the magnetic field sensor, based on the Hall effect, which produces an output voltage proportional to the magnetic field strength. There are also temperature sensor integrated circuits that can produce a voltage or current output that is proportional to the temperature. There are electromechanical integrated circuit transducers such as pressure sensors that produce an output voltage proportional to pressure. Miniature solid-state accelerometers based on integrated circuit sensors are also available.

## **Optoelectronic Devices**

A very important category of integrated circuit transducers is that of the optoelectronic devices. These devices range from photodiode or phototransistor-amplifier modules to image sensors containing in the range of one million individual photodiode image-sensing elements. These image-sensing integrated circuit chips also include additional circuitry to properly transfer out (line by line, in a serial output) the information from the two-dimensional array of the image sensor.

There are also integrated circuits used with light emitting diodes (LEDs) and laser diodes for the generation of light pulses for optoelectronic communications systems, including fiber optic systems.

In the case of a fiber optic communications system, a small diameter glass fiber is used as a conduit or waveguide to guide a beam of light from transmitter to receiver. Optoelectronic integrated circuits are used at the transmitting end with LEDs or laser diodes for the generation and emission of the optical signal. Optoelectronic integrated circuits are used at the receiving end with photodiodes or phototransistors for the detection, amplification, and processing of the received signal.

## MINIATURIZED ELECTRONIC CIRCUITS

Jack S. Kilby

Patented June 23, 1964

#3,138,743

An excerpt:

In contrast to the approaches to miniaturization that have been made in the past, the present invention has resulted from a new and totally different concept for miniaturization. Radically departing from the teachings of the art, it is proposed by the invention that miniaturization can best be attained by use of as few materials and operations as possible. In accordance with the principles of the invention, the ultimate in circuit miniaturization is attained by using only one material for all circuit elements and a limited number of compatible process steps for the production thereof.

Kilby patented what we now call the Integrated Circuit. He made whole circuits (with transistors, resistors, and capacitors) using a single semiconductor substrate and diffusing opposing materials onto it to form the circuit elements. This fundamental process has advanced to the point that now millions of transistors are put on a single "chip." (© 1992, DewRay Products, Inc. Used with permission.)

## Defining Terms

**Hybrid integrated circuit:** An electronic circuit package that contains more than one chip. These chips can be a mixture of monolithic ICs, diodes, transistors, capacitors, and resistors.

**Integrated circuit:** An electronic circuit package that contains more than one circuit element.

**Monolithic integrated circuit:** A single-crystal chip of a semiconductor, generally silicon, that contains a complete electronic circuit.

*University of Michigan*

The phenomenal development of optoelectronics has been spurred by the needs of light-wave communication systems, optoelectronic computing, instrumentation, and alternate energy systems. The subject of optoelectronics deals with the interaction of light and optical processes with electronic processes. Devices in which such interactions take place—usually accompanied by an energy conversion process—are called *optoelectronic devices*. Examples are light-emitting diodes, lasers, and photodiodes.

The development of optoelectronic devices has gone hand in hand with the research and development of compound semiconductors. In compound semiconductors such as GaAs, InP, ZnS, and CdTe the **band gap** is *direct* and hence the quantum efficiency is very high. Therefore, these binary compounds and their ternary and quaternary derivatives are extensively used for the design and fabrication of high-performance optoelectronic devices. The detailed band structure of GaAs is shown in [Fig. 114.1](#).

**Figure 114.1** The band structure of gallium arsenide.

## 114.1 Light-Emitting Diodes

The light-emitting diode (LED) is a device that is used extensively for display and sensing applications and can emit light in the visible and infrared regions of the spectrum. A semiconductor LED is usually a forward-biased p-n junction. An LED is characterized by simpler design and fabrication procedures, lower cost, and simpler drive circuitry than a laser.

In a junction LED, photons of near-band-gap energy are generated by the process of *electroluminescence*, in which a large density of electrons injected into a normally empty conduction band by forward bias recombine with holes in the valence band to produce photons of approximately band-gap energy. The photons have random phases and therefore the LED is an

incoherent light source. The spectral line width of this emission is typically 20–50 nm, depending on the materials used. The process of injection luminescence is illustrated in Fig. 114.2.

**Figure 114.2** Injection of minority carriers in a forward-biased p-n junction leading to spontaneous emission of photons.

## Device Structure and Efficiency

The schematic of a typical surface-emitting LED is shown in Fig. 114.3. The p-n junction is formed by diffusion or epitaxy. The junction is placed close to the surface to reduce reabsorption of the emitted light. Also, the junction is configured such that most of the recombination takes place in the top layer. This condition is ensured by having the majority of the current flowing across the diode be accounted for by the motion of those carriers that are injected into the top layer from the bottom layer.

**Figure 114.3** Planar surface-emitting LED structure made by (a) diffusion and (b) epitaxial growth.

(a)

(b)

The overall efficiency,  $\eta_o$ , of an LED is given by

$$\eta_o = \eta_{in} \eta_r \eta_e \quad (114.1)$$

where  $\eta_{in}$ ,  $\eta_r$ , and  $\eta_e$  are, respectively, the injection, radiative recombination, and extraction efficiencies.

For electron injection in an  $n^+$ -p diode,

$$\eta_{in} = \left( 1 + \frac{\mu_h N_A L_e}{\mu_e N_D L_h} \right)^{-1} \quad (114.2)$$

where  $N_A$  and  $N_D$  are the acceptor and donor doping levels,  $\mu_e$  and  $\mu_h$  are the electron and hole mobilities, and  $L_e$  and  $L_h$  are the respective diffusion lengths.

The recombination efficiency  $\eta_r$  is the same as the internal quantum efficiency or radiative efficiency, and

$$\eta_r = \frac{R_r}{R_r + R_{nr}} \quad (114.3)$$

where  $R_r$  and  $R_{nr}$  are the radiative and nonradiative recombination rates, respectively. The extraction efficiency relates to the amount of light that can come out of the device and is characterized by a transmission factor,  $F_T$ , given by

$$F_T = \frac{1}{4} \left( \frac{n_{r2}}{n_{r1}} \right)^2 \left[ 1 - \left( \frac{n_{r1} - n_{r2}}{n_{r1} + n_{r2}} \right)^2 \right] \quad (114.4)$$

where  $n_{r2}$  is the refractive index of the semiconductor, and  $n_{r1} = 1$  (air). In standard practice  $F_T$  is increased by covering the active device with a material (usually plastic) with  $n_r > 1$  and making this encasing in the shape of a dome for maximum extraction of light.

The *responsivity* of an LED is defined as the ratio of the emitted optical power  $P_o$  to the injection current. In other words

$$R = \frac{P_o}{I} = \eta_o \frac{h\nu}{q} = \frac{1.24\eta_o}{\lambda(\mu m)} \text{ (W/A)} \quad (114.5)$$

where  $h\nu$  is the photon energy and the emitted optical power is given by

$$P_o = \frac{h\nu V_\ell}{\sqrt{2} \hbar^3 \tau_r} \left( \frac{m_r^*}{\pi} \right)^{3/2} (kT)^{3/2} \exp \left( \frac{\Delta E_f - E_g}{kT} \right) \text{ (W)} \quad (114.6)$$

where  $V_\ell$  is the volume of the active region,  $\hbar (= h/2\pi)$  is the reduced Planck constant,  $k$  is the

Boltzmann constant,  $\tau_r$  is the recombination lifetime, and  $m_r^*$  is the reduced effective mass, given by

$$m_r^* = \frac{m_e^+ m_h^*}{m_e^* + m_h^*} \quad (114.7)$$

$\Delta E_f$  is the energy difference of the electron and hole quasi-Fermi levels and  $E_g$  is the band gap. The terms  $m_e^*$  and  $m_h^*$  represent the **effective mass** of electrons and holes, respectively.

## Heterojunction and Edge-Emitting LEDs

There are two problems with the simple LED structure described in the previous section. First, the recombination process can be dominated by surface states if the junction is too close to the surface. Second, if the junction is placed far from the surface, not only does the reabsorption of the emitted light increase, but the recombination volume is ill defined by the diffusion length of the injected carriers. Use of a **heterojunction** alleviates both these problems. This device is illustrated in [Fig. 114.4\(a\)](#). First, the density of defect states at a **lattice-matched** heterojunction can be far less than the surface state density, and, second, the heterojunction defines the active volume by confining the injected carriers, and therefore the recombination, in the low-band-gap active layer.

**Figure 114.4** (a) Device structure and band diagram of a forward-biased double heterostructure (DH) LED. (b) Schematic illustration of the structure of a stripe geometry DH InGaAs/InGaAs/InP edge-emitting LED.

A typical edge-emitting LED is illustrated in Fig. 114.4(b). Here the heterojunction serves the dual purpose of confining carriers and confining the optical mode, since the refractive index is inversely proportional to the band gap of a semiconductor. This is a guided wave device, very similar to a laser. However, the end facets are not made, and hence the LED does not have a resonant cavity and feedback. Edge-emitting LEDs are very useful for coupling into optical fibers.

## 114.2 Lasers

---

*Laser* is an acronym for light amplification by stimulated emission of radiation. The first semiconductor laser was invented and demonstrated in 1962. The semiconductor laser is essentially a dielectric optical waveguide terminated by facets, or mirrors, to form a resonant cavity. As opposed to an LED, whose output results from spontaneous emission, the output of a laser results from **stimulated emission** and is coherent.

### Lasing Condition and Gain

Figure 114.5(a) shows the process of creating a nonequilibrium population of electrons and holes by photon absorption. The energy of the absorbed photon is  $E_2 - E_1 = h\nu$ . The quasi-Fermi levels are denoted by  $E_{fn}$  and  $E_{fp}$ , respectively. For stimulated emission to occur from this nonequilibrium population distribution, the condition is

$$E_{fn} - E_{fp} > E \quad (114.8)$$

where  $E = h\nu$  is the energy of the emitted photon. This equation represents the condition for optical gain in a semiconductor. The spectral gain of a semiconductor is given by

$$g(E) = \frac{\sqrt{2}(m_r^*)^{3/2} q^2 p_{cv}^2}{3\pi n_r E_o m_o^2 \hbar^2 c E} (E - E_g)^{1/2} [f_n(E_2) - f_p(E_1)] \quad (\text{cm}^{-1}) \quad (114.9)$$

where  $f_n$  and  $f_p$  are the quasi-Fermi functions defined by the quasi-Fermi levels  $E_{fn}$  and  $E_{fp}$ , respectively, and  $p_{cv}$  is the momentum matrix element. The variation of gain with photon energy for different injection levels is schematically shown in Fig. 114.5(b).

**Figure 114.5** Illustration of absorption and stimulated emission processes in a direct band-gap semiconductor and the corresponding dependence of gain (loss) with photon energy.

The first requirement for lasing is that the gain must be at least equal to the losses. The second requirement is that the radiation must be coherent. For this, the lasing medium must be placed in a resonant cavity in which *selective amplification* of one frequency can take place. In a semiconductor laser a Fabry-Perot cavity is obtained by cleaving the two ends of a waveguide.

## Threshold Condition

The threshold condition is derived in the context of a semiconductor laser in which a Fabry-Perot cavity is made by cleaving both sides of the waveguide so that the length of the cavity is given by  $l = m\lambda/2$ . Here,  $\lambda$  is a wavelength near the peak of the spontaneous emission spectrum and  $m$  is an integer. The cleaved edges—being optically flat to near perfection—serve as the mirrors of the cavity because of the large refractive index difference between the semiconductor material and air. The reflectivity of these cleaved facets is  $\sim 0.32$ , and therefore a good portion of the optical signal is also transmitted.

Consider the schematic in Fig. 114.6, where the laser cavity is of length  $l$  and has mirrors of reflectivity  $R_1$  and  $R_2$  at the two ends. Let  $g$  and  $\gamma$  be the gain and loss coefficients, respectively. The total loss in the system results from a number of processes, which include (1) transmission at the mirrors; (2) absorption, scattering, and diffraction losses at the mirrors; (3) absorption in the cladding regions; and (4) scattering at defects in the medium. The loss coefficient  $\gamma$  includes all the losses except the transmission at the ends.

**Figure 114.6** Schematics of a Fabry-Perot cavity.

We calculate the threshold gain by considering the change in intensity of a beam of light

undergoing a round-trip within the cavity. The light intensity at the center, after traveling the length  $2l$ , is given by

$$\mathcal{I} = \mathcal{I}_0 R_1 R_2 e^{2(g-\gamma)l} \quad (114.10)$$

where  $\mathcal{I}_0$  is the initial intensity. Now if  $g > \gamma$ , the intensity grows and there is net amplification. At threshold, when the round-trip gain exactly equals the losses, the following are true:

$$\mathcal{I} = \mathcal{I}_0 \quad (114.11)$$

$$1 = R_1 R_2 e^{2(g_{th}-\gamma)l} \quad (114.12)$$

where  $g_{th}$  is the threshold gain. Equation (114.12) can be expressed in the form

$$g_{th} = \gamma + \frac{1}{2l} \ln \left( \frac{1}{R_1 R_2} \right) \quad (114.13)$$

## Operating Principles

The operating principle of the junction laser is almost identical to that of the LED, in that a large forward bias is applied to inject minority carriers into an active region. In a homojunction laser this active region is defined by the diffusion length of the minority carriers, whereas in a heterojunction laser the active region is defined by the heterojunction boundaries. The heterojunction also helps in confining the optical mode and forming a dielectric waveguide. This device is schematically shown in Fig. 114.7.

**Figure 114.7** Schematics of a broad-area junction laser with cleaved facets.

Within the active region of the junction laser, the gain will eventually exceed the losses with an enhancement in the rate of stimulated emission. Outside the active region the losses will dominate, as depicted in Fig. 114.7. As the rate of stimulated emission increases in the active region, the round-trip gain in the cavity overcomes losses and lasing commences. The injection current at which this occurs is called the *threshold current*, shown schematically in Fig. 114.8. The nature of the spectral output, shown in Fig. 114.8, also changes as incoherent spontaneous emission below threshold is eventually replaced by dominant laser modes above threshold.

**Figure 114.8** The light-current characteristics of a junction laser and the corresponding spectral outputs.

The current flowing in a junction laser is given by

$$J = qdR_{\text{sp}} \text{ (A/cm}^2\text{)} \quad (114.14)$$

where  $d$  is the thickness of the active region and  $R_{\text{sp}}(\text{cm}^{-3} \cdot \text{s}^{-1})$  is the total spontaneous emission rate and is given by

$$R_{\text{sp}} = \frac{(2m_r^*)^{3/2}}{2\pi^2\hbar^3\tau_r} \int_E f_n(E_2)[1 - f_p(E_1)] (E - E_g)^{1/2} dE \quad (114.15)$$

The threshold current density is then given by

$$J_{th} = qdR_{sp}(n_{th}) \quad (114.16)$$

where  $n_{th}$  is the threshold carrier density. This parameter is obtained as follows. The peak gain is plotted against injected carrier density (or injection current) from Fig. 114.5. The plot is shown in Fig. 114.9. The carrier density for which the gain equals the total loss (or  $g_{th}$ ) is  $n_{th}$ .

**Figure 114.9** Calculated TE mode gain coefficient in a 50 Å GaAs/Al<sub>0.3</sub>Ga<sub>0.7</sub>As lattice-matched quantum well laser at 300 K for various carrier injections ( $10^{12}$  carriers/cm<sup>2</sup>) in steps of  $0.5 \cdot 10^{12}/\text{cm}^2$ . The dashed line is the photon energy ( $E_m$ ) at which the gain coefficient is maximum. (Courtesy of J. Singh and J. P. Loehr, University of Michigan.)

## Power Output

With reference to the light-current output of a laser (Fig. 114.8), the optical power output into the modal volume due to a current  $J(> J_{\text{th}})$  can be expressed as

$$P = A(J - J_{\text{th}}) \frac{\eta_i h\nu}{q} \quad (114.17)$$

where  $A$  is the junction area and  $\eta_i$  is the internal quantum efficiency of the semiconductor. A fraction of this power is coupled out through the cleaved facets as useful laser output and the rest is used to overcome the losses,  $\gamma$ , within the cavity. Therefore, the output power of the laser can be expressed as

$$P_0 = A(J - J_{\text{th}}) \left( \frac{\eta_i h\nu}{q} \right) \frac{(1/2l) \ln(1/R_1 R_2)}{[\gamma + (1/2l) \ln(1/R_1 R_2)]} \quad (114.18)$$

## 114.3 Photodetectors

The three main types of detectors are photoconductors, PIN diodes, and avalanche photodiodes. The first and the third types have internal gain. PIN photodiodes have no internal gain but can have very large bandwidths.

Photodetectors are also classified as *intrinsic* or *extrinsic* devices. An intrinsic photodetector detects light of wavelength close to the band gap of the semiconductor. Photoexcitation creates electron-hole pairs, which contribute to the photocurrent. An extrinsic device detects light of energy smaller than the band-gap energy. In these devices the transition corresponding to the absorption of photons involves impurity or defect levels within the band gap.

## Quantum Efficiency and Responsivity

The external quantum efficiency  $\eta_{\text{ext}}$  of a photodetector is given by

$$\eta = \frac{I_{\text{ph}}/q}{P_{\text{inc}}/h\nu} \quad (114.19)$$

where  $I_{\text{ph}}$  is the photocurrent and  $P_{\text{inc}}$  is the incident optical power. The internal quantum efficiency  $\eta_i$  is the number of pairs created divided by the number of photons absorbed and is usually very high. The external quantum efficiency depends on the absorption coefficient,  $\alpha$ , of the material and the thickness of the absorbing region: If this thickness is  $d$ , then the two efficiencies are related by the equation

$$\eta_{\text{ext}} = \eta_i (1 - e^{-\alpha d}) \quad (114.20)$$

The *responsivity* of a detector,  $R$ , is defined as

$$R = \frac{I_{\text{ph}}}{P_{\text{inc}}} = \frac{\eta q}{h\nu} = \frac{\eta \lambda (\mu\text{m})}{1.24} \text{ (A/W)} \quad (114.21)$$

This relation indicates that for a fixed value of  $\eta$ ,  $R$  should increase linearly with  $\lambda$ . In reality, however,  $\eta$  depends on the absorption coefficient  $\alpha$ , which in turn depends on the incident wavelength  $\lambda$ . Therefore, the long-wavelength cutoff of the spectral response is determined by the absorption edge, or band gap, of the semiconductor. A short-wavelength cutoff also exists because at short wavelengths the value of  $\alpha$  is very large in most semiconductors and all the incident optical energy is absorbed near the surface. The spectral response characteristics of a practical device are illustrated in Fig. 114.10.

**Figure 114.10** Schematic illustration of the responsivity of ideal and real photodetectors.

## Photoconductor

The photoconductor is a simple photodetection device whose operation is based on the increase in conductivity with photoexcitation. The schematic of a photoconductor is shown in Fig. 114.11. The photogenerated electrons and holes move in opposite directions under the applied bias and produce a photocurrent. The active layer can be formed by diffusion, ion implantation, or epitaxial growth. The thickness of the active layer should be large enough so that it can absorb a significant fraction of the incident light but at the same time small enough so as to minimize the noise current resulting from a low resistance of the semiconductor layer. As we will see later, the separation between the contact pads—either in linear or interdigitated form—is also an important parameter in the operation of the device.

**Figure 114.11** Schematic of an InGaAs/InP photoconductor with interdigitated top contacts.

External quantum efficiencies as high as 80 to 90% can be obtained in photoconductors that are thick enough to absorb most of the incident light if an antireflection coating or a wider band-gap window layer is formed on the surface on which light is incident.

A limitation of photoconductive detectors is the noise performance of the device. The noise is principally generated by the large dark current of the device and is known as *Johnson* or *thermal noise*. The resulting noise current,  $i_J$ , is given by

$$\overline{i_J^2} = \frac{4kTB}{R_c} \quad (114.22)$$

where  $B$  is the bandwidth of the device and  $R_c$  is the resistance of the photoconducting channel. The photogenerated electrons and holes move in opposite directions in the active region under the applied bias. The resulting photocurrent will persist until both carriers are collected at the electrodes or until they recombine in the bulk of the semiconductor before reaching the respective contacts. The parameter of importance is the minority-carrier recombination time,  $\tau$ . The time for detection of the photogenerated current is limited by the transit time between electrodes of the faster carrier—usually the electrons. Therefore, the shortest response time (maximum bandwidth) can be obtained by minimizing the distance between the contacts. Note that the persistence of the slower hole in an n-type channel after the electron is collected will increase the response time, and therefore

$$\text{Bandwidth} \propto \frac{1}{\tau} \quad (114.23)$$

However, the continued persistence of the hole in the channel of an n-type photoconductor will draw more electrons to maintain charge neutrality. This constitutes a photocurrent gain,  $\Gamma_G$ , which is defined as

$$\Gamma_G = \frac{\tau}{t_{tr}} \quad (114.24)$$

where  $t_{tr}$  is the transit time of the electrons.

## PIN Photodiode

The p-i-n (or PIN) photodiode is a junction diode that has an undoped i-region ( $p^-$  or  $n^-$ , depending on the method of junction formation) inserted between  $p^+$  and  $n^+$  regions. Because of the very low density of free carriers in the i-region and its high resistivity, any applied bias drops almost entirely across the i-layer, which is fully depleted at zero or a very low value of reverse bias. The depletion layer width must be tailored to meet the requirements of photoresponse and bandwidth. For high response speed, the depletion layer width should be small and for high quantum efficiency, or responsivity, the width should be large. Therefore, a trade-off is necessary. The operation of a PIN photodiode is shown in [Fig. 114.12](#). For practical applications photoexcitation is provided either through an opening in the top contact or through an etched hole in the substrate. The latter reduces the active area of the diode to the size of the incident light beam.

**Figure 114.12** Absorption and carrier generation in a reverse-biased p-i-n diode.

Since there is no internal optical gain in a PIN diode, the maximum internal quantum efficiency  $\eta_i$  is 100% and the gain-bandwidth product is equal to the bandwidth. By careful choice of material parameters and device design, very large bandwidths can be attained. The response speed and bandwidth are ultimately limited either by transit time effects or by circuit parameters.

The equivalent circuit of a PIN diode is shown in Fig. 114.13.  $C_j$  is the junction capacitance originating from the depletion region.  $C_p$  is termed the *parasitic capacitance*, which is external to the wafer.  $L_s$  is the total series inductance, mostly in the leads.  $R_D$  is the diode junction resistance. It has a large value under reverse bias and a very small value under forward bias.  $R_s$  is the series resistance of the diode, which is the sum of the contact resistances and the resistance of the undepleted regions of the diode.  $R_L$  is the load resistance. Typical values of these elements for a reverse-biased diode are listed in Fig. 114.13. The 3-dB bandwidth of a PIN diode can be expressed as

$$f_{3\text{dB}} = \frac{2.8}{2\pi t_r} \quad (114.25)$$

where  $t_r$  is the rise time of the temporal response of a diode to a short optical pulse.

**Figure 114.13** Equivalent circuit of PIN photodiode. Typical values of the circuit elements of a reverse-biased ( $\sim 10\text{V}$ ) InGaAs PIN diode also are listed.

$$R_D = 100 \text{ M}\Omega$$

$$C_j = 80 \text{ fF}$$

$$R_L = 50 \text{ }\Omega$$

$$C_p = 15 \text{ fF}$$

$$R_s = 10 \text{ }\Omega$$

$$L_s = 60 \text{ pH}$$

The external quantum efficiency of the photodiode is given by

$$\eta_{\text{ext}} = \eta_i(1 - R)(1 - e^{-\alpha W}) \quad (114.26)$$

where  $R$  is the reflectivity of the top surface,  $\alpha$  is the absorption coefficient, and  $W$  is the i-region width.

The noise performance of a photodiode is described by the *noise equivalent power* (NEP) and the detectivity,  $D^*$ . The former is given by

$$\text{NEP} = \frac{h\nu}{q\eta} \left[ 2q(I_{\text{ph}} + I_D) + \frac{4kT}{R_{\text{eq}}} \right]^{1/2} (\text{W/Hz}^{1/2}) \quad (114.27)$$

where

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_D} + \frac{1}{R_L} + \frac{1}{R_i} \quad (114.28)$$

$R_D$  and  $R_L$  are indicated in the diode equivalent circuit of Fig. 114.13, and  $R_i$  is the input resistance of the next stage, usually a preamplifier.  $I_{\text{ph}}$  and  $I_D$  are the photocurrent and dark current of the device, respectively. The detectivity is expressed as

$$D^* = \frac{A^{1/2} B^{1/2}}{(\text{NEP})} (\text{cm} \cdot \text{Hz}^{1/2} / \text{W}) \quad (114.29)$$

where  $A$  is the active area of the device and  $B$  is the bandwidth. The reference bandwidth is usually taken as 1 Hz and  $D^*$  is expressed as  $D^*(\lambda f, 1)$ , where  $\lambda$  is the wavelength and  $f$  is the frequency of modulation.

## Heterojunction and Avalanche Photodiodes

One of the essential requirements of a photodiode is a low reverse-bias dark current. In devices made of large-band-gap semiconductors this requirement is easily met. However, for optical communication applications, photodiodes are usually made of  $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ , which has a band gap of 0.75 eV and is lattice matched to InP ( $E_g = 1.35$  eV). Therefore a homojunction diode made of the ternary material will have a large dark current. A solution to this problem is to place the p-n junction in a wider-band-gap, lattice-matched material and absorb the light at  $1.55 \mu\text{m}$  in the lower-band-gap material. The resulting device, with reduced dark current and optimized absorption characteristics, is a heterojunction photodiode, schematically shown in Fig. 114.14.

**Figure 114.14** Two types of heterojunction photodiodes: (a) InGaAs/InP diode made by epitaxy and diffusion and (b) InGaAs/InAlAs/InP diode made by epitaxy.

(a)

(b)

For many applications it is desirable to use a detector with a large sensitivity. Large optical gains can be obtained in an *avalanche photodiode* (APD). The device is essentially a reverse-biased p-n junction that is operated at voltages close to the breakdown voltage. Photogenerated carriers in the depletion region travel at their saturation velocities, and, if they acquire enough energy from the field during such transit, an *ionizing* collision with the lattice can occur. The field necessary to produce an ionization collision is  $\sim 10^5$  V/cm. *Secondary* electron-hole pairs are produced in the process, which again drift in opposite directions, together with the primary carrier, and all or some of them may produce new carriers. The process is known as *impact ionization*, which leads to carrier multiplication and gain. Depending on the semiconductor material and device design, very large avalanche gains ( $\sim 200$  or more) can be achieved, and the avalanche photodiode therefore exhibits very high sensitivity.

## 114.4 Conclusion

---

Some of the most important optoelectronic devices have been briefly described here. More detailed description of their physics and properties are available in the listed references. Another device in which optoelectronic energy conversion takes place is the solar cell, which is also termed a *photovoltaic device*.

### Defining Terms

**Band gap:** The forbidden energy gap in a semiconductor between the top of the valence band and the bottom of the conduction band.

**Effective mass:** Mass of carriers in the lattice of a semiconductor, which is usually different from that of a free carrier due to the presence of the periodic potential in the lattice.

**Heterojunction:** Junction between two semiconductors, usually with different band gaps.

**Lattice matched:** The lattice constants of two semiconductors, usually forming a heterojunction, are equal. They could be a substrate and an epitaxial layer grown on it.

**Stimulated emission:** Emission of light in which all or most of the photons have the same phase, frequency, and direction of propagation—that is, they are *coherent*.

*Delphi Energy & Engine Management Systems*

Power electronic systems deal with the process of converting electrical power from one form to another. The power electronic apparatuses performing the power conversion are called *power converters*. The power conversion is achieved using power semiconductor devices, which are used as switching elements. Power electronic systems cover a wide range of applications, as shown in [Table 115.1](#). The power range of these systems varies from a few watts to several megawatts.

**Table 115.1** Power Electronic Applications

a. Residential	d. Transportation
Refrigeration and freezer	Traction control of electric vehicles
Space heating	Battery chargers for electric vehicles
Air conditioning	Electric locomotives
Cooking	Streetcars, trolleybuses
Lighting	Subways
Electronics (personal computers, other entertainment equipment)	Automotive electronics including engine controls
b. Commercial	e. Utility systems
Heating, ventilating, and air conditioning	High-voltage dc transmission (HVDC)
Central refrigeration	Static var generation (SVG)
Lighting	Supplemental energy sources (wind, photovoltaic)
Computers and office equipment	Energy storage systems
Uninterruptible power supplies (UPS)	Induced-draft fans and boiler feed-water pumps
Elevators	f. Aerospace
c. Industrial	Space shuttle power supply system
Pumps	Satellite power systems
Compressors	Aircraft power systems
Blowers and fans	g. Telecommunications
Machine tools (robots)	Battery chargers

Arc furnaces, induction furnaces  
Lighting  
Industrial lasers  
Induction heating  
Welding

## 115.1 Power Semiconductor Devices

---

The modern age of power electronics began with the introduction of thyristors in the late 1950s. Now there are several types of power devices available for high-power and high-frequency applications. The most notable power devices are gate turnoff thyristors (GTOs), power Darlington transistors, power MOSFETs (metal-oxide silicon field-effect transistors), and insulated gate bipolar transistors (IGBTs). Power semiconductor devices are the most important functional elements in all power conversion applications. The power devices are mainly used as switches to convert power from one form to another.

### Thyristor and Triac

The thyristor, also called the *silicon-controlled rectifier (SCR)*, is basically a four-layer, three-junction PNP device. It has three terminals: anode, cathode, and gate. The device is turned on by applying a short pulse across gate and cathode. Once the device turns on, the gate loses its ability to turn off the device. The turnoff is achieved by applying a reverse voltage across the anode and cathode. There are basically two classifications of thyristors: converter grade and inverter grade. The main difference between a converter-grade and an inverter-grade thyristors is the low turnoff time (in the order of  $\mu s$ ) for the latter. The converter-grade thyristors are slow and are used in natural commutation (or phase-controlled) applications. The inverter-grade thyristors are turned off by forcing the current to zero using external commutation circuit. This requires additional commutating components, thus resulting in additional losses in the inverter. Inverter-grade thyristors have been used in forced commutation applications such as DC-DC choppers and DC-AC inverters. At present, use of thyristors in DC-AC and DC-DC applications is diminishing. But for AC-to-DC power conversion, thyristors are still the best devices. Thyristors are available up to 5000 V, 3000 A.

A triac is functionally a pair of converter-grade thyristors connected in antiparallel. Because of the integration, the triac has poor gate current sensitivity at turn-on and longer turnoff time. A triac is mainly used in phase control application such as in AC regulators for lighting and fan control and in solid-state AC relays.

### Gate Turnoff Thyristor (GTO)

A GTO is a power switching device that can be turned on by a short pulse of gate current and turned off by a reverse gate pulse. This reverse gate current amplitude is dependent on the anode

current to be turned off. Hence there is no need for external commutation circuit to turn it off. Because turnoff is provided by bypassing carriers directly to the gate circuit, its turnoff time is short, thus giving it a greater capacity for high-frequency operation than thyristors. GTOs are used in high-power DC-AC power conversion applications. GTOs are available up to 6000 V, 4000 A.

## Power Transistor

Power transistors are used in applications ranging from a few to several hundred kilowatts and switching frequencies up to about 8 kHz. Power transistors used in power conversion applications are generally NPN type. The device is turned on by supplying sufficient base current, and this base drive has to be maintained throughout its conduction period. It is turned off by removing the base drive and making the base voltage slightly negative [within  $-V_{BE(max)}$ ]. The saturation voltage of the device is normally 0.5 to 2.5 V and increases as the current increases. Hence the on-state losses increase more than proportionately with current. The transistor off-state losses are much lower than the on-state losses because the leakage current of the device when blocking is normally less than a few milliamperes. Because of the relatively larger switching times, the switching loss significantly increases with switching frequency. Power transistors can block only forward voltages. The reverse peak voltage rating of these devices is as low as 5 to 10 volts.

To eliminate high base current requirements, Darlington configurations are commonly used. They are available in monolithic or in isolated packages. The Darlington configuration presents a specific advantage in that it can considerably increase the current switched by the transistor for a given base drive. The  $V_{CE(sat)}$  for the Darlington is generally more than that of a single transistor of similar rating with corresponding increase in on-state power loss. Darlington transistors are available up to 1200 V, 1000 A.

## Power MOSFETs

Power MOSFETs are marketed by various manufacturers with differences in internal geometry and with names such as VMOS, HEXFET, SIPMOS, TMOS, and so on. They have unique features that make them potentially attractive for high-frequency switching applications. They are essentially voltage-driven rather than current-driven devices, unlike bipolar transistors. The gate of a MOSFET is isolated electrically from the source by a layer of silicon oxide. The gate draws only a minute leakage current, of the order of nanoamperes. Hence the gate drive circuit is simple and the power loss in the gate control circuit is practically negligible.

An important feature of the power MOSFET is the absence of secondary breakdown effect, which is present in a bipolar transistor; as a result, the MOSFET has an extremely rugged switching performance. In MOSFETs the drain to source resistance,  $R_{DS(ON)}$ , increases with temperature, and thus current is automatically diverted from the hot spot. Hence it is easy to parallel the MOSFETs. Power MOSFETs are available up to 600 V, 100 A ratings.

## Insulated Gate Bipolar Transistor (IGBT)

The IGBT has the high-input impedance and high-speed characteristics of a MOSFET, with the

conductivity characteristic (low saturation voltage) of a bipolar transistor. The IGBT is turned on by applying a positive voltage between the gate and emitter, and, as in the MOSFET, it is turned off by making the gate signal zero or slightly negative.

Like the power MOSFET, the IGBT does not exhibit the secondary breakdown phenomenon common to bipolar transistors. However, care should be taken not to exceed the maximum power dissipation and specified maximum junction temperature of the device under all conditions for guaranteed reliable operation. The on-state voltage of the IGBT is heavily dependent on the gate voltage. To obtain a low on-state voltage, a sufficiently high gate voltage must be applied. Compared to a MOSFET structure, the IGBT is generally smaller for the same current rating because of its higher current density. The bipolar action in IGBT reduces the speed of the device, so it exhibits a much lower frequency than the MOSFET. The IGBTs cannot be as easily paralleled as MOSFETs. The IGBTs are available up to 1600 V, 1200 A.

## **MOS-Controlled Thyristor (MCT)**

The MCT is basically a thyristor with built-in MOSFETs to turn on and turn off. It is a rugged, high-power, high-frequency, low-conduction-drop device that is more likely to be used in future medium- and high-power applications. The first generation MCTs of 600 V, 75 A are available in the market. Harris Corporation is in the process of releasing second-generation MCTs and high-current modules.

The MCT has three thyristor-type junctions and PNP layers between the anode and the cathode. The p-MCTs are turned on by a negative gate pulse at the gate with respect to the anode and turned off by a positive voltage pulse. Further research is going on to develop n-MCTs. The main advantages of MCTs over IGBTs are the higher current density (thus reduced device size for a given current and voltage rating), low conduction drop, and rugged switching performance. The MCT, because of its superior characteristics, shows a tremendous possibility for applications such as motor drives, high-power uninterrupted power supplies, static VAR compensators, and high-power active power line conditioners.

## **115.2 Power Conversion**

---

The power converters are generally classified as:

1. DC-DC converters (choppers, buck, and boost converters)
2. AC-DC converters (phase-controlled converters)
3. DC-AC converters (inverters)
4. Direct AC-AC converters (cycloconverters)

### **DC-DC Converters**

DC-DC converters are used to convert unregulated DC voltage to regulated or variable DC voltage at the output. They are widely used in switch-mode DC power supplies and in DC motor drive

applications. In DC motor control applications they are called *chopper-controlled drives*. The input voltage source is usually a battery or is derived from AC supply using a diode bridge rectifier. These converters are generally either hard-switched PWM types or soft-switched resonant-link types. There are several DC-DC converter topologies, the most common ones being buck converter, boost converter, and buck-boost converter.

### Buck Converter

A buck converter is also called a *step-down converter*. Its principle of operation is illustrated by Fig. 115.1(a). The IGBT acts as a high-frequency switch. The IGBT is repetitively closed for a time  $t_{\text{on}}$  and opened for a time  $t_{\text{off}}$ . During  $t_{\text{on}}$  the supply terminals are connected to the load and power flows from supply to the load. During  $t_{\text{off}}$  load current flows through the freewheeling diode  $D_1$ , and the load voltage is ideally zero. The average output voltage is given by

$$V_{\text{out}} = D \cdot V_{\text{in}}$$

where  $D$  is the **duty cycle** of the switch and is given by  $D = t_{\text{on}}/T$ , where  $T$  is the time for one period. The term  $1/T$  is the **switching frequency** of the power device IGBT.

**Figure 115.1** DC-DC converter configurations: (a) buck converter; (b) boost converter; (c) buck-boost converter. (Source: Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1993. Power electronics. In *The Electrical Engineering Handbook*, ed. R. C. Dorf, p. 709. CRC Press, Boca Raton, FL. With permission.)

Figure 115.1

(a)

(b)

(c)

### Boost Converter

A boost converter is also called a *step-up converter*. Its principle of operation is illustrated by Fig. 115.1(b). This converter is used to produce higher voltage at the load than the supply voltage. When the power switch is on, the inductor is connected to the DC source and the energy from the supply is stored in it. When the device is off, the inductor current is forced to flow through the diode and the load. The induced voltage across the inductor is negative. The inductor voltage adds to the source voltage to force the inductor current into the load. The output voltage is given by

$$V_{\text{out}} = V_{\text{in}} / (1 - D)$$

Thus, for variation of  $D$  in the range  $0 < D < 1$ , the load voltage  $V_o$  will vary in the range

$$V_{\text{in}} < V_{\text{out}} < \infty$$

### Buck-Boost Converter

A buck-boost converter can be obtained by the cascade connection of the buck and the boost converter. The output voltage  $V_o$ , is given by

$$V_o = V_{\text{in}} \cdot D / (1 - D)$$

The output voltage is higher or lower than the input voltage based on the duty cycle  $D$ . A typical buck-boost converter topology is shown in Fig. 115.1(c). When the power devices are turned on, the input provides energy to the inductor and the diode is reverse biased. When the devices are turned off, the energy stored in the inductor is transferred to the output. No energy is supplied by the input during this interval. In DC power supplies, the output capacitor is assumed to be very large, which results in a constant output voltage. The buck and boost converter topologies enable the four-quadrant operation of a DC motor. In DC drive systems, the chopper is operated in step-down mode during motoring and in step-up mode during regeneration operation.

### Resonant-Link DC-DC Converters

The use of resonant converter topologies in power supplies would help to reduce the switching losses in DC-DC converters and enable the operation at switching frequencies in the megahertz range, which results in reduced size, weight, and cost of the power supplies. Other advantages of resonant converters are that the leakage inductances of the high-frequency transformers and the junction capacitances of semiconductors can be used to further increase the power density of the power supplies. An added advantage is the significant reduction of RFI/EMI. The major disadvantage of resonant converters is increased peak current or voltage stress.

#### *Single-Ended Resonant Converters.*

These type of converters are referred to as *quasi-resonant converters*. Quasi-resonant converters (QRC) do exhibit a resonance in their power section, but, instead of the resonant elements being operated in a continuous fashion, they are operated for only one half of a resonant sine wave at a

time. The topologies within the quasi-resonant converters are simply resonant elements added to many of the basic PWM topologies as shown in Fig. 115.2 and Fig. 115.3 . The QRCs can operate with zero-current switching or zero-voltage switching or both. The power switch in quasi-resonant converters connects the input voltage source to the tank circuit and is turned on and off in the same step fashion as in PWM switching power supplies. The conduction period of the devices is determined by the resonant frequency of the tank circuit. The power switch turns off after the completion of one half of a resonant period. So, the current at turn-on and turnoff transitions is zero, thus eliminating the switching loss within the switch. In zero-voltage switching QRCs, at the turn-on and turnoff of the power devices, the voltage across the device is zero, thus again reducing the switching loss.

**Figure 115.2.** Zero-current resonant switches.

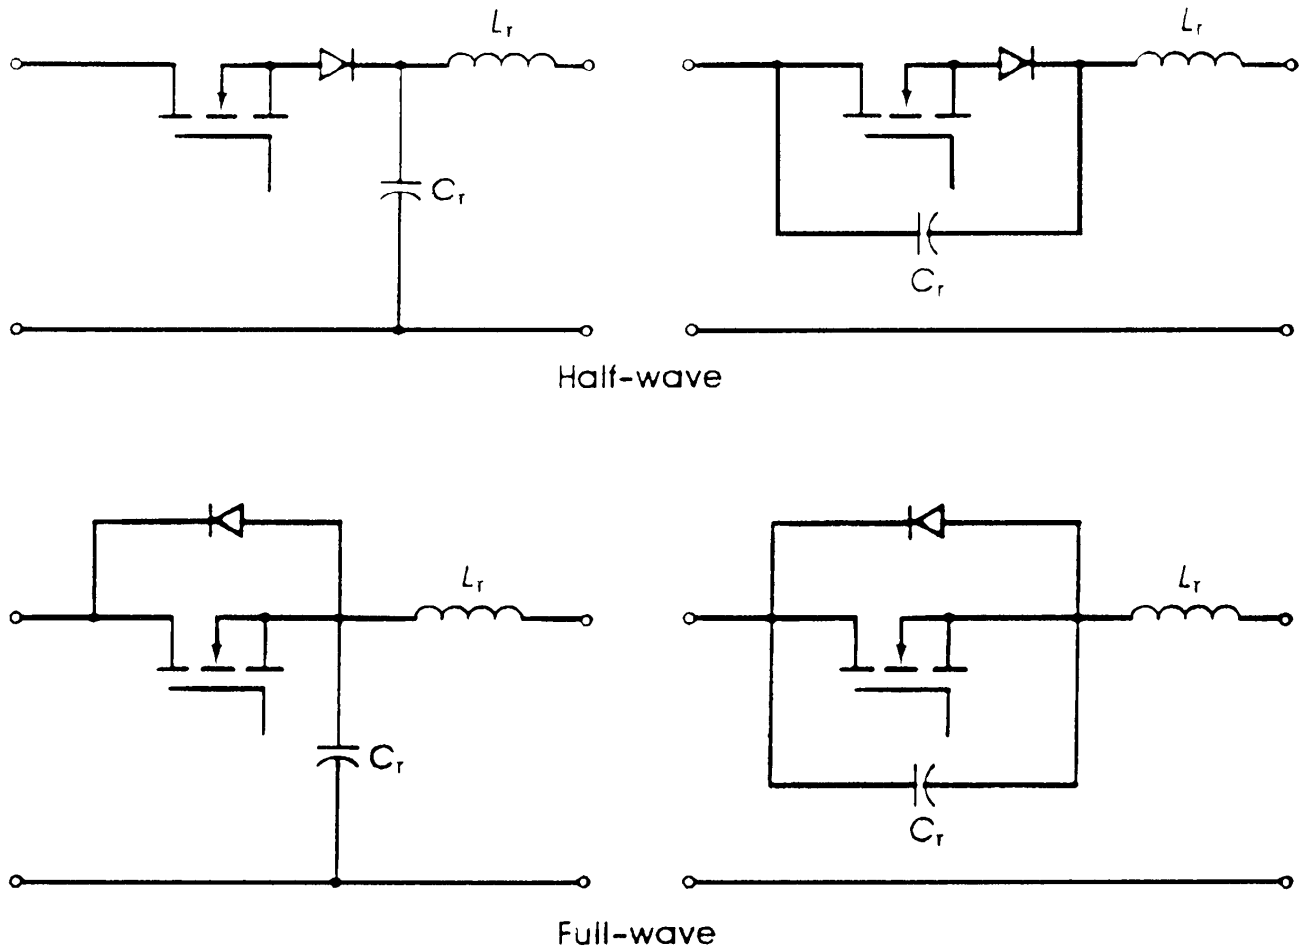

Half-wave, zero-current resonant switches

Full-wave, zero-current resonant switches

**Figure 115.3** Zero-voltage quasi-resonant switches.

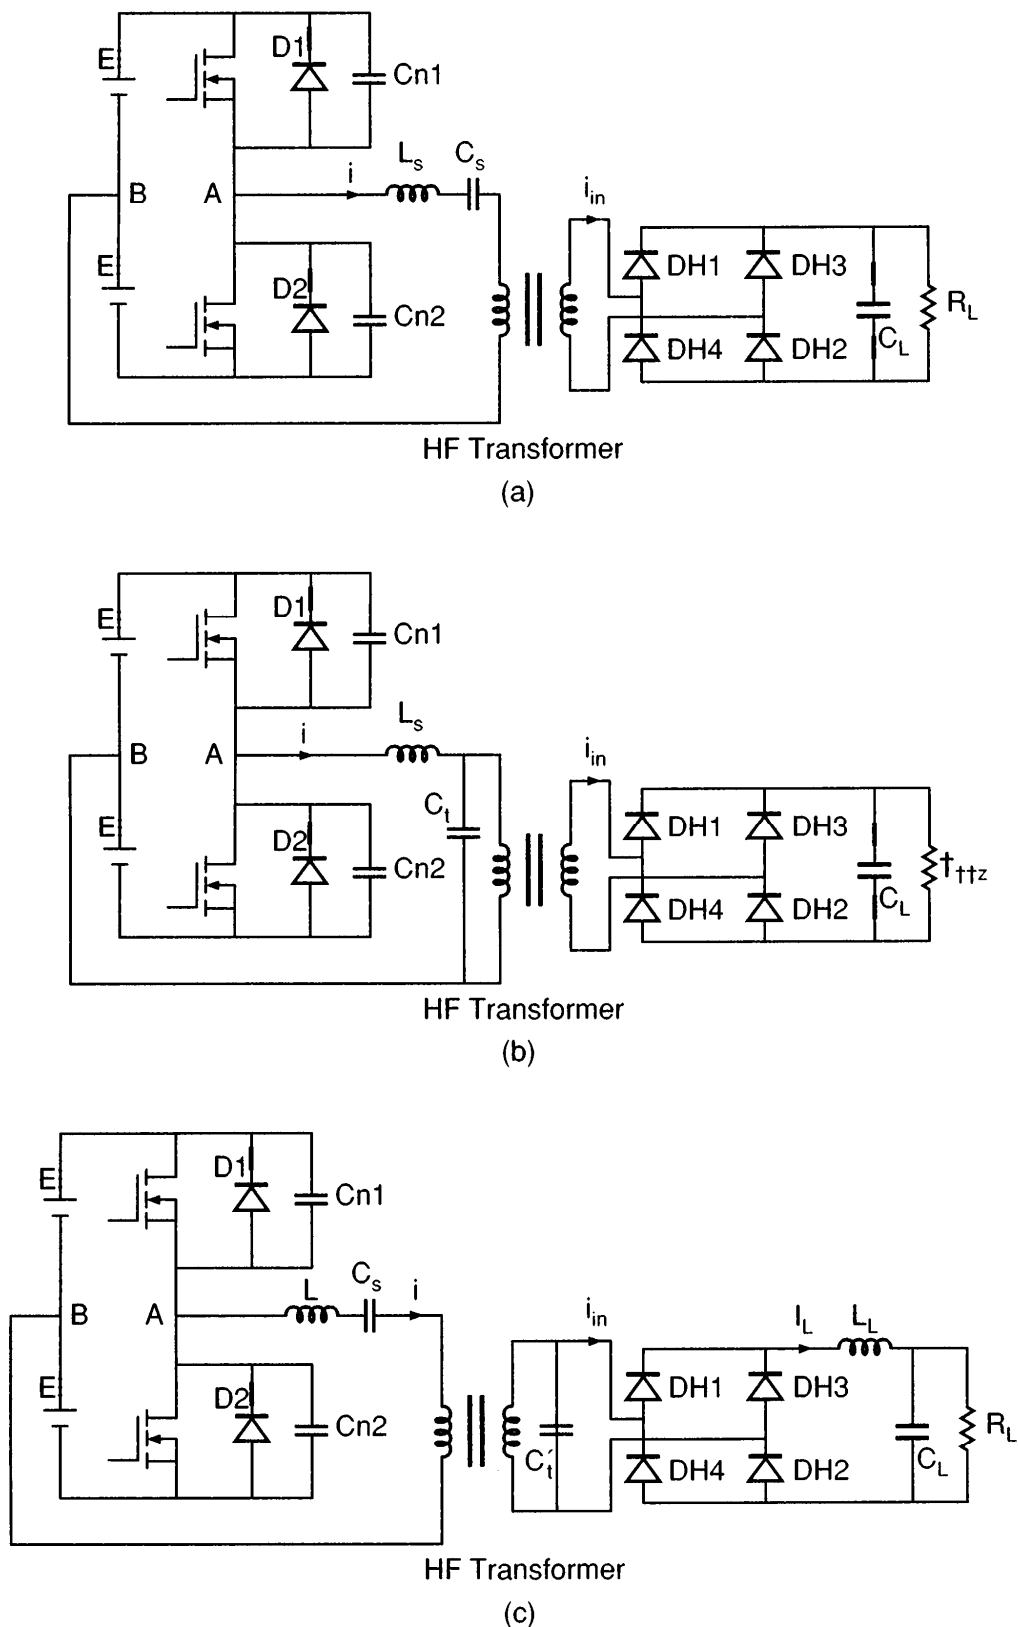

The major problems with the zero-current switching QRC is the high-peak currents through the switch and capacitive turn-on losses. The zero-voltage switching QRCs suffer from increased voltage stress on the power device. The full-wave mode-zero-voltage switching circuit suffers from capacitive turn-on losses.

#### ***Double-Ended Resonant Converters.***

These converters use full-wave rectifiers at the output, and they are generally referred to as resonant converters. A number of resonant converter configurations are realizable by using various resonant tank circuits; the three most popular configurations are the series resonant converter (SRC), the parallel resonant converter (PRC), and the series-parallel resonant converter (SPRC), as shown in [Fig. 115.4](#).

**Figure 115.4** High-frequency resonant converter (half-bridge version) configurations suitable for operation above resonance. (a) Series resonant converter. Leakage inductances of the high-frequency (HF) transformer can be part of resonant inductance. (b) Parallel resonant converter. (c) Series-parallel resonant converter with capacitor  $C_t$  placed on the secondary side of the HF transformer. (Adapted from Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1993. Power electronics. In *The Electrical Engineering Handbook*, ed. R. C. Dorf, p. 720. CRC Press, Boca Raton, FL. With permission.)

Series resonant converters have a high efficiency from full load to part load. Transformer saturation is avoided due to the series-blocking resonating capacitor. The major problems with the SRC are that it requires a very wide change in switching frequency to regulate the load voltage and that the output filter capacitor must carry high-ripple current.

Parallel resonant converters are suitable for low-output voltage, high-output current applications due to the use of filter inductance at the output with low-ripple current requirements for the filter capacitor. The major disadvantage of the PRC is that the device currents do not decrease with the load current, resulting in reduced efficiency at reduced load currents.

The SPRC has the desirable features of both the SRC and the PRC.

Load voltage regulation in resonant converters for input supply variations and load changes is achieved by either varying the switching frequency or using fixed frequency pulse width modulation control.

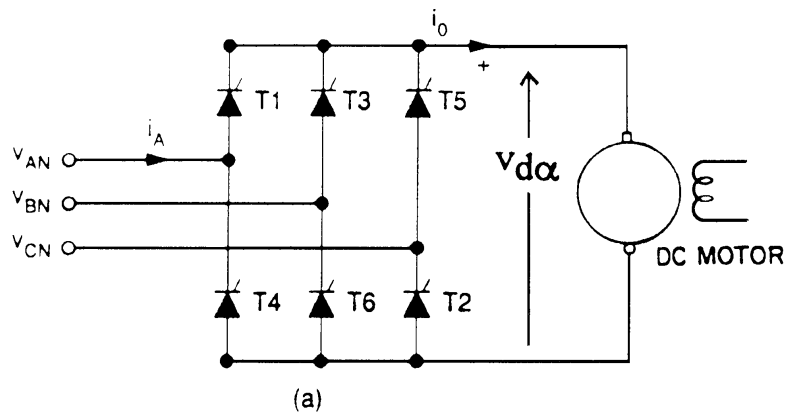

## AC-DC Converters

The basic function of the phase-controlled converter is to convert an alternating voltage of variable amplitude and frequency to a variable DC voltage. The power devices used for this application are generally SCRs. The average value of the output voltage is controlled by varying the conduction time of the SCRs. The turn-on of the SCR is achieved by providing a gate pulse when it is forward biased. The turnoff is achieved by the **commutation** of current from one device to another at the instant the incoming AC voltage has a higher instantaneous potential than that of the outgoing wave. Thus there is a natural tendency for current to be commutated from the outgoing to the incoming SCR without the aid of any external commutation circuitry. This commutation process is often referred to as *natural commutation*.

A three-phase full-wave converter consisting of six thyristor switches is shown in Fig. 115.5(a) . This is the most commonly used three-phase bridge configuration. Thyristors T1, T3, and T5 are turned on during the positive half-cycle of the voltages of the phases to which they are connected, and thyristors T2, T4, and T6 are turned on during the negative cycle of the phase voltages. The reference for the angle in each cycle is at the crossing points of the phase voltages. The ideal output voltage, output current, and input current waveforms are shown in Fig. 115.5(b). The output DC voltage is controlled by controlling the firing angle  $\alpha$ . If the load is a DC motor, the speed of the motor is varied by varying the firing angle  $\alpha$ .

**Figure 115.5** (a) Three-phase thyristor full bridge configuration; (b) output voltage and current waveforms. (Adapted from Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1993. Power electronics. In *The Electrical Engineering Handbook*, ed. R. C. Dorf, p. 704. CRC Press, Boca Raton, FL. With permission.)

**Figure 115.5**

The average output voltage of the converter at a firing angle  $\alpha$  is given by

$$v_{d\alpha} = (3\sqrt{3}/\pi)E_m \cos \alpha$$

where  $E_m$  is the peak value of the phase voltage.

At  $\alpha = 90^\circ$  the output voltage is zero. For  $0^\circ < \alpha < 90^\circ$ ,  $v_{d\alpha}$  is positive and power flows from the AC supply to the DC load. For  $90^\circ < \alpha < 180^\circ$ ,  $v_{d\alpha}$  is negative and the converter operates in the inversion mode. Thus the power can be transferred from the motor to the AC supply, a process known as *regeneration*.

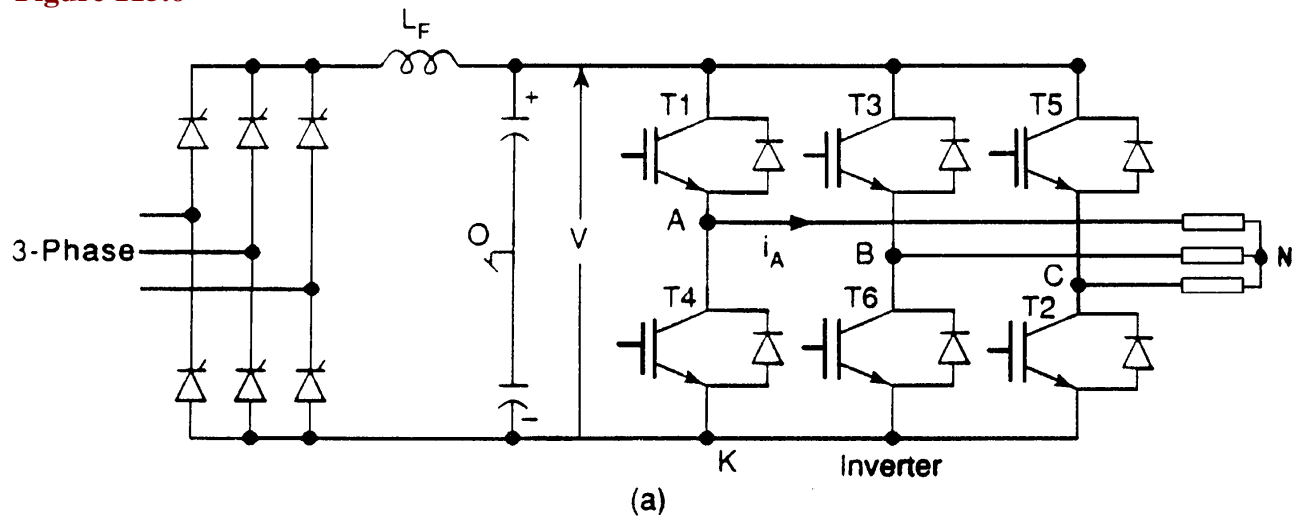

In Fig. 115.5(a), the top or the bottom thyristors could be replaced by diodes. The resulting topology is called *thyristor semiconverter*. With this configuration the input power factor is improved but the regeneration is not possible.

## DC-AC Converters

The DC-AC converters are generally called *inverters*. The AC supply is first converted to DC, which is then converted to a variable-voltage and variable-frequency power. The power conversion stage generally consists of a three-phase bridge converter connected to the AC power source, a DC link with a filter, and the three-phase inverter bridge connected to the load, as shown in Fig. 115.6(a). In the case of battery-operated systems there is no intermediate DC link. An inverter can be classified as a voltage source inverter (VSI) or a current source inverter (CSI). A voltage source inverter is fed by a stiff DC voltage, whereas a current source inverter is fed by a stiff current source. A voltage source can be converted to a current source by connecting a series inductance and then varying the voltage to obtain the desired current. A VSI can also be operated in current-controlled mode and, similarly, a CSI can also be operated in the voltage control mode. These inverters are used in variable-frequency AC motor drives, uninterrupted power supplies, induction heating, static VAR compensators, and so on.

**Figure 115.6** (a) Three-phase converter and voltage source inverter configuration; (b) square-wave inverter waveforms. (Source: Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1993. Power electronics. In *The Electrical Engineering Handbook*, ed. R. C. Dorf, p. 706. CRC Press, Boca Raton, FL. With permission.)

**Figure 115.6**

## Voltage Source Inverter

The inverter configuration shown in Fig. 115.6(a) is the voltage source inverter. The voltage source inverters are controlled either in square-wave mode or in pulse width modulation (PWM) mode. In a square wave mode the frequency of the output is controlled within the inverter; the devices are being used to switch the output circuit between the positive and negative bus. Each device conducts for  $180^\circ$ , and each of the outputs is displaced  $120^\circ$  to generate a six-step waveform as shown in Fig. 115.6(b). The amplitude of the output voltage is controlled by varying DC link voltage. This step is accomplished by varying the firing angle of the thyristors of the three-phase bridge converter at the input. The six-step output is rich in harmonics and hence needs heavy filtering.

In PWM inverters the output voltage and frequency are controlled within the inverter by varying the width of the output pulses. Hence, at the front end, instead of a phase controlled thyristor converter, a diode bridge rectifier can be used. A very popular method of controlling the output voltage and frequency is by sinusoidal pulse width modulation. In this method a high-frequency triangle carrier wave is compared with a three-phase sinusoidal waveform as shown in Fig. 115.7. The power devices in each phase are switched on at the intersection of the sine and triangle waves. The amplitude and frequency of the output voltage are varied, by varying the amplitude and frequency, respectively, of the reference sine waves. The ratio of the amplitude of the sine wave to the amplitude of the carrier wave is called the *modulation index*. The harmonic components in a PWM wave are easily filtered because they are shifted to a higher-frequency region. It is desirable to have a high ratio of carrier frequency to fundamental frequency to reduce the harmonics of lower-frequency components. There are several other PWM techniques mentioned in the literature. The most notable ones are selected harmonic elimination, **hysteresis control**, and the space vector PWM technique.

## Current Source Inverter

Contrary to the voltage source inverter—in which the voltage of the DC link is imposed on the motor windings—the current source inverter shown in Fig. 115.8 has current that is imposed into the motor. Here, the amplitude and phase angle of the motor voltage depend on the load conditions of the motor. The capacitors and series diodes help commutation of the thyristors. One advantage

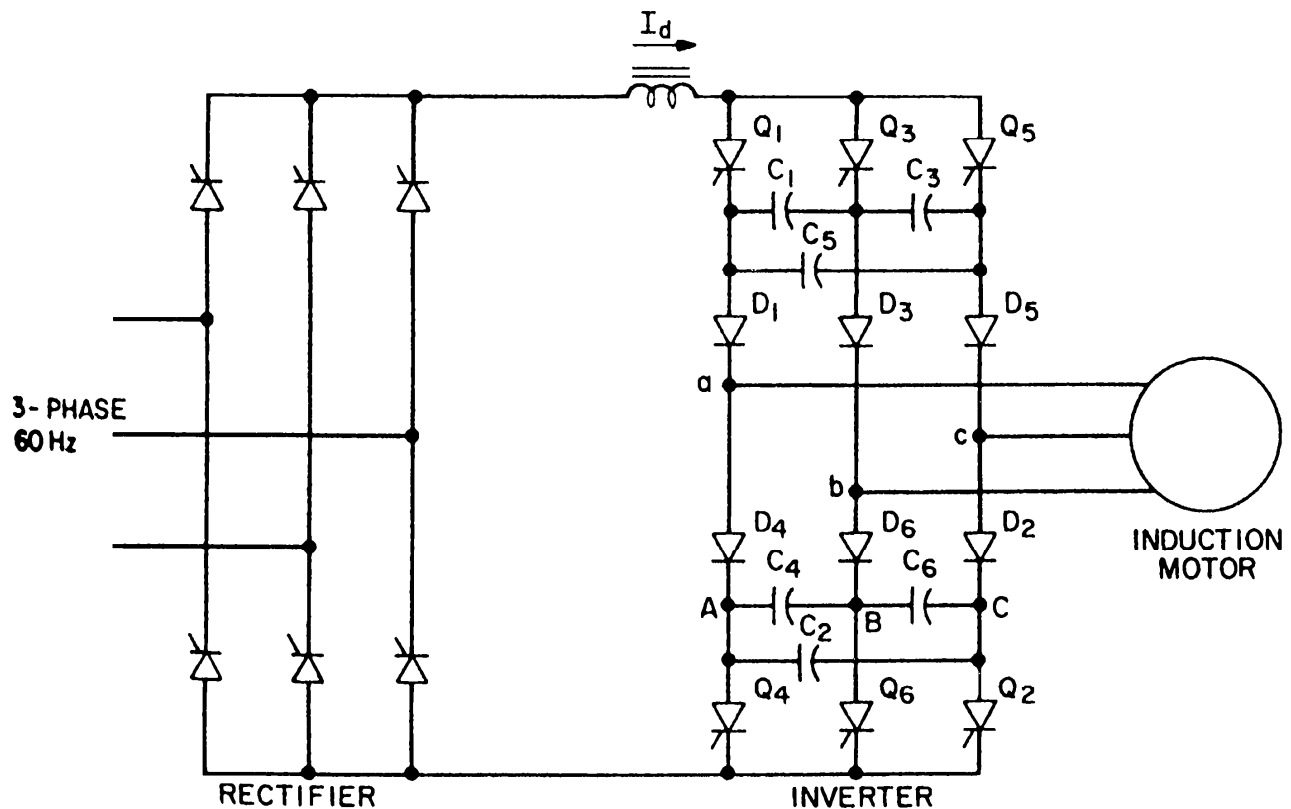

**Figure 115.7** Three-phase sinusoidal PWM inverter waveforms. (Source: Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1993. Power electronics. In *The Electrical Engineering Handbook*, ed. R. C. Dorf, p. 707. CRC Press, Boca Raton, FL. With permission.)

of this drive system is that regenerative braking is easily achieved because the rectifier and inverter can reverse their operation modes. Six-step machine current causes large harmonic heating and torque pulsation, which may be quite harmful at low-speed operation. Another disadvantage is that the converter system cannot be controlled in open loop like in a voltage source inverter.

**Figure 115.8** Force-commutated current-fed inverter control of an induction motor. (Source: Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1993. Power electronics. In *The Electrical Engineering Handbook*, ed. R. C. Dorf, p. 733. CRC Press, Boca Raton, FL. With permission.)

### Resonant-Link Inverter

The use of resonant switching techniques can be applied to inverter topologies to reduce the switching losses in the power devices. They also permit high switching frequency operation to reduce the size of the magnetic components in the inverter unit. In the resonant DC link inverter shown in Fig. 115.9, a resonant circuit is added at the inverter input to convert a fixed DC to a pulsating DC voltage. This resonant circuit enables the devices to be turned on and off during the zero-voltage interval. Zero-voltage switching (ZVS) or zero-current switching (ZCS) is often called *soft switching*. Under soft switching, the switching loss in the power devices is almost eliminated. The EMI problem is less severe because resonant voltage pulses have lower  $dv/dt$  compared to those of hard-switched PWM inverters. Also, the machine insulation is less stretched because of lower  $dv/dt$  resonant voltage pulses. In Fig. 115.9 all the inverter devices are turned on simultaneously to initiate a resonant cycle. The commutation from one device to another is initiated

at the zero-DC link voltage. The inverter output voltage is formed by the integral numbers of quasi-sinusoidal pulses. The circuit consisting of devices Q, D, and the capacitor C acts as an active clamp to limit the DC link voltage to about 1.4 times the diode rectifier voltage  $V_s$ . It is possible to use passive clamp circuits instead of the active clamp.

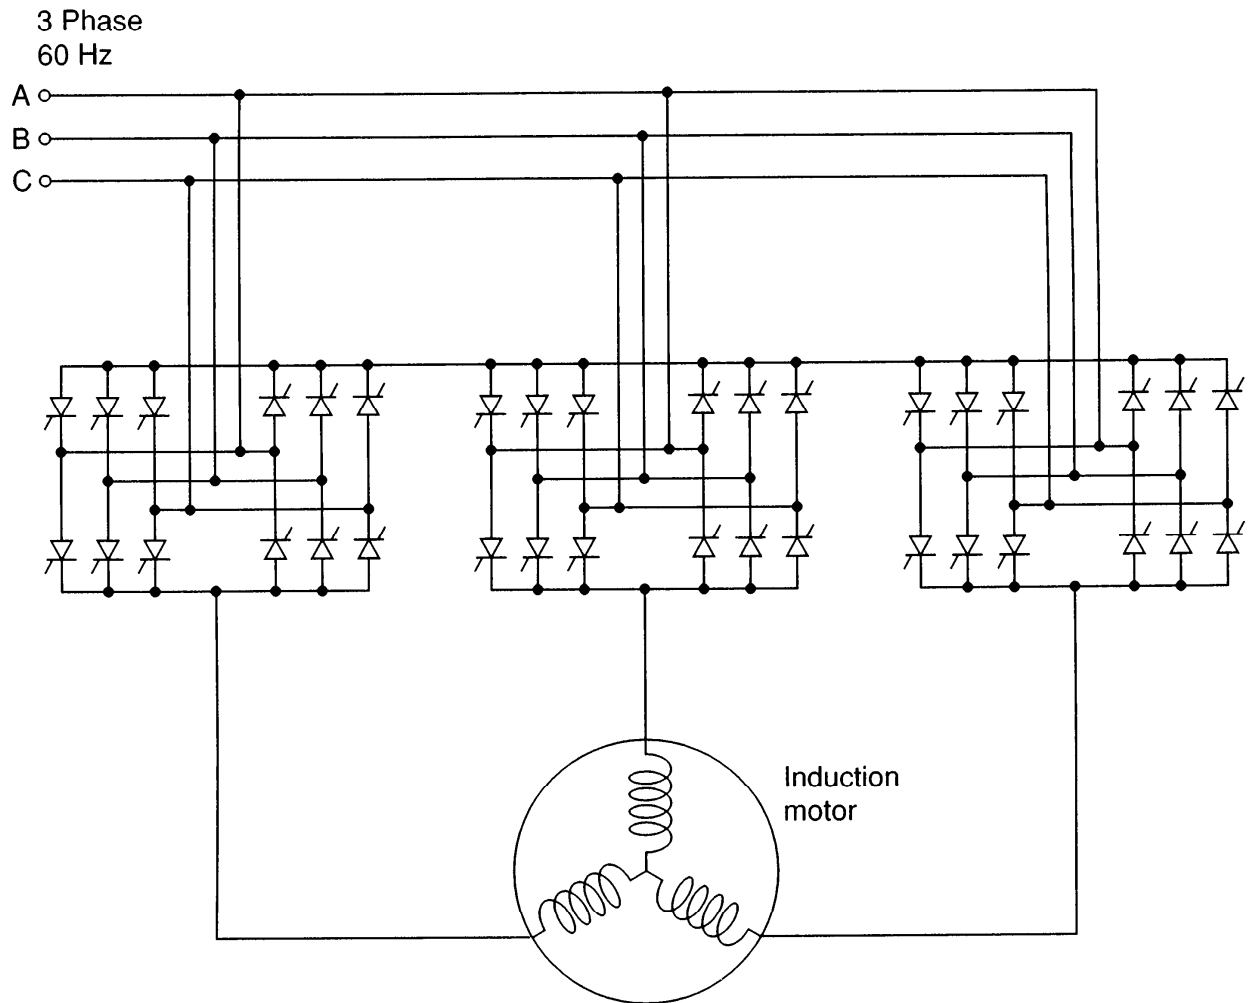

**Figure 115.9** Resonant DC-link inverter system with active voltage clamping. (Source: Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1993. Power electronics. In *The Electrical Engineering Handbook*, ed. R. C. Dorf, p. 708. CRC Press, Boca Raton, FL. With permission.)

## Direct AC-AC Converters

The term *direct conversion* means that the energy does not appear in any form other than the AC input or AC output. The cycloconverters are direct AC-to-AC frequency changers. The three-phase full-wave cycloconverter configuration is shown in Fig. 115.10. Each phase of the three-phase motor is supplied by two antiparallel phase-controlled six-pulse thyristor bridge converters. The output frequency is lower than the input frequency and is generally an integral multiple of the input frequency. The cycloconverter permits energy to be fed back into the utility network without any additional measures. Also, the phase sequence of the output voltage can be easily reversed by the control system. Cycloconverters have found applications in aircraft systems and industrial drives for controlling synchronous and induction motors.

**Figure 115.10** Cycloconverter control of an induction motor.

## Defining Terms

**Commutation:** Process of transferring the current from one power device to another.

**Duty cycle:** Ratio between on-time of a switch and the switching period.

**Forward voltage:** The voltage across the device when the anode is positive with respect to the cathode.

**Full-wave control:** Both the positive and negative half cycle of the waveform is controlled.

**Hysteresis control:** A method of controlling current in which the instantaneous current can vary within a band.

**Isolated:** A power electronic circuit or device having ohmic isolation between the input source

and the load circuit.

**Switching frequency:** The frequency at which the devices are turned on and turned off.

Switching frequency =  $1/(t_{\text{on}} + t_{\text{off}})$ .

## SPACE TELEGRAPHY

*Lee de Forest*

*Patented February 18, 1908*

*#879,532*

An excerpt:

I have determined experimentally that the presence of the conducting member *a*, which as I stated before may be grid-shaped, increases the sensitiveness of the oscillation detector and, inasmuch as the explanation of this phenomenon is exceedingly complex and at best would be merely tentative, I do not deem it necessary to enter into a detailed statement of what I believe to be the probable explanation.

de Forest added a grid-shaped third electrode to a 2-electrode vacuum tube known as a detector, or diode. This one-way electronic "valve" could detect electrical radio signals, but de Forest's third electrode provided a means for increasing the detector's sensitivity or amplifying the signal. de Forest's Audion tube, or triode as it is now known, was the basis of nearly all electronic circuits up to the 1950's and beyond. Today, transistors and integrated circuits have replaced vacuum tubes in all but the highest-power radio and TV transmitter applications. (© 1993, DewRay Products, Inc. Used with permission.)

## A/D and D/A Converters

### 116.1 The Fundamentals of D/A Converters

### 116.2 The Fundamentals of A/D Converters

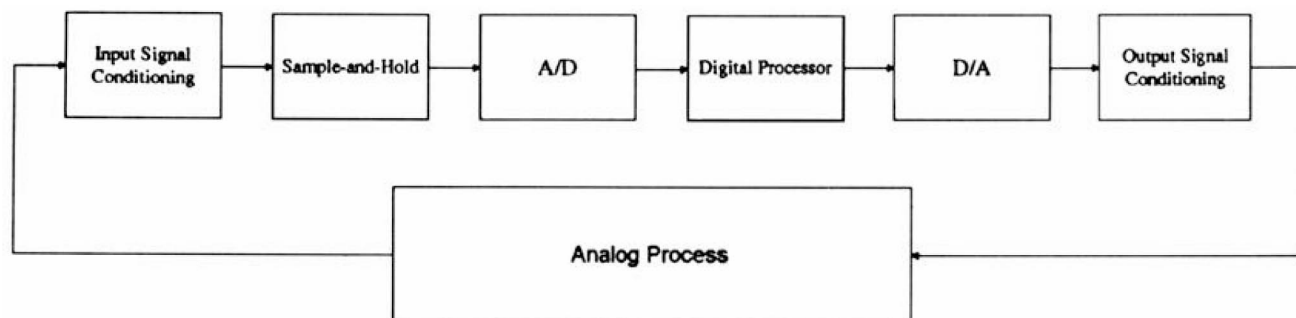

**Jerry C. Hamann**

*University of Wyoming*

*Analog-to-digital* (A/D) and *digital-to-analog* (D/A) converters provide the fundamental interface between continuous-time signals and digital-processing circuitry. These devices find wide application in consumer electronics, instrumentation, data acquisition, signal processing, communication, automatic control, and related areas. The A/D converter provides a discrete-time, discrete-valued **digital encoding** of a real-world signal, typically a voltage. The D/A converter reverses this process by producing a continuous-time, or analog, signal corresponding to a given digital encoding.

The block diagram for an example application including both A/D and D/A functions is given in Fig. 116.1. Here, the digital-processing block might be a dedicated *digital signal processor* (DSP) or a general purpose microprocessor or microcontroller that implements an application-specific signal-processing task. The associated **signal conditioning** blocks provide functionality that might include bandwidth limiting of input signal frequency content, multiplexing of multiple input and output signals, **sample-and-hold** of the input signal, and smoothing of the output analog signals.

**Figure 116.1** Example A/D and D/A application block diagram.

Various methods exist for completing the A/D and D/A conversion tasks. Trade-offs in the specification and selection of a converter typically involve parameters that are closely associated

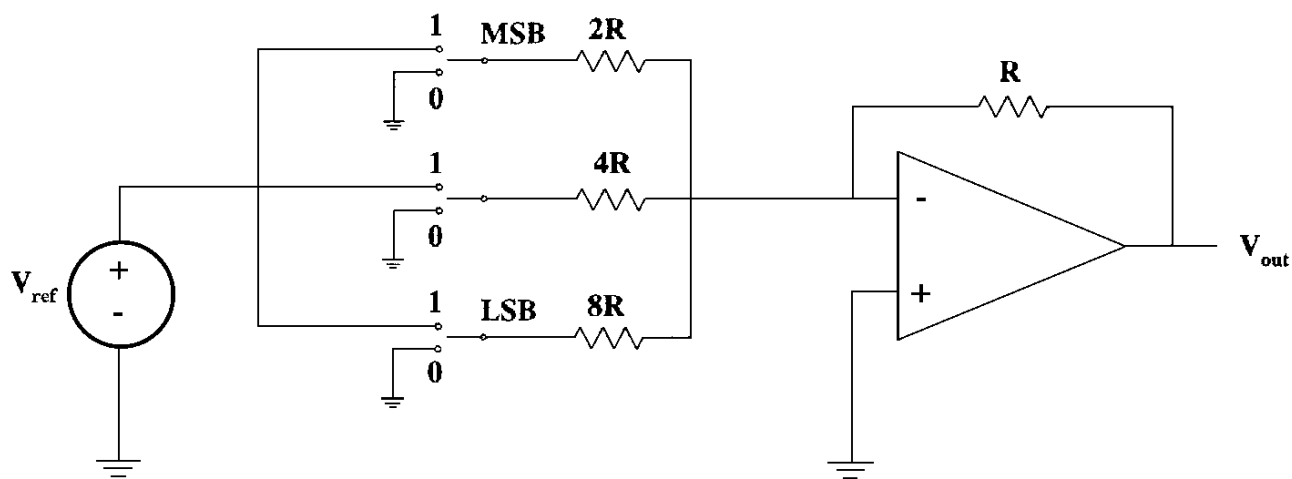

with the conversion method: *resolution* (the number of binary digits  $n$  in the conversion representation) and **conversion rate** (the time required to complete a conversion). Tables 116.1 and 116.2 provide samples of representative converter integrated circuits (ICs) and their associated parameters. Refer to the manufacturer data books listed in the chapter references for further details and additional examples. The interested reader should find in Sheingold [1986] an indispensable reference to the rich field of conversion hardware.

## 116.1 The Fundamentals of D/A Converters

The discussion here is limited to a brief introduction to the most common D/A voltage conversion method. Refer to Loriferne [1982] for a more complete coverage of D/A principles.

The basic architecture of the **multiplying D/A converter** includes a fixed or variable reference voltage source, a network of precision resistors and switches, and an analog summing and buffering stage. For example, the circuit of Fig. 116.2 demonstrates a simple 3-bit D/A. The values of the input bits control the positions of the switches, with all bits equal to 1 yielding an output voltage of  $V_{\text{out}} = -7/8V_{\text{ref}}$ . If the D/A allows the user to supply  $V_{\text{ref}}$ , the multiplying functionality becomes immediately available between input reference voltage and digital encoding.

**Figure 116.2** A simple D/A conversion circuit.

Although the scheme of Fig. 116.2 appears simple and readily generalizable, the required range of precision resistance values for a D/A converter of 8 or more bits of resolution presents an impractical realization for most IC processes. More elaborate resistor/switching arrays can be employed to generate similar functionality with a tighter bound on resistor sizes.

The complexity and potential asynchronous behavior of the D/A switching network introduces a potentially bothersome side effect. For example, if the input digital code switches from 011 to 100, a myriad of possible intermediate switch positions can result (000 being just one possibility). As a result the output voltage may pulse momentarily before settling down to the desired level. This behavior is typically referred to as an output **glitch**. Dedicated signal-conditioning circuitry, either internal to the D/A or supplied by the user externally, may be required to remove such undesirable characteristics.

## 116.2 The Fundamentals of A/D Converters

The brief discussion here is limited to one of the most common A/D voltage conversion methods encountered in contemporary applications. Refer to Seitzer *et al.* [1983] for an in-depth coverage of this and other A/D techniques and Demler [1991] for details of recent high-performance, high-speed technologies.

Many schemes exist for completing the A/D conversion task; **delta-sigma**, **flash**, **integrating**, and **successive approximation** compose the bulk of contemporary implementations. Although these techniques differ in the manner in which they arrive at a digital encoding of the continuous-time signal, many aspects of this quantization can be summarized via the example given in Fig. 116.3. In this plot the continuous-time signal is sampled at well-defined increments of time and represented, at each sample time and until the next sample time, by one of  $2^n$  discrete encoding levels. This finite quantization introduces an unavoidable *quantization error*; see, for example, Oppenheim and Schaffer [1989]. Nonuniformity of the intersample time intervals, as well as the quantum step size between quantization levels, introduces additional errors.

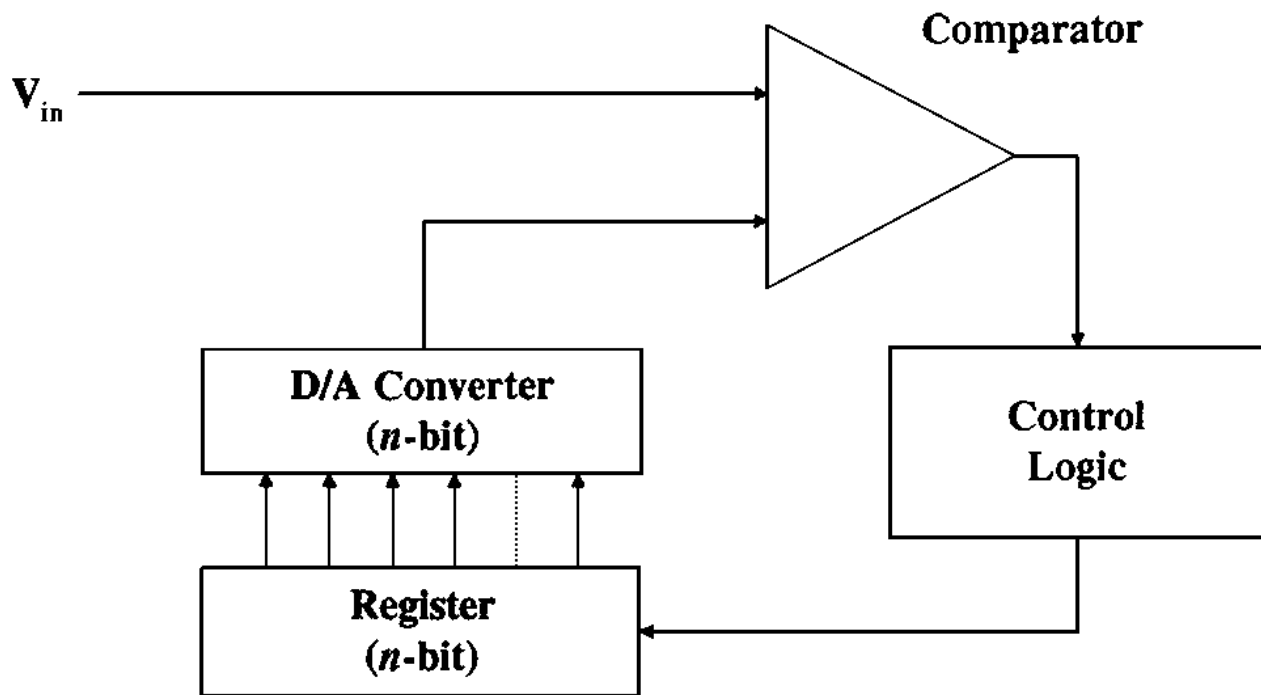

**Figure 116.3** Encoding/discretization consequences of A/D conversion.

To investigate how the A/D quantization might be undertaken, consider the block diagram of a successive approximation architecture given in Fig. 116.4. The role of the control logic is to drive an  $n$ -step iterative algorithm that successively determines the  $n$ -bit quantization from MSB (most significant bit) to LSB (least significant bit). Each new bit is assigned by adding the contribution of the bit to those of the upper bits, which are already assigned. The analog approximation of this sum

is generated by the internal D/A and fed to the input of a comparator along with the signal that is being converted. The decision of the comparator is then utilized by the control logic to either accept the contribution of the new bit or clear the bit before proceeding to the next bit of lesser significance.

**Figure 116.4** Block diagram of a successive approximation A/D.

The conversion process described in the preceding requires a constant input voltage during the approximation steps in order to reduce errors in the converted result. Sample-and-hold circuitry provides precisely this functionality.

## Defining Terms

**Conversion rate:** The time elapsed between the start and completion of the conversion task.

Typically applied in the context of A/D conversion. For D/A conversion, refer to **settling time**.

**Delta-sigma A/D:** Technique for A/D conversion wherein the analog input signal level is compared to an approximate reconstruction of the input at each sampling time. The repeated comparison results in a serial bit stream where the value of each bit denotes whether the input was greater than or less than the approximation at the given sample time. This technique typically involves a very high sampling rate that, when combined with a filtering of the low-resolution comparison results, yields a high-precision, moderate-rate conversion. This technique finds wide application in digital audio.

**Digital encoding:** A variety of binary codes are utilized in conversion hardware. Examples

include *natural binary*, *binary-coded decimal (BCD)*, *Gray code*, *sign-magnitude*, *offset binary*, *twos complement*, and *ones complement*. Some converters allow for use of one or more of these coding schemes.

**Flash A/D:** Technique for A/D conversion that utilizes  $2^n - 1$  comparators, operating in parallel, to provide an  $n$ -bit digitization. This technique provides extremely fast conversion rates, while requiring a large component count in the IC realization.

**Glitch:** When a D/A converter receives a new output request, the asynchronous nature of the switching circuitry can result in momentary spikes or anomalous output values as the converter switches to the new state described by the digital encoding. These spurious changes in the output value are referred to as *glitches*, and the circuitry employed to remove or reduce their effects is said to *deglitch* the output.

**Integrating or ramp A/D:** Technique for A/D conversion wherein the input signal drives an electronic integrator. The height that the integration achieves over a reference time period is utilized to derive the converted value of the input signal. A very popular form of this technique, utilized in many digital multimeters, is the *dual-slope integrating A/D*.

**Multiplying D/A:** A conventional architecture for D/A conversion that utilizes a fixed- or variable-input reference voltage. The resulting output voltage is effectively a scaled product of the input reference voltage and the input digital encoding. In comparison, the *fixed precision reference* conversion architecture utilizes either a precision internal or external reference signal in the multiplication.

**Sample-and-hold:** Circuitry utilized to sample a continuous-time signal at a desired time, then hold the sample constant while an accompanying A/D completes a full conversion. A variant of this idea is the *track-and-hold*, which continuously follows the input signal until instructed to hold.

**Settling time:** With reference to the D/A task, the time elapsed between the change of the input digital encoding and the settling of the output analog signal to within a stated tolerance.

**Signal conditioning:** The general term for circuitry that preconditions the analog signal entering the A/D converter and similarly filters or smooths the output of the D/A.

**Successive approximation A/D:** Technique for A/D conversion wherein a stepwise approximation of the input signal is constructed via a serial hardware comparator algorithm. The algorithm converges to an  $n$ -bit digitization of the input in  $n$  steps by successively assigning the most significant to least significant bits based upon a comparison of the input with the analog equivalent of the bits already assigned.

## **117.1 Introduction**

---

The fundamental idea behind all of a superconductor's unique properties is that **superconductivity** is a quantum mechanical phenomenon on a macroscopic scale created when the motions of individual electrons are correlated. According to the theory developed by John Bardeen, Leon Cooper, and Robert Schrieffer (BCS theory), this correlation takes place when two electrons couple to form a Cooper pair. For our purposes, we may therefore consider the electrical charge carriers in a superconductor to be Cooper pairs (or more colloquially, superelectrons) with a mass  $m^*$  and charge  $q^*$  twice those of normal electrons. The average distance between the two electrons in a Cooper pair is known as the coherence length,  $\xi$ . Both the coherence length and the binding energy of two electrons in a Cooper pair,  $2\Delta$ , depend upon the particular superconducting material. Typically, the coherence length is many times larger than the interatomic spacing of a solid, and so we should not think of Cooper pairs as tightly bound electron molecules. Instead, there are many other electrons between those of a specific Cooper pair allowing for the paired electrons to change partners on a time scale of  $\hbar/(2\Delta)$ , where  $\hbar$  is Planck's constant.

If we prevent the Cooper pairs from forming by ensuring that all the electrons are at an energy greater than the binding energy, we can destroy the superconducting phenomenon. This can be accomplished, for example, with thermal energy. In fact, according to the BCS theory, the critical temperature,  $T_c$ , associated with this energy is

$$\frac{2\Delta}{k_B T_c} \approx 3.5 \quad (117.1)$$

where  $k_B$  is Boltzmann's constant. For low critical temperature (conventional) superconductors,  $2\Delta$  is typically on the order of 1 meV, and we see that these materials must be kept below temperatures of about 10 K to exhibit their unique behavior. Superconductors with high critical temperature, in contrast, will superconduct up to temperatures of about 100 K, which is attractive from a practical view because the materials can be cooled cheaply using liquid nitrogen. A second way of increasing the energy of the electrons is electrically driving them. In other words, if the critical current density,  $J_c$ , of a superconductor is exceeded, the electrons have sufficient kinetic energy to prevent the formation of Cooper pairs. The necessary kinetic energy can also be generated through the induced currents created by an external magnetic field. As a result, if a superconductor is placed in a magnetic field larger than its critical field,  $H_c$ , it will return to its normal metallic state. To summarize, a superconductor must be maintained under the appropriate temperature, electrical current density, and magnetic field conditions to exhibit its special properties. An example of this phase space is shown in Fig. 117.1.

**Figure 117.1** The phase space for the superconducting alloy niobium-titanium. The material is superconducting inside the volume of phase space indicated. [Source: Wilson, M. 1983. *Superconducting Magnets*, Oxford University, New York. With permission.]

## 117.2 General Electromagnetic Properties

The hallmark electromagnetic properties of a superconductor are its ability to carry a static current without any resistance and its ability to exclude a static magnetic flux from its interior. It is this second property, known as the Meissner effect, that distinguishes a superconductor from merely

being a perfect conductor (which conserves the magnetic flux in its interior). Although superconductivity is a manifestly quantum mechanical phenomenon, a useful classical model can be constructed around these two properties. In this section we will outline the rationale for this classical model, which is useful in engineering applications such as waveguides and high-field magnets.

The zero DC resistance criterion implies that the superelectrons move unimpeded. The electromagnetic energy density,  $w$ , stored in a superconductor is therefore

$$w = \frac{1}{2}\varepsilon\mathbf{E}^2 + \frac{1}{2}\mu_o\mathbf{H}^2 + \frac{n^*}{2}m^*\mathbf{v}_s^2 \quad (117.2)$$

where the first two terms are the familiar electric and magnetic energy densities, respectively. (Our electromagnetic notation is standard:  $\varepsilon$  is the permittivity,  $\mu_o$  is the permeability,  $\mathbf{E}$  is the electric field, and the magnetic flux density,  $\mathbf{B}$ , is related to the magnetic field,  $\mathbf{H}$ , via the constitutive law  $\mathbf{B} = \mu_o\mathbf{H}$ .) The last term represents the kinetic energy associated with the undamped superelectrons' motion ( $n^*$  and  $\mathbf{v}_s$  are the superelectrons' density and velocity, respectively). Because the supercurrent density,  $\mathbf{J}_s$ , is related to the superelectron velocity by  $\mathbf{J}_s = n^*q^*\mathbf{v}_s$ , the kinetic energy term can be rewritten

$$n^* \left( \frac{1}{2}m^*\mathbf{v}_s^2 \right) = \frac{1}{2}\Lambda\mathbf{J}_s^2 \quad (117.3)$$

where  $\Lambda$  is defined as

$$\Lambda = \frac{m^*}{n^*(q^*)^2} \quad (117.4)$$

Assuming that all the charge carriers are superelectrons, there is no power dissipation inside the superconductor, and so Poynting's theorem over a volume  $V$  may be written

$$-\int_V \nabla \cdot (\mathbf{E} \times \mathbf{H}) dv = \int_V \frac{\partial w}{\partial t} dv \quad (117.5)$$

where the left side of the expression is the power flowing into the region. By taking the time derivative of the energy density and appealing to Faraday's and Ampère's laws to find the time derivatives of the field quantities, we find that the only way for Poynting's theorem to be satisfied is if

$$\mathbf{E} = \frac{\partial}{\partial t}(\Lambda\mathbf{J}_s) \quad (117.6)$$

This relation, known as the *first London equation* (after the London brothers, Heinz and Fritz), is thus necessary if the superelectrons have no resistance to their motion.

Equation (117.6) also reveals that the superelectrons' inertia creates a lag between their motion and that of the electric field. As a result, a superconductor can support a time-varying voltage drop across itself. The impedance associated with the supercurrent, therefore, is an inductor, and it will be useful to think of  $\Lambda$  as an inductance created by the correlated motion of the superelectrons.

If the first London equation is substituted into Faraday's law,  $\nabla \times \mathbf{E} = -(\partial \mathbf{B} / \partial t)$ , and integrated with respect to time, the *second London equation* results:

$$\nabla \times (\Lambda \mathbf{J}_s) = -\mathbf{B} \quad (117.7)$$

where the constant of integration has been defined to be zero. This choice is made so that the second London equation is consistent with the Meissner effect, as we now demonstrate. Taking the curl of the quasi-static form of Ampère's law,  $\nabla \times \mathbf{H} = \mathbf{J}_s$ , results in the expression  $\nabla^2 \mathbf{B} = -\mu_o \nabla \times \mathbf{J}_s$ , where a vector identity,  $\nabla \times \nabla \times \mathbf{C} = \nabla(\nabla \cdot \mathbf{C}) - \nabla^2 \mathbf{C}$ ; the constitutive relation,  $\mathbf{B} = \mu_o \mathbf{H}$ ; and Gauss's law,  $\nabla \cdot \mathbf{B} = 0$ , have been used. By now appealing to the second London equation, we obtain the vector Helmholtz equation

$$\nabla^2 \mathbf{B} - \frac{1}{\lambda^2} \mathbf{B} = 0 \quad (117.8)$$

where the penetration depth is defined as

$$\lambda \equiv \sqrt{\frac{\Lambda}{\mu_o}} = \sqrt{\frac{m^*}{n^* (q^*)^2 \mu_o}} \quad (117.9)$$

From Eq. (117.8) we find that a flux density applied parallel to the surface of a semi-infinite superconductor will decay away exponentially from the surface on a spatial length scale of order  $\lambda$ . In other words, a bulk superconductor will exclude an applied flux as predicted by the Meissner effect.

The London equations reveal that there is a characteristic length  $\lambda$  over which electromagnetic fields can change inside a superconductor. This penetration depth is different from the more familiar skin depth of electromagnetic theory, the latter being a frequency-dependent quantity. Indeed, the penetration depth at zero temperature is a distinct material property of a particular superconductor.

Notice that  $\lambda$  is sensitive to the number of correlated electrons (the superelectrons) in the material. As previously discussed, this number is a function of temperature, and so only at  $T = 0$  do *all* the electrons that usually conduct ohmically participate in the Cooper pairing. For intermediate temperatures,  $0 < T < T_c$ , there are actually two sets of interpenetrating electron fluids: the uncorrelated electrons providing ohmic conduction and the correlated ones creating supercurrents. This two-fluid model is a useful way to build temperature effects into the London relations.

Under the two-fluid model, the electrical current density,  $\mathbf{J}$ , is carried by both the uncorrelated (normal) electrons and the superelectrons:  $\mathbf{J} = \mathbf{J}_n + \mathbf{J}_s$ , where  $\mathbf{J}_n$  is the normal current density. The two channels are modeled in a circuit, as shown in [Fig. 117.2](#), by a parallel combination of a resistor (representing the ohmic channel) and an inductor (representing the superconducting channel). To a good approximation, the respective temperature dependences of the conductor and inductor are

$$\tilde{\sigma}_o(T) = \sigma_o(T_c) \left( \frac{T}{T_c} \right)^4 \quad \text{for } T \leq T_c \quad (117.10)$$

$$\Lambda(T) = \Lambda(0) \left( \frac{1}{1 - (T/T_c)^4} \right) \quad \text{for } T \leq T_c \quad (117.11)$$

where  $\sigma_o$  is the DC conductance of the normal channel. (Strictly speaking, the normal channel should also contain an inductance representing the inertia of the normal electrons, but typically such an inductor contributes negligibly to the overall electrical response.) Since the temperature-dependent penetration depth is defined as  $\lambda(T) = \sqrt{\Lambda(T)/\mu_o}$ , the effective conductance of a superconductor in the sinusoidal steady state is

$$\sigma = \tilde{\sigma}_o + \frac{1}{j\omega\mu_o\lambda^2} \quad (117.12)$$

where the explicit temperature dependence notation has been suppressed.

**Figure 117.2** A lumped element model of a superconductor.

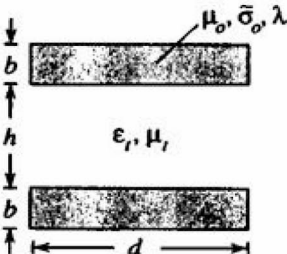

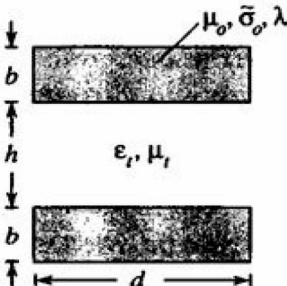

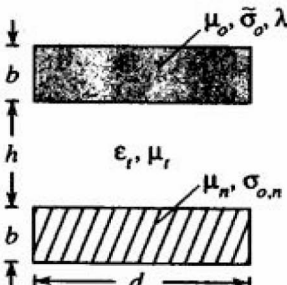

Most of the important physics associated with the classical model is embedded in Eq. (117.12). As is clear from the lumped element model, the relative importance of the normal and superconducting channels is a function not only of temperature but also of frequency. The familiar  $L/R$  time constant, here equal to  $\Lambda\tilde{\sigma}_o$ , delineates the frequency regimes where most of the total current is carried by  $J_n$  (if  $\omega\Lambda\tilde{\sigma}_o \gg 1$ ) or  $J_s$  (if  $\omega\Lambda\tilde{\sigma}_o \ll 1$ ). This same result can also be obtained by comparing the skin depth associated with the normal channel,  $\delta = \sqrt{2/(\omega\mu_o\tilde{\sigma}_o)}$ , to the penetration depth to see which channel provides more field screening. In addition, it is straightforward to use Eq. (117.12) to rederive Poynting's theorem for systems that involve superconducting materials:

$$\begin{aligned}
-\int_V \nabla \cdot (\mathbf{E} \times \mathbf{H}) dv &= \frac{d}{dt} \int_V \left( \frac{1}{2} \epsilon \mathbf{E}^2 + \frac{1}{2} \mu_o \mathbf{H}^2 + \frac{1}{2} \Lambda(T) \mathbf{J}_s^2 \right) dv \\
&+ \int_V \frac{1}{\tilde{\sigma}_o(T)} \mathbf{J}_n^2 dv
\end{aligned} \tag{117.13}$$

Using this expression, it is possible to apply the usual electromagnetic analysis to find the inductance ( $L_o$ ), capacitance ( $C_o$ ), and resistance ( $R_o$ ) per unit length along a parallel plate transmission line. The results of such analysis for typical cases are summarized in [Table 117.1](#).

**Table 117.1** Lumped Circuit Element Parameters Per Unit Length for Typical Transverse Electromagnetic Parallel Plate Waveguides\*

Transmission Line Geometry	$L_o$	$C_o$	$R_o$
 <p>Two identical, thin (<math>\lambda \gg b</math>) superconducting plates</p>	$\frac{\mu_t h}{d} + \frac{2\mu_o \lambda^2}{db}$	$\frac{\epsilon_t d}{h}$	$\frac{8}{db\tilde{\sigma}_o} \left( \frac{\lambda}{\delta} \right)^4$
 <p>Two identical, thick (<math>\lambda \ll b</math>) superconducting plates</p>	$\frac{\mu_t h}{d} + \frac{2\mu_o \lambda}{d}$	$\frac{\epsilon_t d}{h}$	$\frac{4}{d\delta\tilde{\sigma}_o} \left( \frac{\lambda}{\delta} \right)^3$
 <p>One thick (<math>\lambda \ll b</math>) superconducting plate and one thick (<math>\delta_n \ll b</math>) ohmic plate</p>	$\frac{\mu_t h}{d} + \frac{\mu_o \lambda}{d} + \frac{\mu_n \delta_n}{2d}$	$\frac{\epsilon_t d}{h}$	$\frac{1}{d\delta_n \sigma_{o,n}}$

\*The subscript  $n$  refers to parameters associated with a normal (ohmic) plate. Using these expressions, line input impedance, attenuation, and wave velocity can be calculated.

## 117.3 Superconducting Electronics

The macroscopic quantum nature of superconductivity can be usefully exploited to create a new type of electronic device. Because all the superelectrons exhibit correlated motion, the usual wave-particle duality normally associated with a single quantum particle can now be applied to the entire ensemble of superelectrons. Thus, there is a spatiotemporal phase associated with the ensemble that characterizes the supercurrent flowing in the material.

Naturally, if the overall electron correlation is broken, this phase is lost and the material is no longer a superconductor. There is a broad class of structures, however, known as *weak links*, where the correlation is merely perturbed locally in space rather than outright destroyed. Colloquially, we say that the phase "slips" across the weak link to acknowledge the perturbation.

The unusual properties of this phase slippage were first investigated by Brian Josephson and constitute the central principles behind superconducting electronics. Josephson found that the phase slippage could be defined as the difference between the macroscopic phases on either side of the weak link. This phase difference, denoted as  $\phi$ , determined the supercurrent,  $i_s$ , through and voltage,  $v$ , across the weak link according to the Josephson equations,

$$i_s = I_c \sin \phi \quad (117.14)$$

$$v = \frac{\Phi_o}{2\pi} \frac{\partial \phi}{\partial t} \quad (117.15)$$

where  $I_c$  is the critical (maximum) current of the junction and  $\Phi_o$  is the quantum unit of flux. (The flux quantum has a precise definition in terms of Planck's constant,  $h$ , and the electron charge,  $e$ :  $\Phi_o \equiv h/(2e) \approx 2.068 \times 10^{-15}$  Wb). As in the previous section, the correlated motion of the electrons, here represented by the superelectron phase, manifests itself through an inductance. This is straightforwardly demonstrated by taking the time derivative of Eq. (117.14) and combining this expression with Eq. (117.15). Although the resulting inductance is nonlinear (it depends on  $\cos \phi$ ), its relative scale is determined by

$$L_j = \frac{\Phi_o}{2\pi I_c} \quad (117.16)$$

a useful quantity for making engineering estimates.

A common weak link, known as the Josephson tunnel junction, is made by separating two superconducting films with a very thin (typically 20 Å) insulating layer. Such a structure is conveniently analyzed using the resistively and capacitively shunted junction (RCSJ) model shown in Fig. 117.3. Under the RCSJ model an ideal lumped junction [described by Eqs. (117.14) and

(117.15)] and a resistor  $R_j$  represent how the weak link structure influences the respective phases of the super and normal electrons, and a capacitor  $C_j$  represents the physical capacitance of the sandwich structure. If the ideal lumped junction portion of the circuit is treated as an inductor-like element, many Josephson tunnel junction properties can be calculated with the familiar circuit time constants associated with the model. For example, the quality factor  $Q$  of the RCSJ circuit can be expressed as

$$Q^2 = \frac{R_j C_j}{L_j / R_j} = \frac{2\pi I_c R_j^2 C_j}{\Phi_o} \equiv \beta \quad (117.17)$$

where  $\beta$  is known as the Stewart-McCumber parameter. Clearly, if  $\beta \gg 1$ , the ideal lumped junction element is underdamped in that the capacitor readily charges up, dominates the overall response of the circuit, and therefore creates a hysteretic  $i$ - $v$  curve as shown in Fig. 117.4(a). In the case when the bias current is raised from zero, no time-averaged voltage is created until the critical current is exceeded. At this point the junction switches to the voltage  $2\Delta/e$  with a time constant  $\sqrt{L_j C_j}$ . Once the junction has latched into the voltage state, however, the bias current must be lowered to zero before it can again be steered through the superconducting path. Conversely,  $\beta \ll 1$  implies that the  $L_j / R_j$  time constant dominates the circuit response, so that the capacitor does not charge up and the  $i$ - $v$  curve is not hysteretic [Fig. 117.4(b)].

**Figure 117.3** A real Josephson tunnel junction can be modeled using ideal lumped circuit elements.

**Figure 117.4** The  $i$ - $v$  curves for a Josephson junction: (a)  $\beta \gg 1$ , (b)  $\beta \ll 1$ .

Just as the correlated motion of the superelectrons creates the frequency-independent Meissner effect in a bulk superconductor through Faraday's law, so too the macroscopic quantum nature of superconductivity allows the possibility of a device whose output voltage is a function of a static magnetic field. If two weak links are connected in parallel, the lumped version of Faraday's law gives the voltage across the second weak link as  $v_2 = v_1 + (d\Phi/dt)$ , where  $\Phi$  is the total flux threading the loop between the links. Substituting Eq. (117.15) and integrating with respect to time yields

$$\phi_2 - \phi_1 = (2\pi\Phi)/\Phi_o \quad (117.18)$$

showing that the spatial change in the phase of the macroscopic wavefunction is proportional to the local magnetic flux. The structure described is known as a *superconducting quantum interference device (SQUID)* and can be used as a highly sensitive magnetometer by biasing it with current and measuring the resulting voltage as a function of magnetic flux. From this discussion, it is apparent that a duality exists in how fields interact with the macroscopic phase: electric fields are coupled to its rate of change in time and magnetic fields are coupled to its rate of change in space.

## 117.4 Types of Superconductors

The macroscopic quantum nature of superconductivity also affects the general electromagnetic properties previously discussed. This is most clearly illustrated by the interplay of the characteristic lengths  $\xi$ , representing the scale of quantum correlations, and  $\lambda$ , representing the scale of electromagnetic screening. Consider the scenario where a magnetic field,  $H$ , is applied parallel to the surface of a semi-infinite superconductor. The correlations of the electrons in the superconductor must lower the overall energy of the system or else the material would not be superconducting in the first place. Because the critical magnetic field  $H_c$  destroys all the correlations, it is convenient to define the energy density gained by the system in the superconducting state as  $(\frac{1}{2})\mu_o H_c^2$ . The electrons in a Cooper pair are separated on a length scale

of  $\xi$ , however, and so the correlations cannot be fully achieved until a distance roughly  $\xi$  from the boundary of the superconductor. There is thus an energy per unit area,  $(\frac{1}{2})\mu_o H_c^2 \xi$ , that is lost because of the presence of the boundary. Now consider the effects of the applied magnetic field on this system. It costs the superconductor energy to maintain the Meissner effect,  $B = 0$ , in its bulk; in fact, the energy density required is  $(\frac{1}{2})\mu_o H^2$ . However, since the field can penetrate the superconductor a distance roughly  $\lambda$ , the system need not expend an energy per unit area of  $(\frac{1}{2})\mu_o H^2 \lambda$  to screen over this volume. To summarize, more than a distance  $\xi$  from the boundary, the energy of the material is lowered (because it is superconducting), and more than a distance  $\lambda$  from the boundary the energy of the material is raised (to shield the applied field).

Now, if  $\lambda < \xi$ , the region of superconducting material greater than  $\lambda$  from the boundary but less than  $\xi$  will be higher in energy than that in the bulk of the material. Thus, the surface energy of the boundary is positive and so costs the total system some energy. This class of superconductors is known as type I. Most elemental superconductors, such as aluminum, tin, and lead, are type I. In addition to having  $\lambda < \xi$ , type I superconductors are generally characterized by low critical temperatures ( $\sim 5$  K) and critical fields ( $\sim 0.05$  T). Typical type I superconductors and their properties are listed in [Table 117.2](#).

**Table 117.2** Material Parameters for Type I Superconductors\*

Material	$T_c$ (K)	$\lambda_o$ (nm)	$\xi_o$ (nm)	$\Delta_o$ (meV)	$\mu_o H_{co}$ (mT)
Al	1.18	50	1600	0.18	10.5
In	3.41	65	360	0.54	23.0
Sn	3.72	50	230	0.59	30.5
Pb	7.20	40	90	1.35	80.0
Nb	9.25	85	40	1.50	198.0

\*The penetration depth  $\lambda_o$  is given at zero temperature, as are the coherence length  $\xi_o$ , the thermodynamic critical field  $H_{co}$ , and the energy gap  $\Delta_o$ .

Source: Donnelly, R. J. 1981. Cryogenics. In *Physics Vade Mecum*, ed. H. L. Anderson. American Institute of Physics, New York. With permission.

Conversely, if  $\lambda > \xi$ , the surface energy associated with the boundary is negative and lowers the total system energy. It is therefore thermodynamically favorable for a normal–superconducting interface to form inside these type II materials. Consequently, this class of superconductors does not exhibit the simple Meissner effect as do type I materials. Instead, there are now two critical fields: for applied fields below the lower critical field,  $H_{c1}$ , a type II superconductor is in the Meissner state, and for applied fields greater than the upper critical field,  $H_{c2}$ , superconductivity is destroyed. The three critical fields are related to each other by  $H_c \approx \sqrt{H_{c1} H_{c2}}$ .

In the range  $H_{c1} < H < H_{c2}$ , a type II superconductor is said to be in the vortex state because now the applied field can enter the bulk superconductor. Because flux exists in the material, however, the superconductivity is destroyed locally, creating normal regions. Recall that for type II materials the boundary between the normal and superconducting regions lowers the overall energy of the system. Therefore, the flux in the superconductor creates as many normal–superconducting interfaces as possible without violating quantum criteria. The net result is that flux enters a type II superconductor in quantized bundles of magnitude  $\Phi_o$  known as *vortices* or *fluxons* (the former

name derives from the fact that current flows around each quantized bundle in the same manner as a fluid vortex circulates around a drain). The central portion of a vortex, known as the core, is a normal region with an approximate radius of  $\xi$ . If a defect-free superconductor is placed in a magnetic field, the individual vortices, whose cores essentially follow the local average field lines, form an ordered triangular array, or flux lattice. As the applied field is raised beyond  $H_{c1}$  (where the first vortex enters the superconductor), the distance between adjacent vortex cores decreases to maintain the appropriate flux density in the material. Finally, the upper critical field is reached when the normal cores overlap and the material is no longer superconducting. Indeed, a precise calculation of  $H_{c2}$  using the phenomenological theory developed by Vitaly Ginzburg and Lev Landau yields

$$H_{c2} = \frac{\Phi_o}{2\pi\mu_o\xi^2} \quad (117.19)$$

which verifies our simple picture. The values of typical type II material parameters are listed in [Tables 117.3](#) and [117.4](#).

**Table 117.3** Material Parameters for Conventional Type II Superconductors\*

Material	$T_c$ (K)	$\lambda_{GL}(0)$ (nm)	$\xi_{GL}(0)$ (nm)	$\Delta_o$ (meV)	$\mu_o H_{c2,o}$ (T)
Pb-In	7.0	150	30	1.2	0.2
Pb-Bi	8.3	200	20	1.7	0.5
Nb-Ti	9.5	300	4	1.5	13
Nb-N	16	200	5	2.4	15
PbMo <sub>6</sub> S <sub>8</sub>	15	200	2	2.4	60
V <sub>3</sub> Ga	15	90	2–3	2.3	23
V <sub>3</sub> Si	16	60	3	2.3	20
Nb <sub>3</sub> Sn	18	65	3	3.4	23
Nb <sub>3</sub> Ge	23	90	3	3.7	38

\*The values are only representative because the parameters for alloys and compounds depend on how the material is fabricated. The penetration depth  $\lambda_{GL}(0)$  is given as the coefficient of the Ginzburg-Landau temperature dependence as  $\lambda_{GL}(T) = \lambda_{GL}(0)(1 - T/T_c)^{-1/2}$ ; likewise for the coherence length where  $\xi_{GL}(T) = \xi_{GL}(0)(1 - T/T_c)^{-1/2}$ . The upper critical field  $H_{c2,o}$  is given at zero temperature as well as the energy gap  $\Delta_o$ .

Type II superconductors are of great technical importance because typical  $H_{c2}$  values are at least an order of magnitude greater than the typical  $H_c$  values of type I materials. It is therefore possible to use type II materials to make high-field magnet wire. Unfortunately, when current is applied to the wire, there is a Lorentz-like force on the vortices, causing them to move. Because the moving vortices carry flux, their motion creates a static voltage drop along the superconducting wire by Faraday's law. As a result, the wire no longer has a zero DC resistance, even though the material is still superconducting. To fix this problem, type II superconductors are usually fabricated with intentional defects, such as impurities or grain boundaries, in their crystalline structure to pin the vortices and prevent vortex motion. The pinning is created because the defect locally weakens the superconductivity in the material, and it is thus energetically favorable for the normal core of the vortex to overlap the nonsuperconducting region in the material. Critical current densities usually quoted for practical type II materials, therefore, really represent the depinning critical current density where the Lorentz-like force can overcome the pinning force. (The depinning critical current density should not be confused with the depairing critical current density, which represents the current when the Cooper pairs have enough kinetic energy to overcome their correlation. The depinning critical current density is typically an order of magnitude less than the depairing critical current density, the latter of which represents the theoretical maximum for  $J_c$ .)

By careful manufacturing, it is possible to make superconducting wire with tremendous amounts of current-carrying capacity. For example, standard copper wire used in homes will carry about  $10^7$  A/m<sup>2</sup>, whereas a practical type II superconductor like niobium-titanium can carry current densities of  $10^{10}$  A/m<sup>2</sup> or higher even in fields of several teslas. This property, more than a zero DC resistance, is what makes superconducting wire so desirable.

## Defining Terms

**Superconductivity:** A state of matter whereby the correlation of conduction electrons allows a static current to pass without resistance and a static magnetic flux to be excluded from the bulk of the material.

Sub-millimeter-wave heterodyne mixer elements based on superconductor-insulator-superconductor (SIS) tunnel junctions are currently the most sensitive mixer elements available from 100–800 GHz (3–0.4 mm) with noise levels of a few times the limiting value set by quantum mechanics. The primary application of SIS mixers is radio astronomy, where the observation of cold interstellar objects can be aided by ultrahigh-performance heterodyne receiver systems. The device shown was designed by Prof. J. X. Zmuidzinas at the California Institute of Technology (Caltech) and fabricated by the Low Temperature Superconductivity group at Caltech's Jet Propulsion Laboratory, Center for Space Microelectronics Technology under a contract from the National Aeronautics and Space Administration. This particular quasioptically coupled design was fabricated using Niobium superconductor technology and represents the state of the art in the 800 GHz band. The incoming RF radiation is coupled from free space into a pair of slot antennas using a series of lenses. The power absorbed by the antennas is coupled through a superconducting microstrip line impedance transformer into two Nb/AlOx/Nb SIS tunnel junctions. The placement of the microstrip "fans" near the center of the slot antennas causes the junctions to be fed asymmetrically by the RF signal so that the short section of microstrip connecting the two junctions behaves like a shunt inductor. This shunt inductance is designed to tune out the parasitic capacitance of the SIS tunnel junctions in a band about the design frequency. Other superconducting microstrip components serve as a low-pass filter to couple the intermediate frequency (IF) mixing products out of the mixer while confining RF signals to the active device area. ## Further Information

Every two years an Applied Superconductivity Conference is held devoted to practical technological issues. The proceedings of these conferences have been published every other year from 1977 to 1991 in the *IEEE Transactions on Magnetics*.

In 1991 the *IEEE Transactions on Applied Superconductivity* began publication. This quarterly journal focuses on both the science and the technology of superconductors and their applications, including materials issues, analog and digital circuits, and power systems. The proceedings of the Applied Superconductivity Conference now appear in this journal.

At present, most of the digital systems described in this section of the handbook are implemented in CMOS (complementary metal oxide semiconductor) technology. This technology allows for the fabrication of chips with wiring that is several times thinner than a human hair. Each system is packaged into an IC (integrated circuit). The different layers of silicon and metal defining the circuit are then sent for fabrication. Copies of the same circuit, and sometimes different circuits, are fabricated on the same wafer, as shown above. (Photo courtesy of IBM.)

DIGITAL LOGIC DESIGN emerged as a discipline in the early days of computer systems when the need arose for a higher level of abstraction than that provided by electronic circuits. This marked the first time that electrical engineers designed using symbols and blocks that contained a number of sometimes quite complex electronic circuits. In addition, a number of nonengineers (logicians and computer scientists) entered the design process without an intimate knowledge of electronic circuits and electrical engineering. They were able to do so because they were working on a higher level of abstraction which did not require detailed knowledge. As a result, the productivity of designers has increased, as they have been relieved of design details such as speed, signal levels, noise, and power. Digital design was partitioned into *digital circuits*, *digital logic*, and *digital systems* on the highest level.

The digital circuit level concerns the design of digital components, often referred to as a "family" or "library." A set of gates and components is designed to be used by the logic designer working on the next level in the design hierarchy. These circuits must conform to certain electrical requirements and satisfy certain design criteria, such as speed and power consumption. In the beginning, logic components were built as modules which were later integrated on a single chip containing one or several logic gates or even blocks. This development was initiated by the birth of

the first integrated circuit at Texas Instruments in 1959, attributed to Jack Kilby. Today we can integrate millions of logic components on a single VLSI chip.

The consequences of this development have altered the way we design today. Managing such complexity would not be possible without extensive use of computer tools, known as CAD (computer-aided design). Not only is the logic designed with the use of CAD, but the design process itself is done by computers through extensive use of "logic synthesis." What this means is that the design behavior and specifications are described in some sort of language—HDL (hardware description language)—which serves as an entry point. From the specifications given in the HDL description, logic is automatically synthesized by a computer. In this way, it is possible to manage increasingly complex and large designs on a system level, dealing with functional specification and building blocks of high complexity. Not only is it important today to be able to manage the increased complexity of logic, but this task has to be done in an increasingly short time interval, known as the design "turn-around time." Introduction of hierarchy and use of CAD tools not only facilitates the design process, but it is the only way to manage designs consisting of millions of logic transistors.

Besides turn-around time, other issues are starting to dominate the design process. These are design correctness and testability. Testing and ensuring the testability of such increased complexity has become a problem and a discipline in itself. It is not only necessary to meet the increasingly short design time and to design for ever-increasing speed, but it is also necessary that the logic be "testable"; that is, the correctness of its functionality after the manufacturing process has to be guaranteed and detection of any possible faults ensured with a very high degree of confidence. For those reasons, logic design today is increasingly dependent on computer tools, to the point that it is difficult to separate one from the other.

Another very important development in logic design has been the introduction of field programmable logic (FPGA). Its importance is attributed to its ability to be configured very rapidly and often in the field—meaning in the product itself. The configuration process can be as rapid as several tens of milliseconds, allowing virtually flexible and configurable hardware to be used. Being generic and being able to take any shape and form, FPGA is very rapidly replacing logic previously found on the boards, known as "glue logic," usually surrounding large VLSI chips and connecting them in a system. FPGA is very closely integrated with CAD tools, making the FPGA design process automated to the point that it is possible to have "hardware libraries," files containing various designs that can be "loaded" into an FPGA chip during the computation, allowing the best fit to the particular algorithm or software routine. The notion of "reconfigurable hardware" and the abilities that FPGA offers are opening an entirely new realm in the way logic design is done and perceived.

118.3 INVERTER Circuit

118.4 NAND Gates

118.5 NOR Gates

**Richard S. Sandige**

*University of Wyoming*

Logic devices as discussed in this chapter are of the electronic type and are also called **digital circuits and switching circuits**. Electronic logic devices that are manufactured today are primarily transistor-transistor logic (TTL) circuits and complementary metal oxide semiconductor (CMOS) circuits. Specialized electronic design engineers called *digital circuit designers* design TTL and CMOS switching circuits. *Logic* and *system designers* gain familiarity with available logic devices via manufacturer's catalogs.

The AND gate, the OR gate, the INVERTER circuit, the NAND gate, and the NOR gate are the fundamental building blocks of practically all electronic manufactured switching circuits. From these fundamental logic devices, larger blocks such as counters, state machines, microprocessors, and computers are constructed. Construction of larger logic devices is accomplished using the mathematics introduced in 1854 by an English mathematician named George Boole [Boole, 1954]. The algebra he invented is appropriately called *Boolean algebra*. It was not until 1938 that Claude Shannon [Shannon, 1938], a research assistant at Massachusetts Institute of Technology (MIT), showed the world how to use Boolean algebra to design switching circuits.

In the following sections the building blocks for the fundamental logic device are discussed, and their truth table functions and Boolean equations are presented.

---

## 118.1 AND Gates

The AND logic device is referred to as an *AND gate*. The function it performs is the AND function. The function is most easily represented by a table of truth called a *truth table*, as illustrated in Table 118.1.

**Table 118.1** AND Gate Truth Table Function

$A$	$B$	$F$
0	0	0
0	1	0
1	0	0
1	1	1

The values in the truth table are ones and zeroes, but they could just as easily be trues and falses, highs and lows, ups and downs, or any other symbolic entries that are easily distinguished. The output  $F$  is 1 only when both inputs  $A$  and  $B$  are 1, as illustrated in Table 118.1. For all other input values of  $A$  and  $B$  the output values of  $F$  are 0. Figure 118.1(a) shows the logic symbol for an AND gate with two inputs [ANSI/IEEE Std 91-1984]. The Boolean equation that represents the function performed by the AND gate is written as

$$F = A \text{ AND } B \quad \text{or} \quad F = A \cdot B \quad (118.1)$$

**Figure 118.1** (a) AND gate logic symbol with two inputs; (b) logic symbol for a 3-input AND gate; (c) logic symbol for a 4-input AND gate.

The raised dot represents the AND operator and signifies the operation to be performed on the input variables  $A$  and  $B$ , with the result assigned to  $F$ . For  $n$  input **switching variables** there are  $2^n$  rows in the truth table and output values for the switching variable  $F$ . An AND gate can consist of 2 or more inputs. Standard off-the-shelf TTL AND gate devices [Texas Instruments, 1984] have as many as 4 inputs. **Programmable logic devices** (PLDs) that are used to configure larger circuits [Advanced Micro Devices, 1988] either by fuses or by stored charge movement electrically have AND gates with 32 or more inputs. Figures 118.1(b) and 118.1(c) show the logic symbols for a 3-input AND gate and a 4-input AND gate, respectively.

## 118.2 OR Gates

The OR logic device is referred to as an *OR gate*. The function it performs is the OR function. The truth table function for a 2-input OR gate is shown in Table 118.2.

**Table 118.2** OR Gate Truth Table Function

<i>A B</i>	<i>F</i>
0 0	0
0 1	1
1 0	1
1 1	1

Like the AND gate, the OR gate can have many inputs. The output  $F$  for the OR gate is 1 any time one of the inputs  $A$  or  $B$  is 1, as illustrated in [Table 118.2](#). When the input values of  $A$  and  $B$  are both 0, the output value of  $F$  is 0. [Figure 118.2\(a\)](#) shows the logic symbol for an OR gate with two inputs. The Boolean equation that represents the function performed by the OR gate is written as

$$F = A \text{ OR } B \quad \text{or} \quad F = A + B \quad (118.2)$$

**Figure 118.2** (a) OR gate logic symbol with two inputs; (b) logic symbol for a 9-input OR gate; (c) simplified logic symbol for a 9-input OR gate.

The plus sign represents the OR operator and signifies the operation to be performed on the input variables  $A$  and  $B$ , with the result assigned to  $F$ . Standard off-the-shelf TTL AND gate devices are generally limited to 2 inputs. Programmable logic devices (PLDs) that are used to configure larger circuits either by fuses or by stored charge movement electrically have OR gates with as many as 9 or more inputs. [Figure 118.2\(b\)](#) shows a logic symbol for a 9-input OR gate. [Figure 118.2\(c\)](#) shows a simplified logic symbol for a 9-input OR gate.

## 118.3 INVERTER Circuit

The INVERTER circuit, sometimes called the NOT circuit, is the simplest circuit of the fundamental logic devices because it only has one input. Its truth table function is shown in [Table 118.3](#).

**Table 118.3** INVERTER Circuit Truth Table Function

$A$	$F$
0	1
1	0

Notice in [Table 118.3](#) that each output value of  $F$  is just the opposite of each input value for  $A$ . This inverting property provides a simple means of establishing a 1 output when a 0 input is supplied and a 0 output when a 1 input is supplied.

Larger circuits are often formed by connecting the outputs of two or more AND gates to the inputs of an OR gate. This form of configuration is called a **sum-of-products (SOP) form** since the AND gates perform a logic product and the OR gate performs a logic sum—hence the name *sum of products*. [Figure 118.3\(a\)](#) shows the sum-of-products form for a very common logic circuit that performs **modulo 2 addition** called an *exclusive OR*. Observe that the logic symbol for the INVERTER circuit—that is, the triangular symbol with the small circle at the output—is used in two places in the circuit for the exclusive OR. The switching variable  $A$  is inverted to obtain  $\bar{A}$  by one INVERTER circuit, and  $B$  is inverted to obtain  $\bar{B}$  by the second INVERTER circuit. The logic symbol for the exclusive OR circuit is shown in [Fig. 118.3\(b\)](#). The truth table function for the Exclusive OR circuit is illustrated in [Table 118.4](#).

**Figure 118.3** (a) Exclusive OR circuit in SOP form; (b) logic symbol for the exclusive OR circuit.

**Table 118.4** Exclusive OR Circuit Truth Table Function

$A$ $B$	$F$
0 0	0
0 1	1
1 0	1
1 1	0

The Boolean equation for the exclusive OR circuit is

$$F = A \cdot \overline{B} + \overline{A} \cdot B \quad \text{or} \quad F = A \oplus B \quad (118.3)$$

The circled + symbol is the exclusive OR operator, which allows the function to be expressed in a simpler form than the first form, which uses the AND operator (the raised dot), the OR operator (the plus symbol), and the INVERTER operator (the overbar).

## 118.4 NAND Gates

The NAND gate—where NAND stands for NOT AND—is the basic gate perhaps most frequently used. It consists of an AND gate followed by an INVERTER circuit. An off-the-shelf NAND gate is simpler to design, costs less to manufacture, and provides less **propagation delay time** than the equivalent connection of an AND gate followed by an INVERTER circuit. The NAND gate performs the NAND function. The truth table function for a NAND gate with two inputs is shown in [Table 118.5](#).

**Table 118.5** NAND Gate Truth Table Function

$A$ $B$	$F$
0 0	1
0 1	1
1 0	1
1 1	0

The output  $F$  is 0 only when both inputs  $A$  and  $B$  are 1, and for all other input values of  $A$  and  $B$  the output values of  $F$  are 1. As might be expected, the output values of  $F$  in the truth table function for the NAND gate, [Table 118.5](#), are each inverted from those in the truth table function for the AND gate, [Table 118.1](#). The Boolean equation for the NAND gate, Eq. (118.4), is the same as the Boolean equation for the AND gate, Eq. (118.1), with an added overbar to indicate that the output is inverted:

$$F = A \text{ NAND } B \quad \text{or} \quad F = \overline{A \cdot B} \quad (118.4)$$

[Figure 118.4\(a\)](#) illustrates the logic symbol for a NAND gate with two inputs. Notice that the NAND gate logic symbol simply consists of the AND gate logic symbol with a small circle attached to its output. The small circle indicates inversion like the small circle used in the logic symbol for the INVERTER circuit.

**Figure 118.4** (a) NAND gate logic symbol with two inputs; (b) logic symbol for a 13-input NAND gate.

Off-the-shelf TTL NAND gates are available with up to 13 inputs, as illustrated by the logic symbol shown in [Fig. 118.4\(b\)](#) for a 13-input NAND gate.

# 118.5 NOR Gates

The NOR gate consists of an OR gate followed by an INVERTER circuit. NOR is a contraction of NOT OR. Like the NAND gate, an off-the-shelf NOR gate is simpler to design, costs less to manufacture, and provides less propagation delay time than the equivalent connection of an OR gate followed by an INVERTER circuit. The NOR gate truth table function for two inputs is represented in [Table 118.6](#).

**Table 118.6** NOR Gate Truth Table Function

<i>A</i>	<i>B</i>	<i>F</i>
0	0	1
0	1	0
1	0	0
1	1	0

The output *F* is 1 only when both inputs *A* and *B* are 0, and for all other input values of *A* and *B* the output values of *F* are 0. The output values of *F* in the truth table function for the NOR gate,

Table 118.6, are each inverted from those in the truth table function for the OR gate, Table 118.2. The Boolean equation for the NOR gate, Eq. (118.5), is the same as the Boolean equation for the OR gate, Eq. (118.2), with an added overbar to indicate that the output is inverted.

$$F = A \text{ NOR } B \quad \text{or} \quad F = \overline{A + B} \quad (118.5)$$

The logic symbol for a NOR gate with two inputs is shown in Fig. 118.5. The NOR gate logic symbol is represented by the OR gate logic symbol with a small circle attached to its output. As mentioned earlier, the small circle indicates inversion. Off-the-shelf TTL NOR gates are available with up to 5 inputs.

**Figure 118.5** (a) NOR gate logic symbol with two inputs.

**Example.** Suppose a three-person digital voting circuit is needed to allow three judges to make a decision on a proposition, and their decision must be indicated as soon as all votes are made. For three judges there must be  $2^3 = 8$  rows in the truth table such that each row represents a different combination of judges' votes. The entry 101 would represent judge 1 voting yes, judge 2 voting no, and judge 3 voting yes; the decision for this row would be 1, showing a majority ruling, and the proposition would pass. For the case of 001 the decision for the row would be a 0, showing that a majority was not achieved, and the proposition would fail. The complete truth table function for a three-person voting circuit is shown in Table 118.7.

**Table 118.7** Truth Table Function for a Three-Person Voting Circuit

Judge 1	Judge 2	Judge 3	Decision
0	0	0	0
0	0	1	0
0	1	0	0
0	1	1	1
1	0	0	0
1	0	1	1
1	1	0	1
1	1	1	1

The truth table function for the three-person voting circuit cannot be represented by one of the fundamental logic devices. The circuit requires a combination of the fundamental logic devices. By

closely observing the truth table entries, we can write the following Boolean equation for the decision in terms of the three judges' inputs:

$$\begin{aligned} \text{Decision} = & (\text{judge 2 AND judge 3}) \text{ OR } (\text{judge 1 AND judge 3}) \\ & \text{OR } (\text{judge 1 AND judge 2}) \end{aligned} \quad (118.6)$$

which can be written more simply as

$$\text{Decision} = (\text{judge 2} \cdot \text{judge 3}) + (\text{judge 1} \cdot \text{judge 3}) + (\text{judge 1} \cdot \text{judge 2}) \quad (118.7)$$

The circuit for this Boolean equation in SOP form is shown in Fig. 118.6. Each input to the circuit can be supplied by an on/off switch that represent a yes/no vote respectively, and the output can be set up to drive a light *on* (lighted) or *off* (not lighted) to indicate the decision of the voting—where *on* represents a proposition has passed and *off* represents a proposition has failed. Other circuit designs are carried out in a similar manner by logic designers and system designers to build larger circuits and systems.

**Figure 118.6** (a) Three-person voting circuit in SOP form.

Logic devices are operated with voltages, so voltage values are sometimes used for the two distinct values, that is, the 1 and 0 discussed earlier. Each symbolic entry in a truth table thus

represents a range of voltages. Logic circuits of the same family, such as TTL or CMOS, are designed to be used in combination with other devices of the same family without the user worrying about actual voltages required other than  $V_{cc}$  and GND. Most switching circuits today are operated from a 5-volt supply source; however, newer switching circuits are rapidly appearing on the market requiring a 3-volt supply source. Logic devices utilizing a smaller voltage require less power to operate, and portable equipment manufacturers are the first to benefit from this trend in device technology.

## Defining Terms

**Digital circuits and switching circuits:** A class of electronic circuits that operates with two distinct levels.

**Modulo 2 addition:** Binary addition of two single binary digits, as expressed in [Table 118.4](#).

**Programmable logic devices:** Logic devices that are either one time programmable by blowing or leaving fuses intact or many times programmable by moving stored charges electrically.

**Propagation delay time:** Delay time through a logic device from input to output.

**Sum-of-products (SOP form):** Very popular form of Boolean equation representation for a switching circuit, also called AND/OR form, since AND gates feed into an OR gate.

**Switching variable:** Another name for an input variable, output variable, or signal name that can take on only two distinct values.

**$V_{cc}$  and GND:** Power supply connections required of all electronic devices. For a 5-volt logic device, the 5-volt power supply terminal is connected to the  $V_{cc}$  terminal of the device and the power supply ground terminal is connected to the GND terminal of the device.

*University of North Carolina, Charlotte*

A *counter* is a logic circuit whose outputs follow a defined repeating sequence. After the final number in the sequence is reached, the counter outputs return to the first number. To cause the outputs to change from one number in the sequence to the next, a clock signal is applied to the circuit. A *clock signal* is a logic signal that changes from a logic 0 to a logic 1 and from a logic 1 to a logic 0 at regular intervals. The counter outputs change at one of the transitions of the clock signal, either a 0-to-1 transition or a 1-to-0 transition, depending on the design of the counter and logic components used. Counters are widely used in logic systems to generate control signal sequences and to count events.

### 119.1 Binary Counters

---

A common counter is the *binary counter*, whose outputs follows a linearly increasing or decreasing binary number sequence. A *binary-up counter* has outputs that follow a linearly increasing sequence. For example, a 4-bit binary-up counter (a binary-up counter with four outputs) has outputs that follow the sequence: 0000, 0001, 0010, 0011, 0100, 0101, 0110, 0111, 1000, 1001, 1010, 1011, 1100, 1101, 1110, 1111, 0000, (i.e., 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 0, in decimal). A *binary-down counter* is a counter whose outputs follow a counting sequence in reverse order, for example, 1111, 1110, 1101, 1100, 1011, 1010, 1001, 1000, 0111, 0110, 0101, 0100, 0011, 0010, 0001, 0000, 1111, (i.e., 15, 14, 13, 12, 11, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1, 0, 15, in decimal). A *bidirectional counter* is a counter that can count upwards or downwards depending on control signals applied to the circuit. The control signals specify whether the counter is to count up or down.

## 119.2 Arbitrary Code Counters

Counters can also be designed to follow other sequences. Examples include binary counters that count up to a specific number. For example, a 4-bit binary counter could be designed to count from 0 to 4 repeatedly, rather than from 0 to 15 repeatedly. Such counters can be binary counter designs with additional circuitry to reset the counter after the maximum value required has been reached. A *ring counter* generates a sequence in which a 1 moves from one position to the next position in the output pattern. For example, the outputs of a 5-bit ring counter follow the sequence: 10000, 01000, 00100, 00010, 00001, 10000,. A *Johnson counter* or *twisted ring counter* is a ring counter whose final output is "twisted" before being fed back to the first stage, so that when the final output is a 1 the next value of the first output is a 0, and when the final output is a 0 the next value of the first output is a 1. The sequence for a 5-bit Johnson counter is 10000, 11000, 11100, 11110, 11111, 01111, 00111, 00011, 00001, 10000,. Johnson counters have the characteristic that only one digit changes from one number in the sequence to the next number. This characteristic is particularly convenient in eliminating *logic glitches* that can occur in logic circuits using counter outputs. Logic glitches are unwanted logic pulses of very short duration.

## 119.3 Counter Design

Most counters are based upon *D*-type or *J-K* **flip-flops**. *J-K* flops are particularly convenient as they can be made to "toggle" (i.e., change from 0 to 1, or from 1 to 0) if a logic 1 is applied permanently to the *J* output and to the *K* input of the flip-flop. Hence a single *J-K* flip-flop can behave as a one-bit binary counter whose output follows the sequence 0, 1, 0, as shown in Fig. 119.1. We will describe counter designs using the toggle action of *J-K* flip-flops. In Fig. 119.1 the flip-flop output changes on a 1-to-0 transition of the clock signal—that is, a negative **edge-triggered** flip-flop is being used. We shall assume such flip-flops in our designs.

**Figure 119.1** One-bit counter using a *J-K* flip-flop: (a) circuit, (b) output waveform.

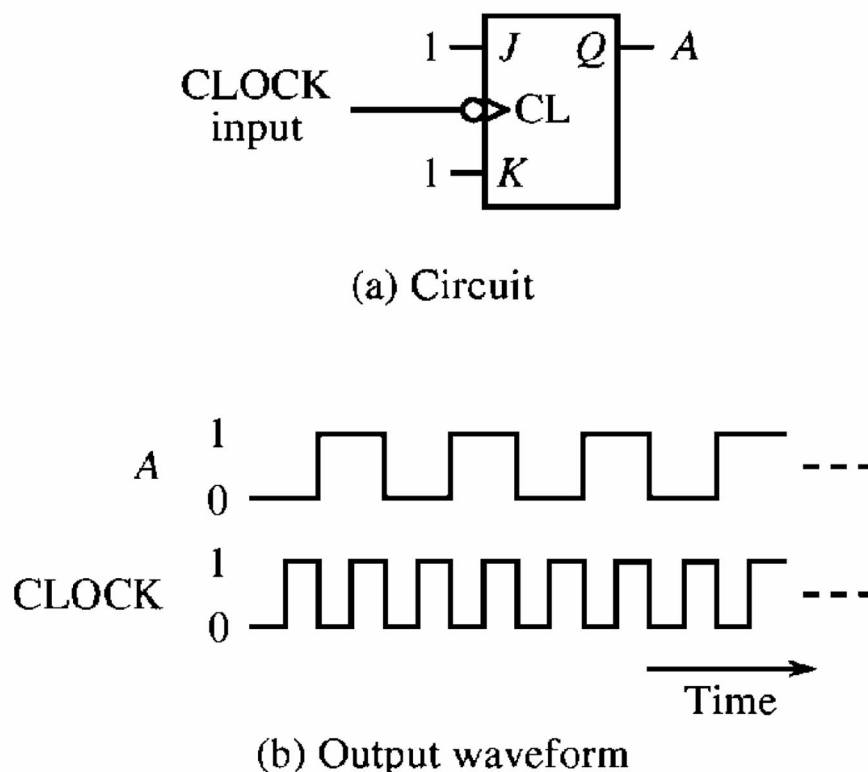

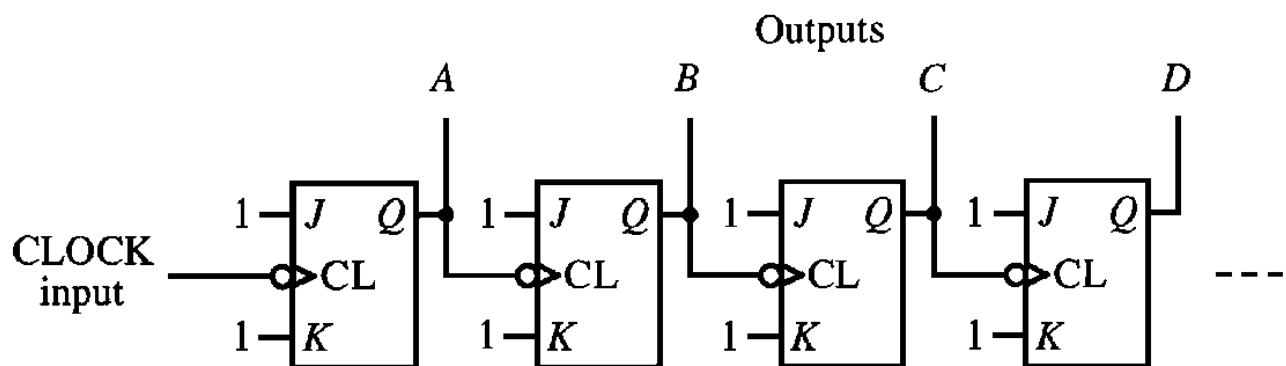

Figure 119.2 shows idealized waveforms of a binary-up counter whose outputs are  $A$ ,  $B$ ,  $C$ , and  $D$ . Such counter outputs can be created in one of several ways. There will be one flip-flop for each output and four flip-flops for a 4-bit counter.

**Figure 119.2** Binary-up counter outputs.

Counter designs can be classified as synchronous or asynchronous. The key characteristic of an *asynchronous counter* is that the output of one stage is used to activate the next stage. A 4-bit asynchronous binary (up) counter is shown in Fig. 119.3. Output  $A$  is the least significant bit of the sequence, and output  $D$  is the most significant bit. We can understand the operation of this counter by referring to the required counter waveforms shown in Fig. 119.2. Output  $A$  is to change when there is a 1-to-0 transition on the clock input signal. Output  $B$  is to change when there is a 1-to-0 transition on output  $A$ . Output  $C$  is to change when there is a 1-to-0 transition on output  $B$ . Output  $D$  is to change when there is a 1-to-0 transition on output  $C$ . These transitions are achieved with the connections shown.

**Figure 119.3** Asynchronous binary counter.

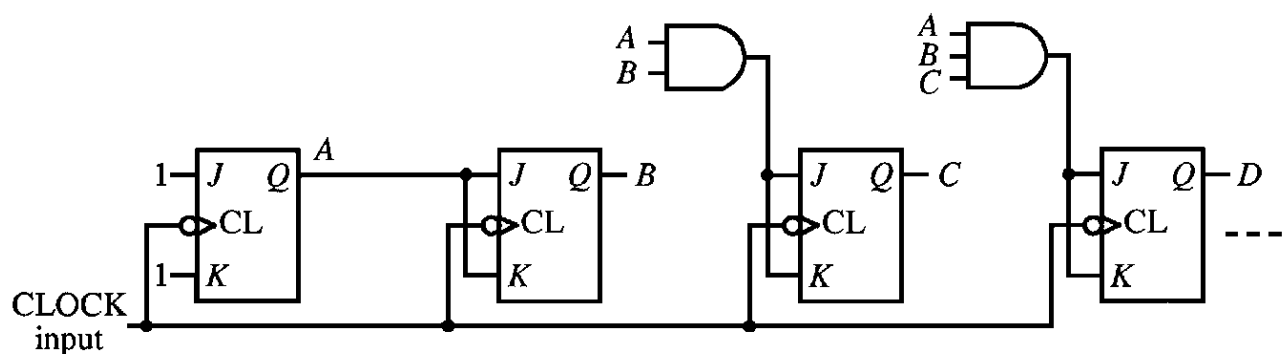

The circuit arrangement can be extended to any number of stages. The counter is asynchronous in nature because each output depends on a change in the previous output. Consequently, there will be a small delay between changes in successive outputs. The delays are cumulative, and the overall

delay between the first output change and the last output change could be significant, for example, from 1111 to 0000. This delay will limit the rate at which clock pulses can be applied (the maximum frequency of operation). Asynchronous binary counters are sometimes called *ripple counters* because the clock "ripples" through the circuit.

In the *synchronous counter* we try to avoid delays between successive outputs by synchronizing flip-flop actions. This step is done by connecting the clock signal to all the flip-flop clock inputs. Consequently, when outputs of flip-flops change, the changes occur simultaneously (ignoring variations between flip-flops). Logic is attached to the flip-flop inputs to produce the required sequence. Figure 119.4 shows one design of a synchronous binary (up) counter. We can understand this design also by examining the counter waveforms of Fig. 119.2. The first stage is the same as the asynchronous counter, and output changes occur on every activating clock transition. The second stage should toggle if, at the time of the activating clock transition, the *A* output is a 1. The third stage should toggle if, at the time of the activating clock transition, the *A* output and the *B* output are both 1. The fourth stage should toggle if, at the time of the activating clock transition, the *A* output, the *B* output, and the *C* output are all 1. These transitions are achieved by applying *A* to the *J-K* inputs of the second stage, the logic function  $A \cdot B$  (i.e., *A* AND *B*) to the third stage, and the logic function  $A \cdot B \cdot C$  (i.e., *A* AND *B* AND *C*) to the fourth stage. In each case an AND gate is used in Fig. 119.4. The toggle action for a fifth stage occurs when all of *A*, *B*, *C*, and *D* are a 1, and hence requires a four-input AND gate. Similarly, the sixth stage requires a five-input AND gate, and so on. An alternative implementation that reduces the number of inputs of the gates to two inputs is shown in Fig. 119.5. However, this particular implementation has the disadvantage that signals may have to pass through several gates to reach the inputs of flip-flops, which will limit the speed of operation of the counter.

**Figure 119.4** Synchronous binary counter.

**Figure 119.5** Synchronous binary counter using 2-input AND gates.

## 119.4 State Machines

Counters are in the logic classification called **sequential circuits**. The outputs of sequential circuits depend on present inputs and past output values, as opposed to **combinational circuits**, in which the outputs depend only on a particular combination of the present input values. Sequential circuits exist in defined *states*. The state of the circuit changes to another state on application of new input values. Such circuits are called *state machines*. Since in all practical circuits there will be a finite number of states, practical state machines are more accurately called *finite state machines*.

A counter is clearly a circuit that exists in defined states; each state corresponds to one output pattern. Other sequential circuits include circuits that detect particular sequences of input patterns (*sequence detectors*). As parts of the required input pattern are received, the circuit state changes from one state to the next, finally reaching the state corresponding to the complete input pattern being received.

Using *state variables*, each state is assigned a unique binary number, which is stored internally. An  $n$ -bit state variable can be used to represent  $2^n$  states. In *one-hot assignment* each state is assigned one unique state variable, which is a 1 when the system is in that state. All other state variables are zero for that state. Hence, with  $n$  states,  $n$  state variables would be needed. Though the one-hot assignment leads to more state variables, it usually requires less complicated logic.

## 119.5 State Diagrams

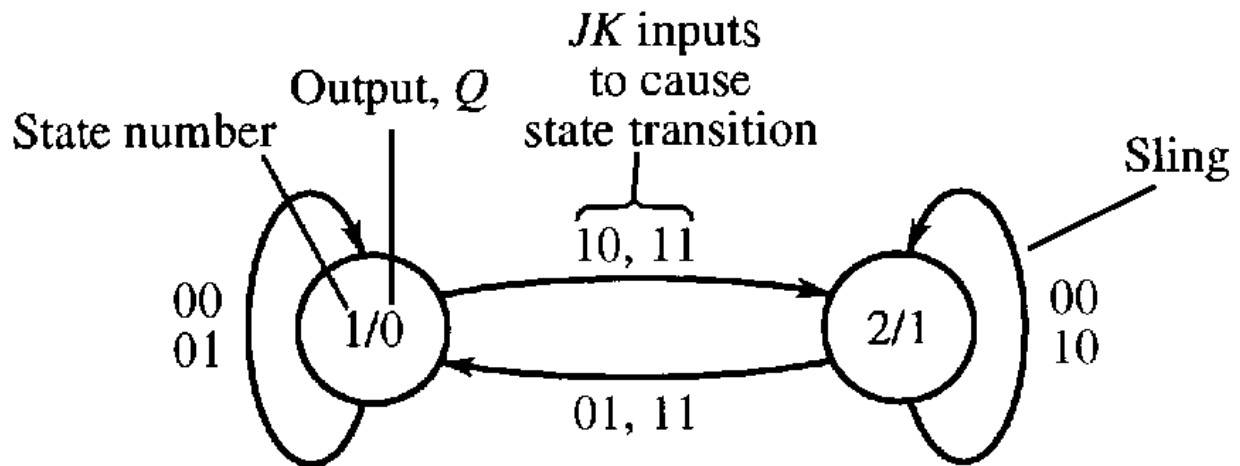

A *state diagram* is a graphical representation of the logical operation of circuits, such as counters, and sequential circuits in general. A state diagram indicates the various states that the circuit can enter and the required input/output conditions necessary to enter the next state. A state diagram of a 3-bit binary (up) counter is shown in Fig. 119.6. States are shown by circles. The state number for the state, as given by the state variables, is shown inside each circle. In a counter the state variables and the counter outputs are the same. Lines between the state circles indicate transitions from one state to the next state, which occurs for a counter circuit on application of the activating clock transition.

**Figure 119.6** State diagram of a binary counter.

Other sequential circuits may have data inputs. For example, a  $J$ - $K$  flip-flop is a sequential circuit in its own right and has  $J$  and  $K$  inputs as well as a clock input. In that case we mark the lines between the states in the state diagram with the required input values to cause the state transition. There are two common forms of state diagram for circuits incorporating data inputs—the *Moore model state diagram* and the *Mealy model state diagram*. In both models the inputs that cause a new state are shown next to the lines. The effects of all combinations of input values must be considered in each state. A line that returns to the same state forms a "sling" and indicates that the state does not change with the particular input values. In the Moore model the outputs are associated with the states and are shown inside the circles. In the Mealy model the outputs are associated with input values and resultant states and are shown next to the transition lines between states. [Figure 119.7](#) shows the Moore model state diagram and the Mealy model state diagram for a  $J$ - $K$  flip-flop. The fundamental difference between the Moore model state diagram and the Mealy model state diagram is that, in the Moore model state diagram, each state always generates a defined output, whereas, in the Mealy model state diagram, states can generate various outputs depending upon present input values. Each model can represent any sequential circuit, though the number of states may be greater in the Moore model state diagram than in the Mealy model state diagram. The information given in the state diagram can be produced in a table called a *state table*.

**Figure 119.7** State diagrams of a *J-K* flip-flop: (a) Moore model state diagram, (b) Mealy model state diagram.

(a) Moore model state diagram

(b) Mealy model state diagram

## 119.6 State Diagrams Using Transition Expressions

An alternative form of state diagram that is particularly suitable for a state machine with a large number of states marks each line with a Boolean expression that must be true for the transition to occur. All expressions associated with each node must be exclusive of each other (i.e., no combinations of values must make more than one expression true). Also, the set of expressions must 0

cover all combinations of variables. This form of state diagram for a  $J$ - $K$  flip-flop is shown in Fig. 119.8. In this diagram we can see clearly that the transition from state 1 to state 2 depends only on  $J$  being a 1, and the transition from state 2 to state 1 depends only on  $K$  being a 1.

**Figure 119.8** State diagram of a  $J$ - $K$  flip-flop, using transition expressions.

## Defining Terms

**Asynchronous sequential logic circuit:** A sequential circuit in which a clock signal does not synchronize changes. In an asynchronous sequential logic circuit, changes in more than one output do not necessarily occur simultaneously. Changes in outputs may depend on other output changes.

**Combinational logic circuit:** A logic circuit whose outputs depend only on present input values.

**Edge triggering:** A mechanism for activating a flip-flop. In positive edge triggering the output changes after a 0-to-1 logic transition on the clock input. In negative edge triggering the output changes after a 1-to-0 logic transition on the clock input.

**Flip-flop:** A basic logic circuit that can maintain its output at either 0 or 1 permanently, but whose output can "flip" from 0 to 1 or "flop" from 1 to 0 on application of specific input values. Common flip-flops are the  $S$ - $R$  flip-flop, the  $J$ - $K$  flip-flop, and the  $D$ -type flip-flop. The names are derived from the letters used for the inputs.

**Programmable logic sequencers:** A logic circuit in the family of programmable logic devices (PLDs) containing the components to implement a synchronous sequential circuit. A programmable logic sequencer has gates and flip-flops with user-selectable feedback connections. See *PAL@ Device Data Book Bipolar and CMOS*, Advanced Micro Devices, Inc., Sunnyvale, CA, 1990; *Digital System Design Using Programmable Logic Devices* by P. Lala, Prentice Hall, Englewood Cliffs, NJ, 1990; or *Programmable Logic*, Intel Corp., Mt. Prospect, IL, 1994, for further details.

**Propagation delay:** The very short time period in a basic logic circuit between the application of a new input value and the generation of the resultant output.

**Sequential logic circuit:** A logic circuit whose outputs depend on previous output values and

present input values. Sequential circuits have memory to maintain the output values.

**Synchronous sequential logic circuit:** A sequential circuit in which a clock signal initiates all changes in state.

## Further Information

The topic of counters and state machines can be found in most logic design books, a sample of which is listed in the reference section. *Contemporary Logic Design* by Katz is very readable and thorough for the electrical engineer. Other logic design books include:

Prosser, F. P. and Winkel, D. E. 1987. *The Art of Digital Design*, 2nd ed. Prentice Hall, Englewood Cliffs, NJ.

McCalla, T. R. 1992. *Digital Logic and Computer Design*. Macmillan, New York.

Some books, such as the book by McCalla, integrate logic design with computer design because logic design is used in the design of computers.

# Microprocessors and Microcontrollers

---

120.1 Digital Hardware Systems

120.2 Processors

120.3 Assembly Language

120.4 Some Real Microprocessors and Microcontrollers

**Fredrick J. Hill**

*University of Arizona*

A *processor* executes coded instructions on electronically stored data. The stream of coded instructions has usually been translated (compiled and assembled) from an alphanumeric representation to vectors of 1s and 0s and is stored in the same electronic medium as the data. A *microprocessor* is a processor fabricated on a single silicon chip of components whose sizes are measured in microns. As such, the microprocessor is an example of a very-large-scale *integrated* (VLSI) *circuit*. It is mounted in a package less than an inch wide and a few inches in length with a row of between 20 and 64 electrical connecting pins projecting from each side or, for more complex processors, a square package with a larger number of pins extending from the bottom. The most sophisticated of the 16-bit and 32-bit microprocessors are suitable for use as principal components of a personal computer. A *microcontroller* is a special kind of a microprocessor.

A microcontroller supplied by a particular vendor will be similar in many respects to the microprocessors intended by that vendor for use in general purpose computers. The microcontrollers will often have a simplified instruction set and will be designed to work with a smaller address space than other microprocessors. The space on the VLSI chip made available by these simplifications is typically used in the realization of *input-output* support functions that would otherwise be realized on separate chips. These actions have the effect of reducing the total parts cost in a microcontroller system, an important consideration if the processor is to be designed into a consumer product for which cost containment is paramount.

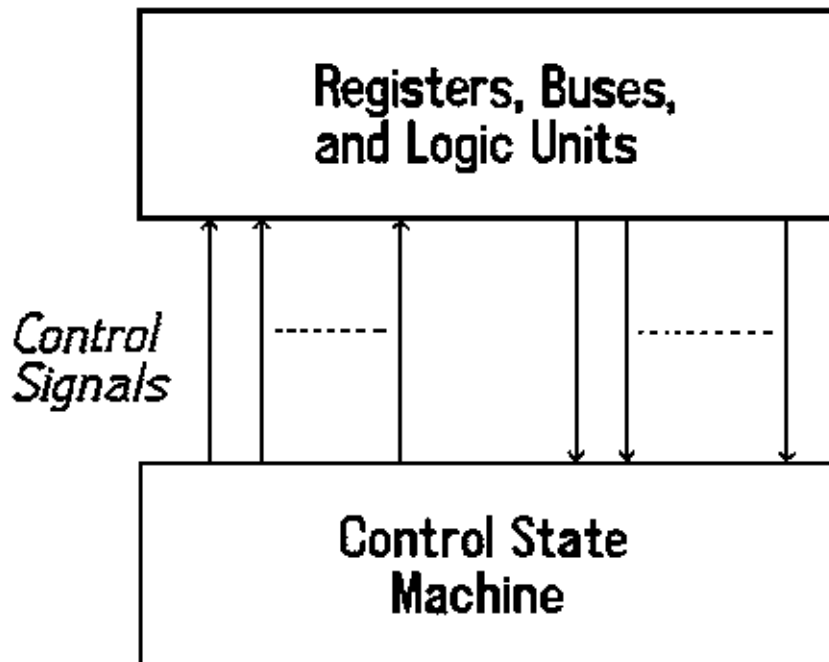

## 120.1 Digital Hardware Systems

---

A complex VLSI chip will consist of interconnected realizations of the logic devices of **Chapter 118** and the state machines of **Chapter 119**. A microprocessor falls within the definition of a sequential circuit or state machine, but the usual state machine notation—that is, state diagrams and state tables—are grossly inadequate for describing *digital hardware systems* with so many possible states. For example, a digital hardware system consisting of only one 32-bit register could assume any one of  $2^{32}$  states. A more powerful medium for describing digital systems—most of

whose memory elements are organized into registers—is depicted in Fig. 120.1. The block labeled "control" represents a state machine that can be described as in Chapter 119. The *data unit* block will consist of registers, *buses*, and combinational logic units. *Definition:* A bus is a conductor or a vector of conductors used for transmitting signals. A bus will typically be driven by multiplexers or tristate logic elements.

**Figure 120.1** Partition into control and data units.

The active state of the control state machine will activate one or more of the control output lines in Fig. 120.1. Each such active control line will trigger one or more activities in the data unit. These activities consist of connecting outputs of logic units or registers to buses; or enabling the loading of the output of a register, logic unit, or bus into a target register. Activities in the data unit will be synchronized by the system master clock, and the control unit may change state once each period of that same clock. One form of notation for describing the structure and function of digital systems conforming to the model of Fig. 120.1 is a *hardware description language*. [One hardware description language that has been approved as a standard is VHDL (Berge 1993).] The following might be a fragment of a description of some digital system in some unspecified hardware description language (HDL):

```

IF control state = q10 THEN
    ABUS = REGISTER4;
    carryin = carry_memory_element
    OBUS = ADD(ABUS; DATABUS; carryin);

```

carry\_memory\_element, REGISTER5 <- OBUS.

By itself this partial description indicates that, whenever the control unit is in state  $q_{10}$ , that REGISTER4 is connected to the bus ABUS. During the same period the sum of the vectors on the ABUS, another bus (perhaps the memory data bus), and the carry memory element propagates through a multiplexer to the OBUS. This sum vector is then loaded into REGISTER5. An adder with bit length compatible with processor data registers will be included in the *arithmetic and logic unit* (ALU) of every microprocessor.

The change of state in the control unit is not described in the fragment just given. To facilitate complete descriptions, the HDL must provide for specification of the appropriate change of state, perhaps as a function of the values of the signals from the data unit to the control unit as shown in [Fig. 120.1](#).

## 120.2 Processors

---

Not every digital hardware system satisfying the model of [Fig. 120.1](#) is a processor. A processor must include the capability to access data and process programs from a memory module, as depicted in [Fig. 120.2](#). The memory module will usually consist of several VLSI chips separate from the processor chip. The ALU incorporates the combinational logic necessary to implement the arithmetic, logical, or shifting operations that can be carried out by the processor. As suggested by the HDL fragment in the previous section, the arguments of these operations are selected from among the program-managed registers in block M and possibly a data vector arriving from memory on DATABUS. The result is loaded into a register in block M.

The set of instructions that is implemented in the ALU and the program manageable register configuration are often called the *architecture* of the processor. A physical implementation of that architecture will require additional logic and some registers hidden from the programmer in block I. [1] One register that must always be present in some form is the *program counter*, PC. The PC controls the sequencing through instructions in the program stored in memory. In the classical processor each instruction cycle begins with the *instruction fetch*. To initiate the instruction fetch PC is connected to the address bus. The instruction stored at the addressed location is then connected by the memory to DATABUS. The processor loads the instruction from data bus into some form of hidden *instruction register*, IR, that controls the execution of the instruction through subsequent periods of the master clock. Execution may require one or more similar memory transactions via the address and data bus to fetch operands from memory and/or to store a result in memory. At the end of the instruction cycle the program counter is incremented to sequence to the instruction stored at the next memory location.

The *instruction set* of every processor must include one or more *branch instructions* to permit the sequence of execution of instructions to be altered based on the results of previous instructions.

**Figure 120.2** Microprocessor system.

The execution of a branch is simply logical determination of a new address followed by its loading into the program counter. In most microprocessors the conditional branches are based on the contents of a set of individual memory elements or *flags* that may be set or cleared by each execution of an instruction through the ALU. Typical flags indicate whether the result was negative, zero, included a carry, or resulted in overflow (a result too large in magnitude to be stored in the intended target register). The flags are often collected to form an 8-bit register in block M.

The term  $n$  in Fig. 120.2 indicates the number of binary bits in a word (vector) that can be passed across the data bus and, therefore, the number of bits in each word of memory. Eight, 16, 32, and 64 are all possible values of  $n$  for a microprocessor. The length of a data register in box M of the processor is often equal to  $n$ . One exception was the original Motorola MC68000, which had 32-bit internal data registers but a 16-bit data bus. The width of the data bus became a limiting factor on the rate at which data could be processed, so the MC68000 was classified as a 16-bit processor.

The number of bits in an address is indicated as  $m$  in Fig. 120.2. Typically,  $16 \leq m \leq 32$ . If  $m = 23$ , there are  $2^{23}$  words in the *memory map*. In most processors internal address registers are included among the program-accessible registers in block M. Sometimes the internal address registers will address data in finer units than the words that can be passed across the data bus. The smallest unit of separately addressed data is the 8-bit byte. For example, consider a processor with a 16-bit data bus and 24-bit internal address registers that map the memory as  $2^{24}$  8-bit bytes (16 megabytes). Only the most significant 23 bits of the address register are connected to the address bus ( $m = 23$ ). Once a 16-bit word is accepted from the data bus the least significant address register bit can be used to select between the two bytes of the data word.

Not every location in the memory map is physically implemented as a word in a *random access memory*. (See **Chapter 121**.) As illustrated in Fig. 120.2, control and data registers within *peripheral interface units* (PIUs) occupy locations in the memory map. Once data are written to the data registers of a PIU, the output process is completed under the control of that interface (a digital hardware system). The process takes place in reverse for input. The processor can provide direction to an I/O process by first writing to the control registers of a PIU. This approach to input/output is called *memory-mapped I/O*. Other blocks of consecutive words in the memory map are occupied by self-describing *read-only memory* (ROM), whereas still other blocks in the memory map remain unused.

## 120.3 Assembly Language

---

Instructions must be stored in memory as vectors of 1s and 0s. A typical instruction word will be partitioned into several fields. The string of 1s and 0s in each field codes some separate feature of what the instruction is to accomplish. Coding instructions in this format and interpreting the coding is a tedious task for the programmer. All information found in a machine-coded instruction for a particular processor may be represented in alphanumeric form in the *assembly language* unique to that processor. The following is one MC68000 assembly language instruction with the corresponding two consecutive machine-coded words.

The instruction will add the operand specified by (A1, D2) to the least significant 16-bit word of the data register D3 and will leave the result in D3. The field specified as 110 tells the processor that (Ax, X) address register, **indirect** with indexing, is the **addressing** mode for the first operand. The extension word is necessary in this case only to indicate that the index register is the data register D2. The address of the first operand is obtained by adding address register A1 to index register D2. This address is then placed on the address bus and the required operand is found on the data bus.

A program that will translate an assembly language program for a particular processor to the corresponding machine-coded program is called an *assembler*. A programmer may write a program directly in assembly language or use a *compiler* to translate to assembly language from a high-level language such as C.

## 120.4 Some Real Microprocessors and Microcontrollers

Some features of a selected subset of microprocessors and microcontrollers are given in [Table 120.1](#). Some of these features are defined at the end of the chapter. The overall performance of the microprocessor chips is directly related to the clock rate, the tabulated parameters, and the other listed features. Sets of standard benchmark programs have been devised to provide empirical measurement of performance. These benchmarks are usually applied to complete microcomputer systems (workstations), including memory, secondary storage, and input/output mechanisms, rather than bare processors.

**Table 120.1** Features of Select Microprocessors and Microcontrollers

Processor	IntroDate	Data Bus	ClockRate	Address Bus	Features <sup>*</sup>
Intel 8080	1975	8 bits		16 bits	
MC6800	1976	8 bits	2 MHz	16 bits	
Intel 8086	1978	16 bits	8 MHz	20 bits	FPCP, DNR
MC6805	1979	8 bits	2 MHz	16 bits	CNTRL, simplified 6800
MC68000	1981	16 bits	8 MHz	23 bits	FPCP, DNR

MC68HC11	1984	8 bits	4 MHz	16 bits	CNTRLR
MC68040	1989	32 bits	25 MHz	30 bits	C, FPPL, IPL, DNR
Intel 486	1991	32 bits	66 MHz	30 bits	C, IPL, FP, DNR
MC68332	1991	16 bits	17 MHz	24 bits	CNTRLR, 68000 based
DEC alpha	1992	64 bits	200 MHz	34 bits	C, FPPL, IPL
SuperSparc	1992	32 bits	100 MHz	32 bits	C, FPPL, IPL
MPC601	1993	64 bits	80 MHz	32 bits	C, FPPL, IPL
Intel Pentium	1993	32 bits	66 MHz	30 bits	C, FPPL, IPL, DNR

\* Features: CNTRLR, microcontroller; C, on-chip **cache**; FPCP, floating point **coprocessor** chip available; FP, internal floating point; FPPL, floating point **pipeline**; IPL, integer **pipeline**; DNR, definitely not **RISC**.

Notice the 20-bit address bus of the Intel 8086, which could address  $2^{20} = 2^{10} \cdot 2^{10} = 1 \text{ kilo- byte} \cdot 2^{10} = 1 \text{ megabyte}$  of memory. In 1978 this appeared to be a very large memory space. The decision to tie the operating system MSDOS firmly to that amount of memory was a very costly one to those responsible for applications software development over the life of that operating system.

Only Motorola microcontrollers are listed in Table 120.1, but most IC vendors offer a line of microcontroller chips. The user pressure for conformity to a single architecture and a single operating system—which allowed Intel to be the volume-dominant producer of microprocessor chips—is not operative for microcontrollers. Compatibility is not important where programs are hidden from the user in noncomputer products. The advanced features that increase the aggregate rate at which information is processed are not of much interest in microcontroller applications. In place of the features listed in Table 120.1 small blocks of random access memory, user-programmable ROM (PROM), and PIUs are included on the same VLSI chip as the processor.

## Defining Terms

**Cache:** A high-speed buffer storage containing continuously updated copies of the most recently used words from main memory.

**Coprocessor:** A digital hardware system that does not interpret or execute programs but performs operations on data under the direction of a processor.

**Indirect addressing:** An addressing mode in which the first address determined in the execution of an instruction is not the address of the operand but is the *address of the address* of the operand.

**Pipeline:** Beginning execution of a new instruction prior to completion of another instruction of the same class. Several instructions may be in various stages of completion in a pipeline at one time.

**RISC:** Reduced instruction set computer. A processor described as RISC will usually have few instruction formats and a single instruction length. It will have few addressing modes and no indirect addressing. Memory access and operations on data are not specified in the same

instruction.

This chapter deals primarily with relatively fast electronic memory systems. Slower magnetic media, other storage media, and input output interfaces are only briefly discussed. Read/write memory, read-only memory, static memory, dynamic memory, cache memory, volatility of memory, relative speed of memory, and applications of memory are the major topics that are discussed. Trade-offs, advantages, and disadvantages are considered for various memory systems in the following sections. This approach provides insight as to the applications for which each type of memory system is used and why.

---

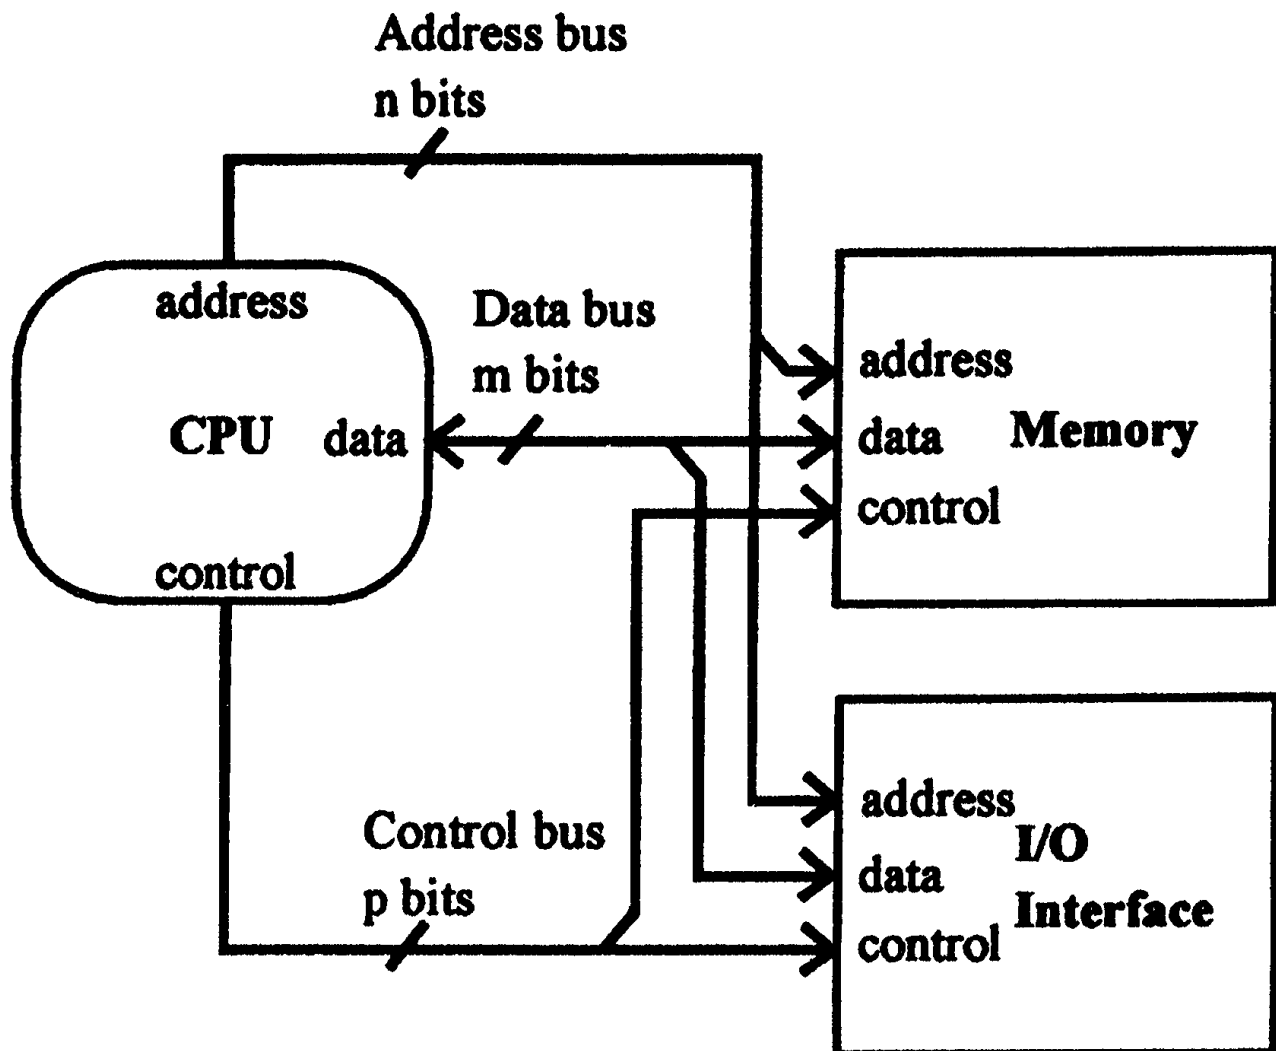

## 121.1 CPU, Memory, and I/O Interface Connections

---

Most applications that employ memory systems contain a processor or a central processing unit (CPU). The CPU carries out basic instructions that require moving data between internal registers and memory or between internal registers and an input/output (I/O) interface. Accomplishing this task usually requires a minimum of three types of buses, as illustrated in [Fig. 121.1](#). The CPU provides the locations or addresses where the data must come from during a memory read cycle or go to during a memory write cycle. The bus that conveys these locations to the memory and I/O interface is called the *address bus*. For an address bus of  $n$  bits there are  $2^n$  storage locations available. When the memory and I/O interface are both accessed via the same address lines and the same control lines, as illustrated in [Fig. 121.1](#), the interface is called *memory-mapped I/O*.

**Figure 121.1** CPU, memory, and I/O interface for a memory-mapped I/O architecture.

When the I/O interface is accessed as an address space separate from the memory address space, the address bus lines are interpreted as port addresses of the CPU, and separate control bus lines exist between the CPU and the I/O interface to direct data into or out of requested ports on the CPU via special I/O instructions. In the case of processors that have separate I/O and memory control signals, memory-mapped I/O can always be used by ignoring both the separate I/O control signals and the special I/O instructions and using only those processor instructions that relate to memory. Using only memory instructions to access both memory and I/O in the memory space of the CPU generally increases the flexibility of the overall system and also makes the system easier to program. A necessary requirement for the programmer of a memory-mapped I/O memory

system is a **memory map** that shows where all device locations exist.

Data, the contents of an address in a memory-mapped I/O system as illustrated in [Fig. 121.1](#), are read from the memory space on a CPU memory read cycle and written to the memory space on a CPU memory write cycle. An example of a memory read cycle and a memory write cycle timing diagram for a static RAM device will be presented later. Data travel on the **bidirectional data bus** in one direction at a time. The number of bits (data bus lines) associated with the data bus is dependent on the design of the CPU and ranges from a minimum of 4 bits for early microprocessors to as many as 32 bits for current microprocessors. Since heavy competition exists between major companies that manufacture microprocessors such as Motorola, Intel, IBM, Hewlett-Packard, and others, the push for 64 data bits and beyond for newer designs is underway. A larger number of data bits usually allows programs to be written more efficiently and also provides speed improvements in program execution since more bytes of data can be moved with fewer memory read or write cycles.

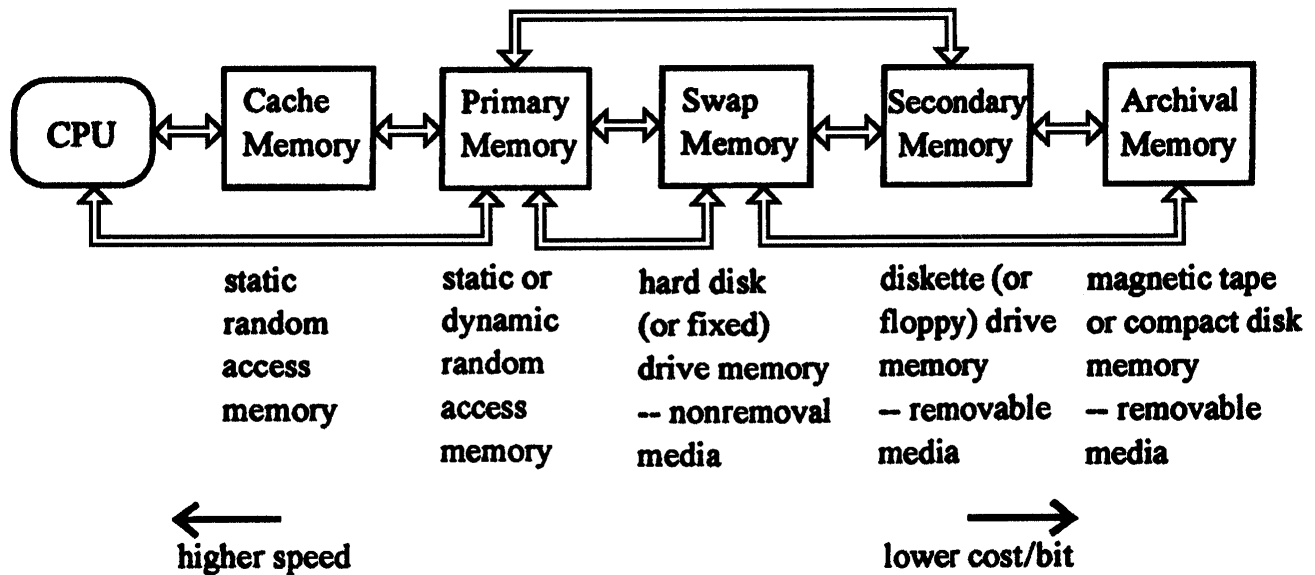

The control bus lines in a memory-mapped I/O system are routed to the memory and the I/O interface as illustrated in [Fig. 121.1](#). The I/O interface provides a data path for reading and writing data to the outside world that is beyond the system's existing memory system. The number of bits associated with the control bus is dependent on the architectural design of the complete system.

## 121.2 CPU Memory Systems Overview

---

A few of the various types of memory devices that can be connected to a CPU are illustrated in the memory systems connected to the CPU in [Fig. 121.2](#). The interconnections (all possible interconnections are not shown) must each have an address bus, a data bus, and a control bus, as discussed earlier. The **cache memory** block closest to the CPU usually contains static random access memory (RAM). Static RAM can also be used for primary memory; however, primary memory is usually designed with dynamic RAM, which operates at a slower speed and is less expensive than static RAM. Dynamic RAM must be constantly refreshed (about every 2 to 8 milliseconds) or stored data is lost. Only one transistor per storage location is required in a dynamic RAM, compared to several transistors per storage location in a static RAM, where refresh is not required. [Fig. 121.2](#) also provides a general indication of where other types of memory such as hard (or fixed) drive memory, diskette (or floppy) drive memory, and magnetic tape or compact disk memory fit into a memory system relative to speed and cost/bit. Both static and dynamic RAMs are volatile types of memory. When power is removed, the content of the data in all storage locations is lost. The memory devices used for swap memory, secondary memory, and archival memory shown in [Fig. 121.2](#) are all nonvolatile memory. When power is removed from nonvolatile memory, the content of the data in all storage locations is preserved. Swap, secondary, and archival memories are all slower and cost less per bit than static and dynamic memories. This chapter will concentrate only on the faster or higher-speed types of static and dynamic memories that are contained in blocks closer to the CPU.

**Figure 121.2** Overview of a CPU memory system.

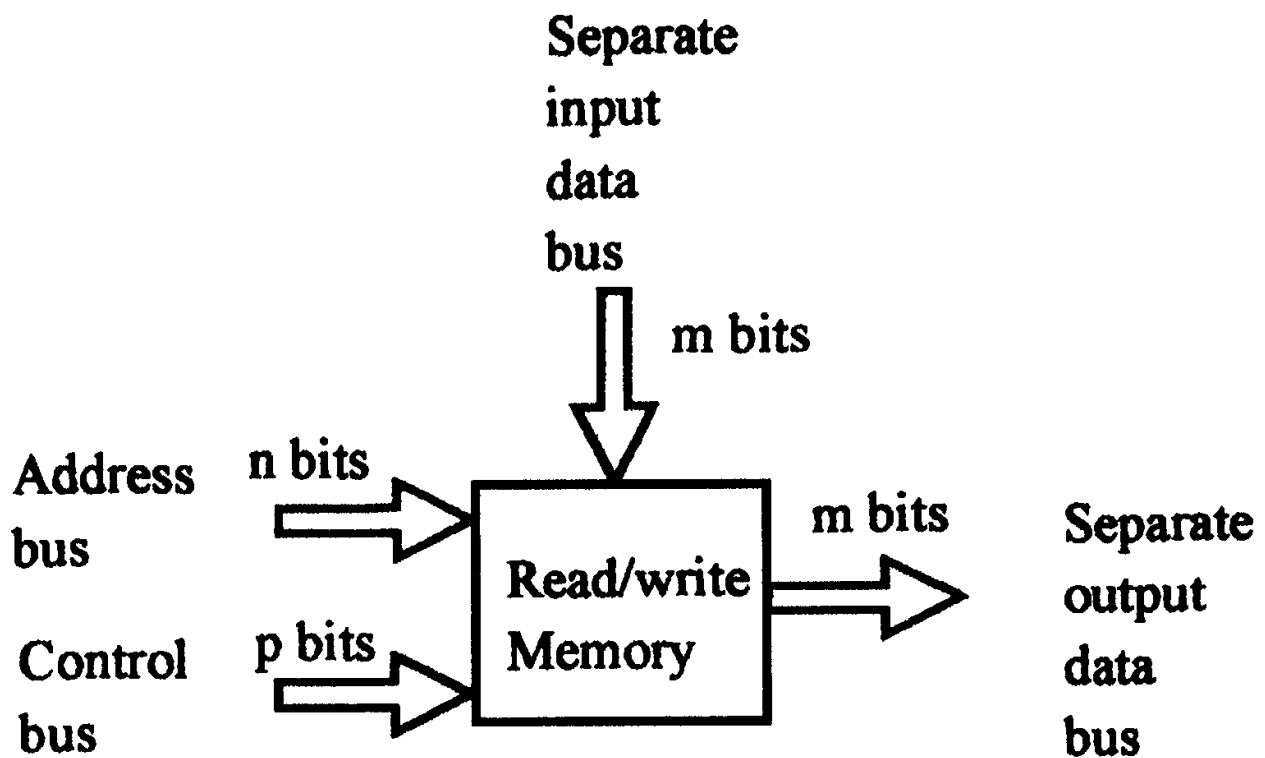

### 121.3 Common and Separate I/O Data Buses

Memory system blocks that consist of RAMs either utilize RAM devices that provide the input and output data lines via a common I/O data bus, as shown in Fig. 121.3(a), or utilize RAM devices that provide the input and output data lines on separate I/O data buses, as shown in Fig. 121.3(b). Memory systems that use memory blocks with a common I/O data bus have the advantage of costing less and taking up less printed circuit (PC) board space than those that use memory blocks with separate I/O data buses. Systems that use memory blocks with separate I/O data buses, however, have the advantage that **three-state buffers** can be added to the separate output data bus to eliminate **bus contention**, a problem in high-speed designs. Memory blocks that use either a common I/O bus or separate I/O buses are referred to as *single-port memory blocks* since data can only be accessed sequentially via a memory read cycle or a memory write cycle.

**Figure 121.3** (a) Memory block with a common I/O data bus; (b) memory block with separate I/O data buses.

(a)

(b)

Some memory system blocks utilize dual-port memory devices, which allow data to be written to an input port while other data are read at a separate output port at the same time. The video

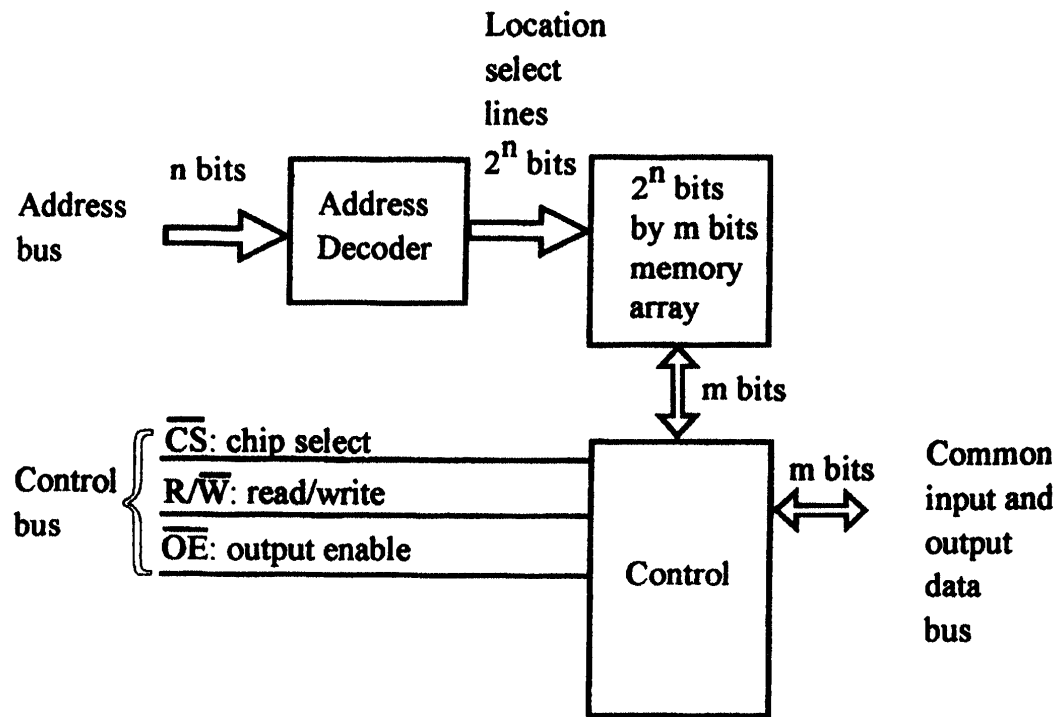

memory of fast computer workstations is often designed using dual-port static memory devices called *VRAMs* (video random access memory). VRAMs have two ways to access data simultaneously. Data can be accessed through a parallel RAM port and through a serial access memory (SAM) port. VRAMs are specialized devices that are specifically designed for use as display memories in **bit-mapped** graphic systems. Because of their multiple-access capability and functional flexibility, VRAM devices are usually the most expensive memory devices. It is also common in high-speed designs to have a dedicated video processor that issues video commands to speed up the video memory system.

## 121.4 Single-Port RAM Devices

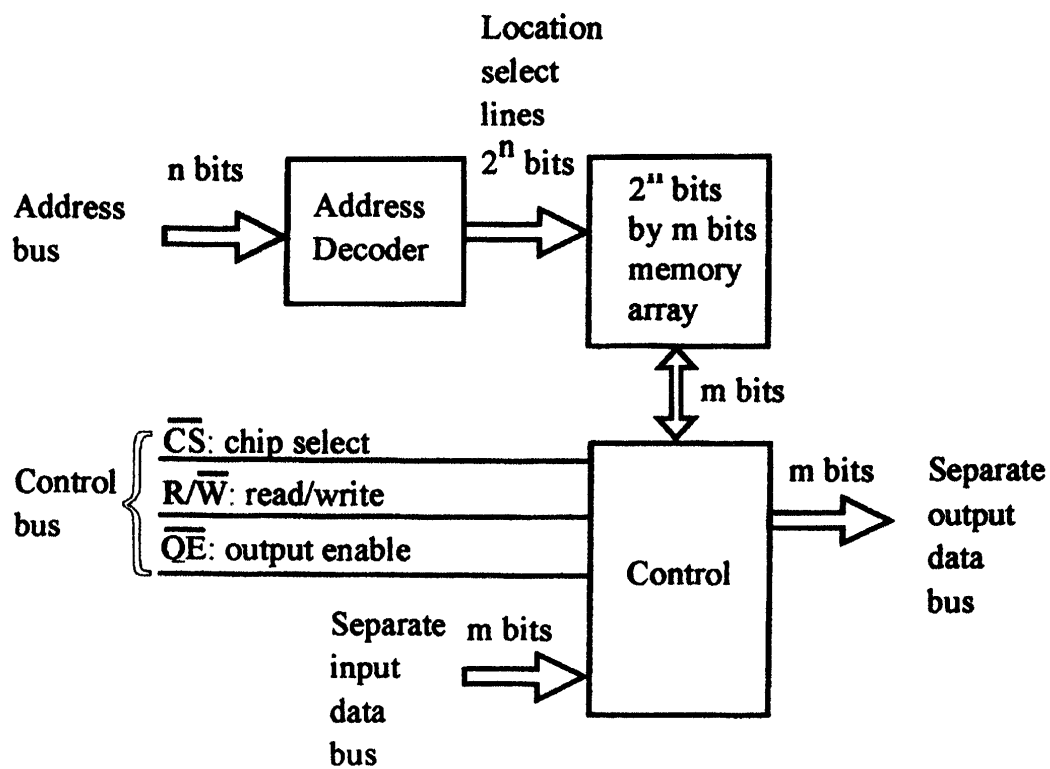

---

[Figure 121.4\(a\)](#) shows a block diagram of a static RAM device with a common I/O data bus. A block diagram of a static RAM device with separate I/O data buses is shown in [Figure 121.4\(b\)](#). In both types of RAM devices an address **decoder** is required to decode the  $n$  bits of address to determine one among the  $2^n$  location in the memory array where data is stored (written) or retrieved (read). Both types of RAM devices also can contain a chip select line, a read/write line, and an output enable line. Output data is read from a static RAM device via the data bus—that is, data out valid—when the chip select line ( $\overline{\text{CS}}$ ) is activated, the read/write control line ( $\text{R}/\overline{\text{W}}$ ) is activated for read, and output enable line ( $\overline{\text{OE}}$ ) is activated. These details are illustrated in the simplified timing diagram for the memory read cycle of a static RAM device as shown in [Fig. 121.5\(a\)](#). The  $\overline{\text{CS}}$  and  $\overline{\text{OE}}$  lines must both be pulled to a low-voltage logic state to be activated, since they both contain an overbar. The  $\text{R}/\overline{\text{W}}$  line must be pulled to a high-voltage logic state to be activated for read (no overbar over R). Abbreviations in the memory read cycle timing diagram are provided in [Table 121.1](#).

**Figure 121.4** (a) Static RAM device with a common I/O data bus; (b) static RAM device with separate I/O data buses.

**Table 121.1** Abbreviations for the Memory Read Cycle Timing Diagram

Abbreviation	Meaning
$t_{\text{MRC}}$	Memory read cycle time
$t_{\text{AA}}$	Address access time
$t_{\text{CSA}}$	Chip select access time
$t_{\text{OEOV}}$	Output enable to output valid time

Input data are written to a static RAM device via the data bus—that is, data in valid—when the chip select line ( $\overline{\text{CS}}$ ) is activated, the read/write line ( $\text{R}/\overline{\text{W}}$ ) is activated for write (pulled to a low-voltage logic state), and the output enable line ( $\overline{\text{OE}}$ ) is not activated (pulled to a high-voltage logic state). These details are illustrated in the simplified timing diagram for the memory write cycle of a static RAM device as shown in Fig. 121.5(b). Abbreviations in the memory write cycle timing diagram are provided in Table 121.2.

**Table 121.2** Abbreviations for the Memory Write Cycle Timing Diagram

Abbreviation	Meaning
$t_{\text{MWC}}$	Memory write cycle time
$t_{\text{CSEW}}$	Chip select to end of write time
$t_{\text{WPW}}$	Write pulse width time
$t_{\text{DSU}}$	Data setup time
$t_{\text{DH}}$	Data hold time

## 121.5 Additional Types of Memory Devices

Other types of memory devices that can be located close to the CPU are **read-only memories** (ROMs), programmable read-only memories (PROMs), ultraviolet read-only memories (UVPROMs), and electrically erasable read-only memories (EEPROMs). Notice that all of these devices are read-only devices in normal operation. Data can be stored permanently in the case of the ROM and PROM devices or can be restored up to about 100 times in the case of the UVPROM and EEPROM devices. ROMs are programmed at the factory by metallic masks and cannot be reprogrammed by the user. PROMs are generally programmed in the field using a **universal programmer** by blowing or leaving fuses intact; these are called *one-time-programmable* (OTP) devices. UVPROMs are programmed in the field using a universal programmer, and programmed data can be erased using an ultraviolet light source through a quartz window located on top of the chip. The time it takes to erase the device is about 15 to 45 minutes, depending on the intensity of the light source. Once erased, the UVPROM can be reprogrammed. EEPROMs, the latest technology, can be programmed using a universal programmer, and then they can be erased by electrical pulses in less than a minute.

When developing a ROM-based system, engineers often use EEPROMs, since the turnaround

time (the time for erasing and reprogramming) is very small to fix mistakes in programmed bit patterns. Engineers usually prefer to work with EEPROMs, until all the bugs are ironed out of a design, before committing to a ROM or PROM for the final design. ROMs are used in memory systems in computers to store information that needs to be accessed fast at power-up (such as the boot ROM that starts a PC system). EEPROMs are also used to store information that doesn't change very often, such as date, time, and configuration information.

ROMs and PROMs are permanently nonvolatile, whereas UVPROMs and EEPROMs are nonvolatile for approximately ten years after being programmed. ROMs are very inexpensive per part after an up-front high cost is paid to the manufacturer for making the mask. To program PROMs, UVPROMs, and EEPROMs requires the user to purchase a universal programmer. A high-end universal programmer can run a few thousand dollars, whereas a programmer that programs only certain types of PROMs can cost as little as four or five hundred dollars. PROMs are a little more expensive per part compared to ROMs and require that the user purchase a programmer. The next most expensive devices are UVPROMs and EEPROMs. To erase UVPROMs requires that the user purchase an ultraviolet light source in addition to a universal programmer. EEPROMs can be programmed and erased with a universal programmer.

Speeds of the various devices are generally given with the ROM as the fastest, the PROM the next fastest, and the UVPROM and EEPROM much slower. [Table 121.3](#) provides a quick reference concerning cost/part, speed, and so forth for ROM and PROM-type devices.

**Table 121.3** Summary of ROM and PROM-Type Devices

Device	Cost/Part	Speed	Nonvolatile	Programmer
ROM	Lowest <sup>1</sup>	Fastest	Permanently	N/A
PROM	Low	Fast	Permanently	Required
UVPROM	Higher	Slow	Semipermanently <sup>2</sup>	Required <sup>3</sup>
EEPROM	Higher	Slow	Semipermanently <sup>2</sup>	Required

<sup>1</sup>Up-front high cost must be paid to manufacturer for making the mask.

<sup>2</sup>Stores data for approximately ten years.

<sup>3</sup>An ultraviolet light source is also required to erase these devices.

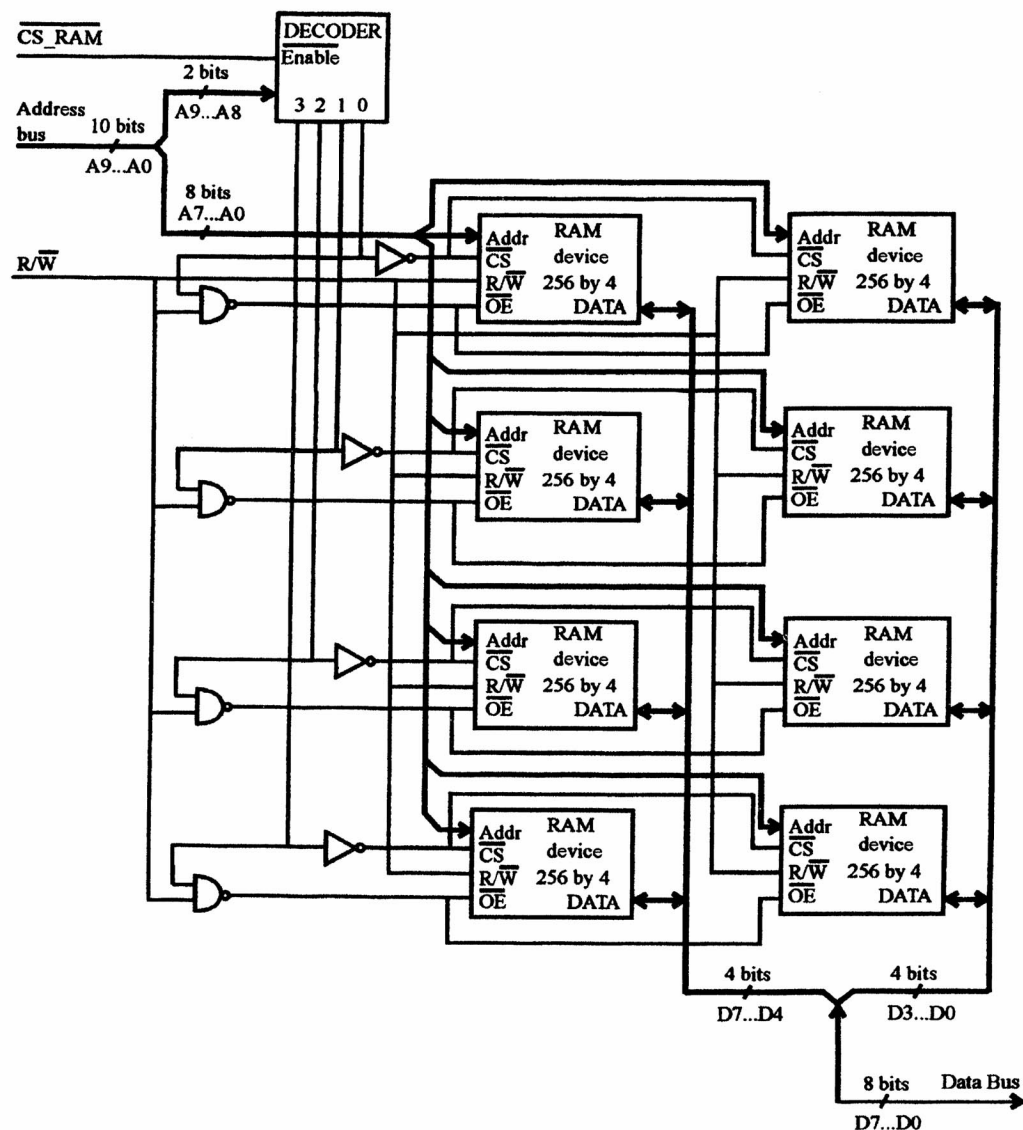

The timing diagram of interest for ROM users and the various PROM devices is the memory read cycle. The universal programmer provides the required memory write cycle for data storage for PROM devices. The memory read cycle is basically the same as the memory read cycle shown in [Fig. 121.5\(a\)](#). The  $R/\overline{W}$  signal for PROM devices is replaced by a program signal  $\overline{PGM}$  used to perform a memory write cycle. After the device is programmed the program signal  $\overline{PGM}$  is disabled or not activated (pulled to a high-voltage logic state) so that the device can only be read.

## 121.6 Design Examples

In general, a cache memory system and a primary memory system often require a larger number of address bits and data bits than single-chip RAM devices can supply. This condition requires that several RAM devices be connected together to form the design for a cache or primary memory system.

Figures 121.6 and 121.7 illustrate the designs for two separate memory system blocks using static RAM devices. The first memory system design shown in Fig. 121.6 addresses 1024 locations each 8 bits wide. The RAM devices used in this design have only 256 addresses with a common I/O 4-bit-wide data bus. This situation requires using a decoder to decode four ranges of addresses and two RAM devices simultaneously. The decoder requires 2 bits from the address bus to select the four different address ranges. Output enable for the two RAMs that are selected for a memory read cycle is obtained by ANDing the read/write signal with the decoder output that selects the required address range. Each RAM device requires 8 bits from the address bus to select among the 256 locations in its memory. Each RAM device only provides 4 bits of content at each memory location from 0 through 1023, thus requiring two RAM devices for each address.

**Figure 121.6** A  $1024 \times 8$ -bit static RAM memory system using  $256 \times 4$ -bit RAM devices with a common I/O data bus.

**Figure 121.7** A  $1024 \times 8$ -bit static RAM memory system using  $1024 \times 1$ -bit RAM devices with a common I/O data bus.

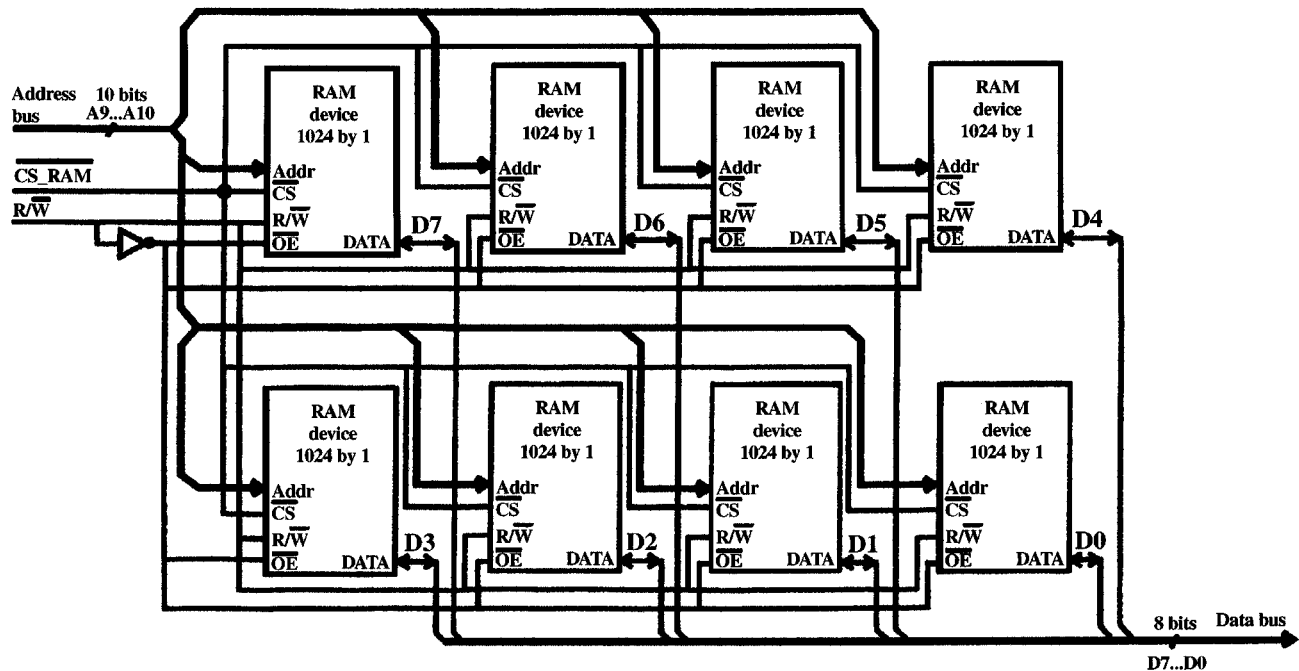

Fig. 121.7 illustrates a simpler memory system design that also addresses 1024 locations each 8 bits wide. In this design 1024-bit RAM devices organized as 1024 words of 1 bit are used. Eight RAM devices must be used to obtain 8 bits of data. The address bus supplies all the RAM devices simultaneously without the need for an external address decoder, thus simplifying the design. Expanding the memory to 8192 addresses using instances of this design requires an external address decoder for chip select logic.

The simplest design for a memory system that addresses 1024 locations each 8 bits wide uses a single 8192-bit RAM device organized as 1024 words of 8 bits. In this design the address bus and the data bus are connected directly to the RAM device. Cost, speed, printed circuit board space, and so forth are factors that need to be considered in choosing the best memory system design for a particular application.

## Defining Terms

**Bus contention:** A condition that occurs on a bus when two or more devices try to output opposite logic levels on the same bus line.

**Bidirectional data bus:** A bus that allows data to flow in either direction.

**Bit mapped:** A graphic display that has 1 bit (or more) of display memory for each possible pixel or dot on the display.

**Cache memory:** A high-speed memory that can contain small segments of a program that can be accessed faster than primary or bulk memory.

**Decoder:** A logic device that converts a binary code applied to  $i$ -input lines to  $2^i$  different output lines.

**Memory map:** A table that specifies the location or address of every memory or I/O device that a

CPU can access.

**Read-only memories:** Memories that are preprogrammed with data that can only be read under normal operation.

**Three-state buffers:** Buffers that have a third output state—that is, a state that is off, or high impedance, to effectively disconnect the outputs—in addition to the normal high- and low-voltage output states.

**Universal programmer:** A programming unit that can program various varieties of PROMs, erase EEPROMs, and program programmable logic array (PLA) and programmable array logic (PAL) devices.

Conclusions

### Michael D. Ciletti

*University of Colorado, Colorado Springs*

The size and complexity of very-large-scale integrated (VLSI) circuits preclude manual design. Designers of VLSI circuits typically use specialized software tools in a workstation-based interactive environment. This chapter reviews important aspects of computer-aided circuit design and simulation and presents an introduction of the use of hardware description languages for design description and design simulation/verification of digital circuits. Digital simulation of analog circuits is also introduced.

## 122.1 Design Flow

---

The design flow of a methodology for designing VLSI circuits consists of a structured sequence of steps, beginning with design entry and culminating in the generation of a database containing geometric detail of the masks that will be used to fabricate the design. These steps can be summarized as follows:

- Create a description of the design (design entry).
- Establish testability of the design.
- Verify the functionality of the design (simulation).
- Develop a gate-level realization of the design.
- Verify the timing specifications.
- Place and route the design.
- Evaluate the timing performance of the routed design.
- Produce database for mask generation.

Multiple passes may be necessary through all or part of this flow. Other design flows are

possible, and this design flow can be modified depending on the particular technology that is being used. For example, formal verification tools may be used in place of simulation, and a synthesis tool may be used to produce the gate-level realization.

Design specifications summarize the functional behavior and timing requirements of the design. They may include power and area constraints and additional information that is relevant to the task. Design entry is the step of encapsulating a representation of the design. This representation may be in a variety of forms, such as a schematic. The testability of the design is generally addressed early in the design process to allow detection of untestable circuitry. The addition of hardware might be required, such as the insertion of a scan path into a sequential circuit. If the design is already in a form that is bound to a particular hardware realization, the timing specifications of the design can be verified by a static analysis of the paths in the circuit or by simulation. The place and route step may involve a full-custom layout of high-performance circuitry or semicustom layout of standard cells or gate arrays (field- or mask-programmable). In either case the physical layout must be re-verified to confirm that the implementation not only realizes the desired functional behavior but also meets the externally imposed timing constraints of the design and the timing constraints imposed by storage elements (flip-flops) used in the design itself.

This chapter will focus on two steps in the overall design flow: design entry and simulation. *Design entry* is the process by which a description of the design is encapsulated in a database that serves all subsequent steps in the design flow. A designer may perform this step by drawing paper-and-pencil schematics, by using a schematic entry tool, by using a hardware description language, or by selecting and interconnecting high-level macros representing hardware functional components. The two modes of entry that are of interest here are schematics and hardware description languages.

## 122.2 Schematic Entry

---

A schematic entry tool allows the designer to select and interconnect schematic symbols (icons) representing hardware components. Connections are made by graphical wires and buses representing physical signals in a circuit. The schematic entry software creates and manages a database containing the topological and incidental information created at the schematic, and this software also creates interfaces that will allow other design flow steps to access the database. For example, the information in the topological description can be used by a simulation tool to establish a database for simulating the design represented by the schematic. [Figure 122.1](#) shows a simple schematic of a half-adder logic circuit generated by a schematic entry tool. Schematic entry tools have become popular during the past ten years as the computational power of desktop interactive computer graphics has become capable of supporting complex design tasks at reasonable speeds.

**Figure 122.1** Schematic of a half-adder.

## 122.3 Hardware Description Languages

Schematic entry focuses attention on structural detail of the design and is an appealing mode of entry because engineers are familiar with this traditional visual format. The objects in a schematic representation are high-level blocks and/or gate-level circuits. Structural modeling consists of interconnecting these objects to create a structure that has a desired behavior. A **hardware description language** (HDL) is a computer-based programming language having special constructs and semantics to model, represent, and simulate the functional behavior and timing of digital hardware. An HDL supports structural, behavioral, and mixed descriptions of a design. Unlike schematic-based design, behavioral modeling uses HDL-based constructs and/or procedural code to describe the desired behavior without explicit binding to hardware.

Recently developed HDLs, such as Verilog [Thomas, 1991; Sternheim *et al.*, 1993] and VHDL [Navabi, 1993], provide an alternative mode of design entry by allowing the designer to create a text description of the circuit without relying on a schematic. The text itself can be generated on an ordinary terminal and is very portable. Some examples of Verilog descriptions are given as follows:

```
module Flip_flop(q,data_in,clk,rst);
input data_in,clk,rst;
output q;
always @ (posedge clk)
begin
    if(rst ==1) q = 0;
    else q = data_in;
end
endmodule
```

The basic element of design encapsulation in Verilog is a "module." The code in the flip-flop module declared here updates the value of the output  $q$  whenever the clock has a positive (rising)

edge, provided that the reset line is not asserted.

Verilog also supports a *register transfer logic* (RTL) description with several built-in language operators. The use of RTL is illustrated as follows:

```
module bitwise_or (y,A,B); // RTL model
  input [7:0] A,B;
  output [7:0] y;
  assign y = A | B;
endmodule
```

This bitwise-or module uses the built-in operator "|" to implement the "bitwise or" of the data words. The "assign" keyword effects an event-scheduling rule that updates the value of y whenever A or B changes. An event is said to occur whenever a signal changes value. Note that the Verilog language operators used in RTL design (such as the "|" operator) have implied logic. Their use simplifies the task of writing Verilog descriptions of behavior.

The text that follows declares a model of a half-adder circuit (see [Fig. 122.1](#)) as a structural connection of CMOS standard cells xorf201, nanf201, and invf101.

```
module Add_half_structural (S,C,A,B);
  output S,C;
  input A, B;
  wire C_bar;
  xorf201 G1 (S,A,B);
  nanf201 G2 (C_bar,A,B);
  invf101 G3 (C,C_bar);
endmodule
```

The description declares the name of the module, the input and output ports of the module, a wire that is used internally for a connection, and a list of instantiations of the library cells/ modules. The arguments of the instantiated modules correspond directly to the physical wires that would interconnect their hardware counterparts.

HDLs allow a design to be represented abstractly, or behaviorally, without any binding to particular hardware elements. The fragments of text that follow show two alternative descriptions of a half-adder. The first fragment uses built-in language operators in an RTL style to implement a 4-bit-slice adder. (Here { } denotes a concatenation operator, which in this example creates a 5-bit wide data path from operations on the 4-bit buses and the c\_in bit.) Verilog features built-in data types and operators that make this style of modeling very easy to implement.

```
module adder_4_RTL (sum, c_out, a,b,c_in);
  output [3:0] sum;
  output c_out;
  input [3:0] a,b;
  assign {c_out,sum} = a + b + c_in
```

**endmodule**

The next description is a fragment of procedural code that implements a behavioral model of a carry look-ahead adder [[Sternheim \*et al.\*, 1993](#)].

```
module add_4_CLA (sum, c_out, a,b,c_in);
  output [3:0] sum;
  output c_out;
  input [3:0] a,b;
  reg [3:0] carrychain;
  wire [3:0] gen = a & b; // bitwise and (carry generate);
  wire [3:0] prop = a ^ b; // bitwise xor (carry propagate);
  always @ a or b or c_in // event "or"
    begin: carry_generation_block
      integer i;
      carrychain[0] = gen[0] + (prop[0] & c_in);
      for(i = 1; i <= 3; i = i + 1)
        begin
          #0 carrychain[i] = gen[i] + (prop[i] & carrychain[i-1]);
        end
      end
    end
  wire [4:0] shiftedcarry = {carrychain, c_in};
  wire [3:0] sum = prop ^ shiftedcarry;
  wire c_out = shiftedcarry[4];
endmodule
```

A module that is modeled by procedural code has no predetermined binding to hardware. Admittedly, built-in language operators, such as  $+$ , have an implicit binding to hardware, but this binding can be deferred to later in the design flow. This allows the designer to focus on functionality rather than implementation. Both Verilog and VHDL support algorithmic description of behavior through the mechanism of procedural code, which executes serially.

CAD/CAE software vendors provide development and debug environments supporting the designer of HDL-based descriptions of a design. These may include text editors and interactive debuggers.

VHDL, the VHSIC (very-high-speed integrated circuit) HDL, was created under the auspices of the Department of Defense and is now an IEEE standard (IEEE 1076-1987). Verilog was created as a proprietary language, became very popular as a widely used industry tool, and then was placed in the public domain in 1990. It is presently in the final stages of becoming an IEEE standard [IEEE 1364]. Both languages support high-level abstract descriptions of digital systems; Verilog also has built-in gate-level and switch-level functional primitives.

## Simulation of HDL-Modeled Circuits

Simulators are available for simulating the behavior of digital circuits described by either Verilog or VHDL. These simulators provide a fast, efficient, visual representation of the behavior of a digital circuit. Logic simulation is usually done on event-driven simulators, which exploit the topological latency that is characteristic of digital circuits.

Simulation of a circuit that has been modeled by an HDL requires that a *design unit test bench* (DUTB) be developed to apply stimulus to the unit under test (UUT). A test bench for a nand latch (cross-coupled nand primitives) module is given in the following:

```
module DUTB_Nand_latch;
  reg preset, clear;
  wire q, qbar;
  Nand_latch(q, qbar, preset, clear); // Instantiate the UUT
  initial
  begin // Create stimulus to UUT
    $monitor ($time, "preset = %b   clear = %b   q = %b   qbar = %b", preset, clear, q, qbar);
    #10  preset = 0;      clear = 1;
    #10  preset = 1;
    #10  clear = 0;
    #10  clear = 1;
    #10  preset = 0;
    #10  $finish;
  end
endmodule
```

This DUTB applies stimulus to the inputs of the nand latch at intervals of 10 simulation units. The \$monitor system task effects a listing of the output shown in the following table. (Note: In this example the nand latch has a unit delay between an event on one of its inputs and the resulting event on its output. The value "x" denotes an unknown logic value.)

0	preset = x	clear = x	q = x	qbar = x
10	preset = 0	clear = 1	q = x	qbar = x
11	preset = 0	clear = 1	q = 1	qbar = x
12	preset = 0	clear = 1	q = 1	qbar = 0
20	preset = 1	clear = 1	q = 1	qbar = 0
30	preset = 1	clear = 0	q = 1	qbar = 0
31	preset = 1	clear = 0	q = 1	qbar = 1
32	preset = 1	clear = 0	q = 0	qbar = 1
40	preset = 1	clear = 1	q = 0	qbar = 1

In addition to providing the standard output listing, a variety of tools offered by vendors of CAD/CAE software provide graphical output of simulation results.

## 122.4 Trade-offs between HDLs and Schematic Entry

---

There are some trade-offs that can be noted between schematic entry and HDL-based design entry. From the standpoint of support, a schematic-driven paradigm requires a color-graphic workstation (or suitably enhanced PC); language-based entry is easily done at a terminal, and an engineer can work at a remote site without requiring local support.

Editing a design that is described by an HDL can be shorter and simpler than the task of editing a design described by schematics. The task of removing, relocating, and rebinding schematic objects can be time consuming if the schematic itself is very dense and/or complex.

HDLs support a higher level of abstraction than can be described by schematics. A schematic can certainly have a symbol of any functional unit, but this must eventually be represented in terms of lower-level detail that is ultimately expressed as a structural description. An HDL can embody a behavior with no reference whatsoever to structural detail.

Schematic entry focuses the designer's attention on structural detail; a designer using an HDL can focus on structural detail, functional behavior, or a mixture of the two. HDLs support a top-down design methodology (TDM), in which a design is hierarchically decomposed in simpler, hierarchically organized functional units. In Verilog the nested instantiation of modules is the mechanism by which hierarchical decomposition of a design is accomplished. The actual partitioning may be done according to functionality, but no restriction is implied by the language itself. In a TDM the design is created in a top-down fashion; it is verified in a bottom-up sequence, beginning with verification of the lowest levels of the hierarchy and proceeding to verification of the integrated design. The hierarchical decomposition of a 4-bit adder is given below. The top-level module contains four instantiations of full adders, which themselves contain instantiations of half adders and glue logic; the half adders are defined in terms of modules declared in the cell library.

```
module Add_rca_4 (Sum,C_out,A,B,C_in);
  output Sum,C_out;
  input A,B,C_in;
  wire [3:0] Sum,A,B;
  wire C_out,C_in4,C_in3,C_in2,C_in;
  Add_full G1 (Sum[3],C_out,A[3],B[3],C_in4);
  Add_full G2 (Sum[2],C_in4,A[2],B[2],C_in3);
  Add_full G3 (Sum[1],C_in3,A[1],B[1],C_in2);
  Add_full G4 (Sum[0],C_in2,A[0],B[0],C_in);
endmodule

module Add_full(S,C_out,A,B,C_in);
  output S,C_out;
  input A,B,C_in;
  wire S1,C1,C2,C_out_bar;
  Add_half G1 (S1,C1,A,B);
  Add_half G2 (S,C2,S1,C_in);
  norf201 G3 (C_out_bar,C1,C2);
```

```

    invf101 G4 (C_out,C_out_bar);
endmodule
module Add_half(S,C,A,B);
    output S,C;
    input A,B;
    wire C_bar;
    xorf201 G1 (S,A,B);
    nanf201 G2 (C_bar,A,B);
    invf101 G3 (C,C_bar);
endmodule

```

HDLs support rapid prototyping of a design by allowing a designer to focus attention on the functionality of a design rather than its physical/structural implementation. This factor dramatically shortens the time required to create and verify a design. Shortening the design cycle allows more changes to be made in less time, thereby increasing the likelihood that a design error will be found before its effects became widespread. The ease of considering design alternatives in an HDL context can stimulate and encourage consideration of design alternatives.

Tools now exist that automatically create a schematic from the HDL description, resulting in another attractive feature of HDLs. Thus a schematic is actually a by-product of the HDL design flow. This approach to design greatly shortens the design cycle. The designer must, however, conform to a style that ensures synthesizable results.

## 122.5 HDLs and Synthesis

---

The Verilog HDL is a key element in modern design flows that incorporate logic synthesis tools. These tools begin with a behavioral description of the functionality of the design and then create an optimal logic-level description. This description can then be mapped onto a particular technology to meet timing and area constraints.

## 122.6 Transistor-Level Design and Simulation

---

Digital simulation of a circuit's analog waveforms has been popular for decades, especially since the creation of SPICE [Tuinenga, 1988]. This tool uses mathematical descriptions of active and passive circuit elements such as transistors and other components. These models provide a closer approximation of the actual analog waveforms that will be generated in the physical circuit. This additional resolution/detail comes at the price of greatly increased simulation times and memory requirements. The underlying models of the devices themselves are typically more complex than those used to support digital simulation.

Transistor-level simulators rely on numerical integration techniques, such as the Newton-Raphson method, and exploit the sparsity of the underlying matrices that result from applying Kirchhoff's laws to the possibly nonlinear circuit. In practice these simulators are used effectively to verify the timing performance of critical subcircuits, such as a detailed transient analysis of a memory design, rather than that of an entire system. The text that follows shows a

fragment of SPICE code that describes the simple double-pole low-pass filter section shown in [Fig. 122.2](#).

```
Vgen 1 0 AC 1
R1 1 2 500
L1 2 3 10 mH
C1 3 0 1 uF
.AC DEC 100 100 HZ 10 KHz
.PROBE
.END
```

The first line of the code specifies an independent AC voltage source connected between node 1 and the reference node 0. This source has a level of 1. Each of the next three lines begins with a label specifying the type and identity index of a component, the indices of a pair of nodes to which the component is connected, and the value of the component in default or specified physical units. Then the AC source is specified to have a logarithmic sweep in decades from 100 Hz to 10 kHz in steps of 100 Hz. The .PROBE command is a PSpice [Tuinenga, 1988] statement that creates a database from simulation of the circuit. This database can then be examined to view various features of the response of the circuit. In this example a Bode plot of the filter response will be created.

**Figure 122.2** Low-pass filter section.

The following code describes a transient analysis of the same circuit that was considered earlier:

```
Vgen 1 0 pw1(0,0.1m,1 5.1m, 0)
R1 1 2 500
L1 2 3 10 mH
C1 3 0 1 uF
.TRAN 1m 10m
.PROBE
.END
```

Here, the source is programmed as a piecewise linear waveform describing a pulse that has a 0.1 ms transition from 0 to 1 and lasts for 5 ms. The .TRAN statement specifies that the transient waveform should be plotted in steps of 1 ms beginning at time = 0 (default) and ending at time 10 ms.

SPICE-like software typically supports the following analysis tasks:

- Transient analysis
- Steady state analysis
- Temperature analysis
- Frequency response
- Small-signal transfer function
- Sensitivity analysis
- Thevenin equivalent circuit
- Monte Carlo analysis
- Group delay analysis

Many variations of SPICE are available from CAD/CAE software vendors.

## Conclusions

Powerful software tools exist to support circuits designers. These tools offer substantial gains in productivity in the overall engineering effort.

## Defining Terms

**Hardware description language:** A computer-based programming language having special constructs and semantics to model, represent, and simulate the functional behavior and timing of digital hardware.

**SPICE:** A software language used to create digital simulations of analog circuits. The acronym stands for *simulation program with integrated circuit emphasis*. SPICE was developed at the University of California, Berkeley; it is a public domain tool.

**Verilog:** An HDL that is widely used in industry to describe and simulate digital systems. It is in the final stages of becoming an IEEE standard. It supports hierarchical decomposition, switch- and gate-level structural modeling, RTL/data flow modeling, and procedural modeling, including concurrent activity flows. It has built-in data types.

**VHDL:** An HDL that was developed under the support of the Department of Defense and is an IEEE standard. It supports hierarchical decomposition, data flow, and procedural modeling. It has user-defined data types.

*Santa Clara University*

There are several types of equipment that are used to verify and test digital circuits. The type depends on the design itself and the stage at which it is tested. Logic analyzers are "testers" that combine general purpose characteristics with ease of use. They allow engineers to measure digital signals in a fashion similar to oscilloscopes; the  $x$  axis represents the time and the  $y$  axis, the voltage sampled. Logic analyzers evolved from oscilloscopes in the early 1970s; in a later section, we will distinguish between the use of analyzers and the use of oscilloscopes. Logic analyzers come in various sizes and with a variety of features. They may be used to measure one signal or several signals simultaneously. To explain how they work, it is important to present some basic concepts. The following sections will first describe the nature of digital signals, then explain what an analyzer is and how it is used in testing digital circuits.

## **123.1 Nature of Digital Signals**

---

Digital signals are waveforms that assume either a low-limit  $V_L$  (logic state 0) or a high-limit  $V_H$  (logic state 1). The exact values of these two limits are technology-dependent. An example of a digital signal is shown in [Fig. 123.1](#). In its ideal form it is a square wave but not necessarily periodic. Due to delays within the devices and interconnect, the rise and fall of the signal are not instantaneous. For a typical pulse, the rate of rise (or fall) is usually called the *slew rate*. The higher the slew rate is, the faster the operation of the circuit. Proper operation of digital circuits is

dependent on the arrival of the waveform at various nodes of the circuit at the appropriate time.

**Figure 123.1** Digital signals: ideal versus actual.

Verifying the correctness of a digital signal involves state and timing measurement. The state is the value of the signal at any time, either state 0 or state 1. If the signal is above a certain reference  $V$ , it is logic 1; if it is below this reference, it is logic 0. This is illustrated in Fig. 123.2. For the logic analyzer to reconstruct the waveform examined, measurements need to be taken at various time instants. The collection of such measurements forms a sample that is interpreted by the analyzer, displayed, and possibly stored for further analysis. This process is called **sampling** and is done at various sampling points. In a sense, sampling is like taking snapshots of the waveform. Sampling also serves in time analysis. In the remainder of this chapter we will learn how the analyzer works in both state and timing capacities, but first let us understand sampling and its importance in logic analyzer operations.

**Figure 123.2** Sampling a waveform and reconstructing it.

## 123.2 Signal Sampling

Figure 123.2 shows a digital waveform, the sampling points, and the possible displays of the analyzer. The collected sample is stored in a buffer and used to reconstruct the waveform as illustrated in the figure. Sampling is a very important process in the operation of logic analyzers. If the signal is changing at 1MHz, then it alternates between high and low every  $T = 0.5 \mu\text{s}$ . To accurately reconstruct this signal, we must sample it at least every  $0.5 \mu\text{s}$ . That is, the sampling rate has to be at least double that of the rate at which the signal is changing. The size of the sample is limited to the size of the buffer. A normal buffer size contains 1K (1024) sample points. For a sampling rate of 2 megasamples per second, the buffer will hold data for  $512 \mu\text{s}$ .

The logic analyzer is always sampling. When the user triggers it for display, it will show the waveform before and after the **trigger**. The triggering is done in one of two modes: level and edge. Both modes will be described later in conjunction with timing and state analysis.

## 123.3 Timing Analysis

Time analysis is very crucial to the performance of digital circuits. For proper functioning of a circuit the signal must arrive at various nodes at precise times within a tolerance. Whenever the state changes from 0 to 1 or vice versa for two consecutive sampling points, the analyzer recognizes that the signal went through a transition during the period between these two points. This transition is then interpreted as having occurred at the second sampling instant, as illustrated in Fig. 123.3. However, there is uncertainty about where the transition has really occurred. The first transition, 0 to 1, occurred just after sample point 1, but it is only recorded at sample point 2. Similarly, the transition from 1 to 0 occurred right before sample point 4, where it was recorded. Since  $\delta_1 > \delta_2$ , the recording at sample point 4 is more accurate than at point 2.

**Figure 123.3** Sampling accuracy.

The interval of time between two sample points, the *sampling period*, denoted in the figure by  $\Delta$ , is the maximum uncertainty in timing measurement. Thus the shorter the sampling period is, the higher is the resolution. This period has to be smaller than any pulse width measured by the logic analyzer. Otherwise, the pulse may not be recorded at all, or it might be recorded as having the sampling period as its width. Both cases are shown in Fig. 123.3 for the pulses b and c.

Increasing the sampling rate for a certain **buffer depth** results in a narrower window. Alternately, keeping the same window requires a *deeper buffer*. It is possible to reduce the buffer depth by storing only the sample points following transitions, as illustrated in Fig. 123.4. Of all fifteen sample points, only five are stored. Since the analyzer is sampling digital data, only the transition is relevant. This scheme is called **transitional sampling**.

**Figure 123.4** Transitional sampling.

Monitored Signal

Logic analyzers are not intended as parametric measuring instruments. They are used to determine timing relationship. We will consider such use of logic analyzers later in the chapter. Next, we will examine the second type of analysis—state analysis.

## 123.4 State Analysis

In an earlier section we used the term *state* to refer to the value of the signal on a certain node of the circuit. However, the advantage of the logic analyzer is in providing a means to determine the signal value on several nodes of the circuit. The **state** of a certain circuit is the collection of signals (0 or 1) on some lines of the circuit. The set of nodes may be the lines of a bus or the output of a counter.

The operation of the majority of digital circuits is synchronized by one signal called the *clock*. As the clock transitions from 0 to 1 (positive edge) or from 1 to 0 (negative edge), the signals propagate through the circuit and stabilize before the next clock edge. The clock is usually periodic, with duty cycle less than 50%. Thus, to observe the state of a circuit, it is convenient to use the system clock as the reference. The logic analyzer will capture the state of the circuit as the edge of the clock occurs. This mode of operation is called *edge triggering*.

Consider the example shown in Fig. 123.5 for a 4-bit binary counter. The count is read on  $Q_1 Q_2 Q_3 Q_4$ . These nodes form the state of the counter. Displayed also are the system clock and an asynchronous clear that returns the counter to 0 whenever asserted.

**Figure 123.5** Edge- and level trigger.

It is also possible to request the data when the circuit is in a certain state, say 1010. In such a case, *level trigger*—specification of a level to start the capture of the data—is used. Every signal of the state—here, four—is measured by a channel. Besides observing the display, users may need to examine the values. For this 4-bit counter, using binary notations is manageable. It would be difficult, though, to use this representation for a 32-bit bus; instead, hexadecimal numbers would be used.

Now that we are familiar with the operation of logic analyzers, we will briefly describe its components.

## 123.5 Components of a Logic Analyzer

A logic analyzer consists of the functional blocks shown in Fig. 123.6: a data acquisition block; a data analyzer block that is part of the CPU; a memory; a display; and several ports that allow connection to a PC, printer, and other instruments. The interface between the data acquisition and the unit under test (UUT) is called the *pod*. The CPU is microprocessor based, but the data acquisition is usually an application-specific integrated circuit (ASIC). As IC technology advances the size and the cost of analyzers decreases. Portable analyzers may be used for on-site testing.

**Figure 123.6** Components of a logic analyzer.

## 123.6 Advanced Features of Logic Analyzers

---

- Modern logic analyzers interface with PCs for postprocessing of the data. This data can be edited by the PC editor and also exported to a spreadsheet for further analysis.
- A logic analyzer can be bundled with a digitizing oscilloscope and thus work as three instruments in one—for timing analysis, state analysis, and parametric measurements. For intermodule analysis the data is viewed simultaneously by the three modules.
- Utilities are also available to translate state analyses files into test pattern generation files to minimize time-consuming data entries.

## 123.7 Applications of Logic Analyzers

---

Although logic analyzers bear resemblance to digitizing oscilloscopes, their applications are not identical. Scopes are usually used when high fidelity is necessary in replicating every variation, no matter how small, in the waveform, and when timing between two or more events needs to be measured with high accuracy. The scope is suitable for parametric measurements.

Logic analyzers, on the other hand, are not as accurate in measuring time and voltages. They do have, however, many other equally important assets that have helped advance the state of the art of digital design. In the digital domain the signal is either high or low; the ripples in the waveform profile are of no consequence to proper operation of the product. It is more important to show that the actual waveforms of the circuit are as the designer expected. Logic analyzers are also useful in determining timing relationships among data lines of a bus or any group of various nodes in the UUT. This fact was illustrated earlier with the example of the 4-bit counter.

Logic analyzers are used for design verification during the development and integration cycle of digital systems. They are also useful in production testing. The product itself may be a microprocessor-based circuit or an ASIC.

The effectiveness of the logic analyzer depends on its characteristics. For example, analyzers with only a few channels are not efficient for testing a large circuit. If the maximum speed of an analyzer is under that of the UUT, it is useless for such a UUT. Also, logic analyzers must have sufficient capacity for data acquisition.

## A Paradox

Logic analyzers are built of digital ICs that need to function at a speed higher than that of the UUT. They are used to develop tomorrow's ICs that are supposed to have higher performance than the products of today. To build a design tool for a customer who uses state-of-the-art devices, one must have the next-generation devices to make the tool effective for the present generation. And that is physically impossible.

## Defining Terms

**Buffer depth:** The size of the acquisition memory.

**Sampling:** The process of recording signals at specific moments, called *sample points*, over a period of time.

**State:** The logic values of a collection of nodes in the circuit that depend on the transition in the clock of the circuit.

**Transitional sampling:** Storing samples indicating change of level.

**Trigger:** Signal entered by the user to flag the acquisition.

TELECOMMUNICATIONS IS ONE OF THE WORLD'S most influential and most rapidly evolving technologies. New and emerging telecommunications services hold the promise of dramatically changing the speed, extent, and connectivity of communications among humans and of information sharing among computers. Such services include wireless personal communications connected globally through satellite networks, and optical fiber communication networks that permit the transmission of data at enormous rates.

Telecommunications technology is based largely on the two closely allied engineering fields of communications and signal processing. Fundamentally, communications deals with the transmission of information through physical channels by electronic means, while signal processing deals with methods of transforming or combining electronic signals into more useful

forms. Thus, the principles of communications provide functional descriptions of ways in which information can be incorporated in and extracted from physical signals to maximize communications capacity, and the principles of signal processing provide efficient transforms, algorithms, and filters to perform these functions.

This section provides information on the underlying principles and some major applications of the two fields of communications and signal processing. The contributions to this section can be grouped into three categories: signal processing principles, communications principles, and communications applications. The first two contributions (**Chapters 124 and 125**) cover the three fundamental areas of signal processing noted above, namely, transforms, algorithms, and filter design. The techniques described in these chapters provide the means by which signals can be treated to perform many of the functions required by communication systems. The next three contributions (**Chapters 126–128**) describe the basic principles underlying three major functional areas of electronic communications: modulation and detection, coding, and networking. Modulation refers to the impression of messages onto signals that are suitable for transmission through a physical communication channel, and detection is the reverse process; coding deals with the treatment of the messages themselves to counteract errors incurred in the communications channel; and networking deals with the issues arising when multiple communicating partners are connected through a shared medium. The final three contributions (**Chapters 129–131**) cover the basics of the three most rapidly developing areas of commercial communications: satellite communications, mobile radio communications, and optical communications.

## 124.1 Fourier Transforms

---

One method used extensively calls for replacing the continuous Fourier transform by an equivalent *discrete Fourier transform* (DFT) and then evaluating the DFT using the discrete data. But evaluating a DFT with 512 samples (a small number in most cases) requires more than  $1.5 \cdot 10^6$  mathematical operations. It was the development of the **fast Fourier transform (FFT)**, a computational technique that reduces the number of mathematical operations in the evaluation of the DFT to  $N \log_2(N)$  (approximately  $2.5 \cdot 10^4$  operations for the 512-point case mentioned above), that made DFT an extremely useful tool in almost all fields of science and engineering.

A data sequence is available only within a finite time window from  $n = 0$  to  $n = N - 1$ . The transform is discretized for  $N$  values by taking samples at the frequencies  $2\pi/NT$ , where  $T$  is the time interval between sample points. Hence, we define the DFT of a sequence of  $N$  samples for  $0 \leq k \leq N - 1$  by the relation

$$\begin{aligned}
 F(k-\Omega) &\doteq \mathcal{F}_d\{f(nT)\} = T \sum_{n=0}^{N-1} f(nT) e^{-j2\pi nkT/NT} \\
 &= T \sum_{n=0}^{N-1} f(nT) e^{-j\Omega Tnk}, \\
 n &= 0, 1, \dots, N-1 \quad (124.1)
 \end{aligned}$$

where

$$\begin{aligned}
 N &= \text{number of sample values} \\
 T &= \text{sampling time interval} \\
 (N-1)T &= \text{signal length} \\
 f(nT) &= \text{sampled form of } f(t) \text{ at points } nT \\
 \Omega &= \frac{2\pi}{T} \frac{1}{N} = \frac{\omega_s}{N} = \text{the frequency sampling interval} \\
 e^{-j\Omega T} &= N\text{th principal root of unity} \\
 j &= \sqrt{-1}
 \end{aligned}$$

The inverse IDFT is given by

$$\begin{aligned}
 f(nT) &\doteq \mathcal{F}_d^{-1}\{F(k-\Omega)\} = \frac{1}{NT} \sum_{k=0}^{N-1} F(k-\Omega) e^{j2\pi nkT/NT} \\
 &= \frac{1}{NT} \sum_{k=0}^{N-1} F(k-\Omega) e^{j\Omega Tnk} \quad (124.2)
 \end{aligned}$$

The sequence  $f(nT)$  can be viewed as representing  $N$  consecutive samples  $f(n)$  of the continuous signal, whereas the sequence  $F(k-\Omega)$  can be considered as representing  $N$  consecutive samples  $F(k)$  in the frequency domain. Therefore, Eqs. (124.1) and (124.2) take the compact form

$$\begin{aligned}
 F(k) &\doteq \mathcal{F}_d\{f(n)\} \\
 &= \sum_{n=0}^{N-1} f(n) e^{-j2\pi nk/N} = \sum_{n=0}^{N-1} f(n) W_N^{nk}, \\
 k &= 0, \dots, N-1 \quad (124.3)
 \end{aligned}$$

$$\begin{aligned}
 f(n) &\doteq \mathcal{F}_d^{-1}\{F(k)\} \\
 &= \frac{1}{N} \sum_{k=0}^{N-1} F(k) e^{j2\pi nk/N} = \sum_{k=0}^{N-1} F(k) W_N^{-nk}, \\
 n &= 0, \dots, N-1 \quad (124.4)
 \end{aligned}$$

where  $W_N = e^{-j2\pi/N}$ , and  $j = \sqrt{-1}$ . An important property of the DFT is that  $f(n)$  and  $F(k)$  are uniquely related by the transform pair in Eqs. (124.3) and (124.4).

We observe that the functions  $W^{kn}$  are  $N$ -periodic; that is,

$$W_N^{kn} = W_N^{(k+N)n} = W_N^{k(n+N)}, \quad k, n = 0, \pm 1, \pm 2, \dots \quad (124.5)$$

As a consequence, the sequence  $f(n)$  and  $F(k)$  as defined by Eqs. (124.3) and (124.4) are also  $N$ -periodic.

It is generally convenient to adopt the convention

$$\{f(n)\} \longleftrightarrow \{F(k)\} \quad (124.6)$$

to represent the transform pair in Eqs. (124.3) and (124.4).

## Properties of the DFT

A detailed discussion of the properties of DFT can be found in the references cited at the end of this chapter. The following list gives a few of these properties that are of value for the development of the fast Fourier transform.

### 1. Linearity

$$\{af(n) + by(n)\} \longleftrightarrow \{aF(k) + bY(k)\} \quad (124.7a)$$

### 2. Complex conjugate. If $N/2$ is an integer and $\{f(n)\} \longleftrightarrow \{F(k)\}$ , then

$$F\left(\frac{N}{2} + \ell\right) = F^*\left(\frac{N}{2} - \ell\right), \quad \ell = 0, 1, \dots, \frac{N}{2} \quad (124.7b)$$

where  $F^*(k)$  denotes the complex conjugate of  $F(k)$ . This identity shows the folding property of the DFT.

### 3. Reversal

$$\{f(-n)\} \longleftrightarrow \{F(-k)\} \quad (124.8)$$

### 4. Time shifting

$$\{f(n + \ell)\} \longleftrightarrow \{W^{-\ell k} F(k)\} \quad (124.9)$$

### 5. Convolution of real sequences. If

$$y(n) = \frac{1}{N} \sum_{\ell=0}^{N-1} f(\ell)h(n - \ell), \quad n = 0, 1, \dots, N - 1 \quad (124.10)$$

then

$$\{y(n)\} \longleftrightarrow \{F(k)H(k)\} \quad (124.11)$$

6. *Correlation of real sequences.* If

$$y(n) = \frac{1}{N} \sum_{\ell=0}^{N-1} f(\ell)h(n + \ell), \quad n = 0, 1, \dots, N - 1 \quad (124.12)$$

then

$$\{y(n)\} \longleftrightarrow \{F(k)H^*(k)\} \quad (124.13)$$

7. *Symmetry*

$$\left\{ \frac{1}{N} F(n) \right\} \longleftrightarrow \{f(-k)\} \quad (124.14)$$

8. *Parseval's theorem*

$$\sum_{n=0}^{N-1} f^2(n) = \frac{1}{N} \sum_{k=0}^{N-1} |F(k)|^2 \quad (124.15)$$

where  $|F(k)| = F(k)F^*(k)$  .

**Example 124.1.** Verify Parseval's theorem for the sequence  $\{f(n)\} = \{1, 2, -1, 3\}$  .

**Solution.** With the help of Eq. (124.3) we obtain

$$\begin{aligned} F(k)|_{k=0} &= F(0) = \sum_{n=0}^3 f(n)e^{-j\frac{2\pi}{4}kn} \Big|_{k=0} \\ &= (1e^{-j\frac{\pi}{2}\cdot 0\cdot 0} + 2e^{-j\frac{\pi}{2}\cdot 0\cdot 1} - e^{-j\frac{\pi}{2}\cdot 0\cdot 2} + 3e^{-j\frac{\pi}{2}\cdot 0\cdot 3}) \\ &= 5 \end{aligned}$$

Similarly, we find

$$F(1) = 2 + j; \quad F(2) = -5; \quad F(3) = 2 - j$$

Introducing these values in Eq. (124.15) we obtain

$$\begin{aligned}
1^2 + 2^2 + (-1)^2 + 3^2 &= \\
\frac{1}{4}[5^2 + (2+j)(2-j) + 5^2 + (2-j)(2+j)] & \\
\text{or} & \\
15 &= \frac{60}{4}
\end{aligned}$$

which is an identity as it should have been.

## Relation between DFT and Fourier Transform

The sampled form of a continuous function  $f(t)$  can be represented by the  $N$  equally spaced sampled values  $f(n)$  such that

$$f(n) = f(nT), \quad n = 0, 1, \dots, N-1 \quad (124.16)$$

where  $T$  is the sampling interval. The length of the continuous function is  $L = NT$ , where  $f(N) = f(0)$ .

We denote the sampled version of  $f(t)$  by  $f_s(t)$ , which can be represented by the expression

$$f_s(t) = \sum_{n=0}^{N-1} [Tf(n)]\delta(t - nT) \quad (124.17)$$

where  $\delta(t)$  is the Dirac or impulse function.

Taking the Fourier transform of  $f_s(t)$  in Eq. (124.17) we obtain

$$\begin{aligned}
F_s(\omega) &= T \int_{-\infty}^{\infty} \sum_{n=0}^{N-1} f(n)\delta(t - nT)e^{-j\omega t} dt \\
&= T \sum_{n=0}^{N-1} f(n) \int_{-\infty}^{\infty} \delta(t - nT)e^{-j\omega t} dt \\
&= T \sum_{n=0}^{N-1} f(n)e^{-j\omega nT} \quad (124.18)
\end{aligned}$$

Equation (124.18) yields  $F_s(\omega)$  for all values of  $\omega$ . However, if we are interested only in values of  $F_s(\omega)$  at a set of discrete equidistant points, then Eq. (124.18) is expressed in the form [see also Eq. (124.1)]

$$F_s(k) = T \sum_{n=0}^{N-1} f(n) e^{-jkn} \Omega T, \quad k = 0, \pm 1, \pm 2, \dots, \pm \frac{N}{2} \quad (124.19)$$

where  $\Omega = 2\pi/L = 2\pi/NT$ . Therefore, comparing Eqs. (124.3) and (124.19), we observe that we can find  $F(\omega)$  from  $F_s(\omega)$  using the relation

$$F(k) = F_s(\omega)|_{\omega=k\Omega} \quad (124.20)$$

## Power, Amplitude, and Phase Spectra

If  $f(t)$  represents voltage or current waveform supplying a load of 1 ohm, the left-hand side of Parseval's theorem [Eq. (124.15)] represents the power dissipated in the 1-ohm resistor. Therefore, the right-hand side represents the power contributed by each harmonic of the spectrum. Thus the **DFT power spectrum** is defined as

$$P(k) = F(k)F^*(k) = |F(k)|^2, \quad k = 0, 1, \dots, N-1 \quad (124.21)$$

For real  $f(n)$  there are only  $(N/2 + 1)$  independent DFT spectral points as the complex conjugate property shows [Eq. (124.7)]. Hence, we write

$$P(k) = |F(k)|^2, \quad k = 0, 1, \dots, \frac{N}{2} \quad (124.22)$$

The *amplitude spectrum* is readily found from that of a power spectrum, and it is defined as

$$A(k) = |F(k)|, \quad k = 0, 1, \dots, N-1 \quad (124.23)$$

The power and amplitude spectra are invariant with respect to shifts of the data sequence  $\{f(n)\}$ .

The **phase spectrum** of a sequence  $\{f(n)\}$  is defined as

$$\varphi_f(k) = \tan^{-1} \left[ \frac{\text{Im}\{F(k)\}}{\text{Re}\{F(k)\}} \right], \quad k = 0, 1, \dots, N-1 \quad (124.24)$$

As in the case of the power spectrum, only  $(N/2 + 1)$  of the DFT phase spectral points are independent for real  $\{f(n)\}$ . For a real sequence  $\{f(n)\}$  the power spectrum is an *even function* about the point  $k = N/2$  and the phase spectrum is an *odd function* about the point  $k = N/2$ .

## Observations

1. The frequency spacing  $\Delta\omega$  between coefficients is

$$\Delta\omega = -\Omega = \frac{2\pi}{NT} = \frac{\omega_s}{N} \quad \text{or} \quad \Delta f = \frac{1}{NT} = \frac{f_s}{N} = \frac{1}{T_o} \quad (124.25)$$

2. The reciprocal of the record length defines the frequency resolution.
3. If the number of samples  $N$  are fixed and the sampling time is increased, the record length and the precision of frequency resolution is increased. When the sampling time is decreased, the opposite is true.
4. If the record length is fixed and the sampling time is decreased ( $N$  increases), the resolution stays the same and the computed accuracy of  $F(n-\Omega)$  increases.
5. If the record length is fixed and the sampling time is increased ( $N$  decreases), the resolution stays the same and the computed accuracy of  $F(n-\Omega)$  decreases.

## Data Windowing

To produce more accurate frequency spectra it is recommended that the data are weighted by a **window** function  $\{w(n)\}$ . Hence, the new data set will be of the form  $\{f(n)w(n)\}$ . The following are the most commonly used windows:

1. *Triangle (Fejer, Bartlet) window*

$$w(n) = \begin{cases} \frac{n}{N/2}, & n = 0, 1, \dots, \frac{N}{2} \\ w(N-n), & n = \frac{N}{2}, \dots, N-1 \end{cases} \quad (124.26)$$

2.  $\cos^\alpha(x)$  window

$$\begin{aligned} w(n) &= \sin^2 \left( \frac{n}{N} \pi \right), \quad n = 0, 1, \dots, N-1, \quad \alpha = 2 \\ &= 0.5 \left[ 1 - \cos \left( \frac{2n}{N} \pi \right) \right] \end{aligned} \quad (124.27)$$

This window is also called the *raised cosine* or *Hann window*.

3. *Hamming window*

$$w(n) = 0.54 - 0.46 \cos \left( \frac{2\pi}{N} n \right), \quad n = 0, 1, \dots, N-1 \quad (124.28)$$

4. *Blackman window*

$$w(n) = \sum_{m=0}^K (-1)^m a_m \cos \left( 2\pi m \frac{n}{N} \right),$$

$$n = 0, 1, \dots, N-1, \quad K \leq \frac{N}{2} \quad (124.29)$$

For  $K = 2$ ,  $a_0 = 0.42$ ,  $a_1 = 0.50$ , and  $a_2 = 0.08$ .

5. *Blackman-Harris window*. Harris used a gradient search technique to find three- and four-term expansions of Eq. (124.29) that either minimized the maximum side-lobe level for fixed main-lobe width or traded main-lobe width for minimum side-lobe level (see [Table 124.1](#)).

6. *Centered Gaussian window*

$$w(n) = \exp \left[ -\frac{1}{2} \alpha \left( \frac{n}{N/2} \right)^2 \right],$$

$$0 \leq |n| \leq \frac{N}{2}, \quad \alpha = 2, 3, \dots \quad (124.30)$$

As  $\alpha$  increases, the main lobe of the frequency spectrum becomes broader and the side-lobe peaks become lower.

7. *Centered Kaiser-Bessel window*

$$w(n) = I_0[\pi\alpha \sqrt{1.0 - \left( \frac{n}{N/2} \right)^2}] / I_0[\pi\alpha],$$

$$0 \leq |n| \leq \frac{N}{2} \quad (124.31)$$

where

$I_0(x)$  = zero-order modified Bessel function

$$= \sum_{k=0}^{\infty} \left( \frac{(x/2)^k}{k!} \right)^2$$

$$k! = 1 \times 2 \times 3 \times \dots \times k$$

$$\alpha = 2, 2.5, 3 \quad (\text{typical values}) \quad (124.32)$$

**Table 124.1** Blackman-Harris window parameters

	Parameter Values

$a_3$	—	—	0.01168	0.00188

## Fast Fourier Transform

One of the approaches to speed the computation of the DFT of a sequence is the *decimation-in-time method*. This approach involves breaking the  $N$ -point transform into two  $(N/2)$ -point transforms, then breaking each  $(N/2)$ -point transform into two  $(N/4)$ -point transforms, and continuing the above process until the two-point transform is obtained. We start with the DFT expression and factor it into two DFTs of length  $N/2$ :

$$\begin{aligned}
 F(k) &= \sum_{n=0}^{N-2} f(n)W_N^{kn} & n \text{ even} \\
 &+ \sum_{n=1}^{N-1} f(n)W_N^{kn} & n \text{ odd}
 \end{aligned} \quad (124.33)$$

Letting  $n = 2m$  in the first sum and  $n = 2m + 1$  in the second, Eq. (124.33) becomes

$$F(k) = \sum_{m=0}^{(N/2)-1} f(2m)W_N^{2mk} + \sum_{m=0}^{(N/2)-1} f(2m+1)W_N^{(2m+1)k} \quad (124.34)$$

However, because of the following identities,

$$W_N^{2mk} = (W_N^2)^{mk} = e^{-j\frac{2\pi}{N}2mk} = e^{-j\frac{2\pi}{N/2}mk} = W_{N/2}^{mk} \quad (124.35)$$

and the substitution  $f(2m) = f_1(m)$  and  $f(2m+1) = f_2(m)$ ,  $m = 0, 1, \dots, N/2 - 1$ , Eq. (124.33) takes the form

$$\begin{aligned}
F(k) &= \sum_{m=0}^{(N/2)-1} f_1(m) W_{N/2}^{mk} \\
(N/2) &= \text{point DFT of even indexed sequence} \\
&+ W_N^k \sum_{m=0}^{(N/2)-1} f_2(m) W_{N/2}^{mk} \\
(N/2) &= \text{point DFT of odd indexed sequence} \\
k &= 0, \dots, N/2 - 1
\end{aligned} \tag{124.36}$$

We can also write Eq. (124.36) in the form

$$\begin{aligned}
F(k) &= F_1(k) + W_N^k F_2(k), \\
k &= 0, 1, \dots, N/2 - 1 \\
F\left(k + \frac{N}{2}\right) &= F_1(k) + W_N^{k+N/2} F_2(k) \\
&= F_1(k) - W_N^k F_2(k), \\
k &= 0, 1, \dots, N/2 - 1
\end{aligned} \tag{124.37}$$

where  $W_N^{k+N/2} = -W_N^k$  and  $W_{N/2}^{m(k+N/2)} = W_{N/2}^{mk}$ . Since the DFT is periodic,  $F_1(k) = F_1(k + N/2)$  and  $F_2(k) = F_2(k + N/2)$ .

Next we apply the same procedure to each  $N/2$  sample, where  $f_{11}(m) = f_1(2m)$  and  $f_{21}(m) = f_2(2m + 1)$ ,  $m = 0, 1, \dots, (N/4) - 1$ . Hence,

$$\begin{aligned}
F_1(k) &= \sum_{m=0}^{(N/4)-1} f_{11}(m) W_{N/4}^{mk} + W_N^{2k} \sum_{m=0}^{(N/4)-1} f_{21}(m) W_{N/4}^{mk}, \\
k &= 0, 1, \dots, \frac{N}{4} - 1
\end{aligned} \tag{124.38}$$

or

$$\begin{aligned}
F_1(k) &= F_{11}(k) + W_N^{2k} F_{21}(k) \\
F_1\left(k + \frac{N}{4}\right) &= F_{11}(k) - W_N^{2k} F_{21}(k), \\
k &= 0, 1, \dots, \frac{N}{4} - 1 \quad (124.39)
\end{aligned}$$

Therefore, each of the sequences  $f_1$  and  $f_2$  have been split into two DFTs of length  $N/4$ .

**Example 124.2.** To find the FFT of the sequence  $\{2, 3, 4, 5\}$  we first bit-reverse the elements from position  $\{00, 01, 10, 11\}$  to position  $\{00, 10, 01, 11\}$ . The new sequence is  $\{2, 4, 3, 5\}$  (see also Fig. 124.1). Using Eqs. (124.36) and (124.37) we obtain

$$\begin{aligned}
F_1(0) &= \sum_{m=0}^1 f_1(m)_2^{m \cdot 0} \\
&= f_1(0)W_2^0 + f_1(1)W_2^0 \\
&= f(0) \cdot 1 + f(2) \cdot 1
\end{aligned}$$

$$\begin{aligned}
F_1(1) &= \sum_{m=0}^1 f_1(m)W_2^{m \cdot 1} \\
&= f_1(0)W_2^{0 \cdot 1} + f_1(1)W_2^1 \\
&= f(0) + f(2)(-j)
\end{aligned}$$

$$\begin{aligned}
F_2(0) &= W_4^0 \sum_{m=0}^1 f_2(m)W_2^{m \cdot 0} \\
&= f_2(0)W_2^0 + f_2(1)W_2^0 \\
&= f(1) + f(3)
\end{aligned}$$

$$\begin{aligned}
F_2(1) &= W_4^1 \sum_{m=0}^1 f_2(m)W_2^{m \cdot 1} \\
&= W_4^1 [f(1)W_2^0 + f(3)W_2^1] \\
&= W_4^1 f(1) - W_4^1 f(3)
\end{aligned}$$

From Eq. (124.37) the output is  $F(0) = F_1(0) + W_4^0 F_2(0)$ ,  $F(1) = F_1(1) + W_4^1 F_2(1)$ ,  $F(2) = F_1(0) - W_4^0 F_2(0)$ , and  $F(3) = F_1(1) - W_4^1 F_2(1)$ . Figure 124.2 shows an eight-point decimation-in-time FFT. (See also Table 124.2)

## Computation of the Inverse DFT

To find the inverse of FFT using an FFT algorithm, we use the relation

$$f(n) = [\text{FFT}(F^*(k))]^*/N \quad (124.40)$$

## 124.2 Walsh-Hadamard Transform

### Walsh Functions

In 1923 Walsh developed a complete orthogonal set of rectangular functions known as Walsh functions. The first eight functions are shown in Fig. 124.3. These signals have been widely used to perform nonsinusoidal orthogonal transforms in various digital signal processing applications since they can essentially be computed using addition and subtraction only.

**Figure 124.3** Walsh functions.

Every signal  $f(t)$  absolutely integrable in  $0 \leq t \leq 1$  can be equated in a series of the form

$$f(t) = \sum_{k=0}^{\infty} d_k \text{Wal}_w(k, t) \quad (124.41)$$

where

$$d_k = \int_0^1 f(t) \text{Wal}_w(k, t) dt, \quad k = 0, 1, 2, \dots \quad (124.42)$$

The above series converges uniformly to  $f(t)$  if it is continuous in  $0 \leq t \leq 1$  and converges in the mean where  $f(t)$  is discontinuous.

The Walsh-Hadamard transforms are analogous to the discrete Fourier transform. The basis functions are sampled Walsh functions, which can be expressed in terms of the Hadamard matrices  $\underline{H}_w(n)$ . An  $\underline{H}_w(3)$  is shown in Fig. 124.4, where  $n = \log_2 N$ .

**Figure 124.4** Hadamard matrix.

$$\underline{H}_W(3) = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\ 1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\ 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \\ 1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \end{bmatrix}$$

Let  $u_i$  and  $v_i$  be the  $i$ th bits in the binary representation of the integers  $u$  and  $v$ , respectively; then

$$(u)_{\text{decimal}} = (u_{n-1}, u_{n-2}, \dots, u_1 u_0)_{\text{binary}}$$

$$(v)_{\text{decimal}} = (v_{n-1}, v_{n-2}, \dots, v_1 v_0)_{\text{binary}}$$

The Walsh-ordering Hadamard matrix elements are given by

$$h_{uv}^{(w)} = (-1)^{\sum_{i=0}^{n-2} r_i(u) v_i}, \quad u, v = 0, 1, \dots, N-1 \quad (124.43)$$

where

$$\begin{aligned}
 r_0(u) &= u_{n-1} \\
 r_1(u) &= u_{n-1} + u_{n-2} \\
 r_2(u) &= u_{n-2} + u_{n-3} \\
 &\vdots \\
 r_{n-1}(u) &= u_1 + u_0
 \end{aligned}$$

The Hadamard matrices have the following properties:

1.  $\underline{H}_w(k)$  is a symmetric matrix:

$$\underline{H}_w(k) = \underline{H}_w(k)^T \quad (124.44)$$

$T$  stands for transpose.

2.  $\underline{H}_w(k)$  are orthogonal:

$$\underline{H}_w(k) \underline{H}_w(k)^T = 2^k \underline{I}(k) \quad (124.45)$$

where  $\underline{I}(k)$  is a  $(2^k \times 2^k)$  identity matrix.

3. The inverse of  $\underline{H}_w(k)$  is proportional to itself:

$$[\underline{H}_w(k)]^{-1} = (1/2^k) \underline{H}_w(k) \quad (124.46)$$

where  $[\underline{H}_w(k)]^{-1}$  defines the inverse of  $\underline{H}_w(k)$ .

## Walsh-Ordered Walsh-Hadamard Transform (WHT<sub>w</sub>)

The WHT<sub>w</sub> of the data sequence  $\{x(n)\} = \{x(0), x(1), \dots, x(N-1)\}$  is defined by

$$\underline{X}(n) = \frac{1}{N} \underline{H}_w(n) \underline{x}(n) \quad (124.47)$$

where  $\underline{X}(n)$  is the  $k$ th WHT<sub>w</sub> coefficient and

$$\underline{X}(n)^T = [X(0), X(1), \dots, X(N-1)] \quad (124.48)$$

Since  $\underline{H}_w(n)$  is orthogonal and symmetric we find that the inverse Walsh-ordered Hadamard transform IWHT<sub>w</sub> is given by

$$\underline{x}(n) = \underline{H}_w(n) \underline{X}(n) \quad (124.49)$$

**Example 124.3.** Let  $\{x(n)\} = \{1, 2, 2, 1\}$ . To evaluate  $\underline{X}(n)$  for  $k = 0, 1, 2, 3$  we use Eq. (124.47). Hence,

$$\begin{bmatrix} X(0) \\ X(1) \\ X(2) \\ X(3) \end{bmatrix} = \frac{1}{4} \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \\ 1 & -1 & 1 & -1 \end{bmatrix} \begin{bmatrix} 1 \\ 2 \\ 2 \\ 1 \end{bmatrix} = \begin{bmatrix} 6/4 \\ 0 \\ -2/4 \\ 0 \end{bmatrix}$$

From the above example we observe that  $N^2$  additions and/or subtractions are required to compute the  $\text{WHT}_w$  coefficients  $\underline{X}(n)$ ,  $n = 0, 1, \dots, N - 1$ .

## Fast Walsh-Ordered Walsh-Hadamard Transform ( $\text{FWHT}_w$ )

Manz [1972] introduced an  $\text{FWHT}_w$  that has the following steps:

1. Bit-reverse the input sequence and order it in ascending index. For example, if  $\{x(n)\} = \{x(1), x(2), x(3)\} = \{1, 2, 3\}$ , the sequence becomes  $\{\hat{x}(n)\} = \{1, 3, 2\} = \{\hat{x}(0), \hat{x}(1), \hat{x}(2)\}$ .
2. Define a reversal, which is best illustrated by the simple case shown in Fig. 124.5.
3. Define the blocks that are reversed and nonreversed. Figure 124.6 shows the positions of blocks for an  $\text{FWHT}_w$  flow graph for  $N = 8$ .

**Figure 124.5** Reversal and nonreversal steps.

**Figure 124.6** Fast Walsh-Hadamard transform.

**Example 124.4** To find the  $\text{WHT}_w$  of the sequencing  $\{x(n)\} = \{11213213\}$  we proceed as follows:

$x(0) = 1$	$\hat{x}(0)[000] = x(0) = 1$	$x_1(0) = 1 + 1 = 2$	$x_2(0) = 1 + 1 = 2$	$x_3(0) = 1 + 1 = 2$	$\frac{1}{8}X(0) = \frac{14}{8}$
$x(1) = 1$	$\hat{x}(1)[100] = x(4) = 1$	$x_1(1) = 3 + 2 = 5$	$x_2(1) = 5 + 4 = 9$	$x_3(1) = -9 + 5 = -4$	$\frac{1}{8}X(1) = -\frac{4}{8}$
$x(2) = 2$	$\hat{x}(2)[010] = x(2) = 1$	$x_1(2) = 2 + 1 = 3$	$x_2(2) = -3 + 2 = -1$	$x_3(2) = -1 - 1 = -2$	$\frac{1}{8}X(2) = -\frac{2}{8}$
$x(3) = 1$	$\hat{x}(3)[110] = x(6) = 1$	$x_1(3) = 1 + 3 = 4$	$x_2(3) = -4 + 5 = 1$	$x_3(3) = 1 - 1 = 0$	$\frac{1}{8}X(3) = \frac{0}{8}$
$x(4) = 3$	$\hat{x}(4)[001] = x(1) = 1$	$x_1(4) = -1 + 1 = 0$	$x_2(4) = 0 - 1 = -1$	$x_3(4) = -1 + 3 = 2$	$\frac{1}{8}X(4) = \frac{2}{8}$
$x(5) = 2$	$\hat{x}(5)[101] = x(5) = 1$	$x_1(5) = -2 + 3 = 1$	$x_2(5) = 1 + 2 = 3$	$x_3(5) = -3 - 1 = -4$	$\frac{1}{8}X(5) = -\frac{4}{8}$
$x(6) = 1$	$\hat{x}(6)[011] = x(3) = 1$	$x_1(6) = -1 + 2 = 1$	$x_2(6) = 1 + 0 = 1$	$x_3(6) = 1 + 1 = 2$	$\frac{1}{8}X(6) = \frac{2}{8}$
$x(7) = 3$	$\hat{x}(7)[111] = x(7) = 1$	$x_1(7) = -3 + 1 = -2$	$x_2(7) = -2 + 1 = -1$	$x_3(7) = -1 + 1 = 0$	$\frac{1}{8}X(7) = \frac{0}{8}$

The power spectrum of  $\text{WHT}_w$  is given by

$$P_w = X^2(0)$$

$$P_w(s) = X^2(2s - 1) + X^2(2s), \quad s = 1, 2, \dots, \frac{N}{2} - 1$$

$$P_w\left(\frac{N}{2}\right) = X^2(N - 1)$$

## Defining Terms

**Fast Fourier transform (FFT):** A computational technique that reduced the number of mathematical operations in the evaluation of the discrete Fourier transform (DFT) to  $N \log_2(N)$ .

**Phase spectrum:** All phases associated with the spectrum harmonics constitute the phase spectrum.

**Power spectrum:** A power contributed by each harmonic of the spectrum.

**Window:** Any appropriate function that multiplies the data with the intent of minimizing the distortion of the Fourier spectra.

Digital filtering is concerned with the manipulation of **discrete data sequences** to remove noise or extract certain desired information. Discrete or digital signals are somewhat intuitive to human beings despite their rarity in nature. That is, people tend to make and tabulate measurements of physical entities in sets of data values with limited precision, while the entities being measured vary continuously both in their functional dependence and their value.

Although an infinite number of numerical manipulations can be applied to discrete data (e.g., finding the mean value, forming a histogram), the primary objective of digital filtering is to form a discrete output sequence  $y(n)$  from a discrete input sequence  $x(n)$ . In some manner or another, each output data sample is computed from the input data sequence—not just from any one sample, but from many, in fact, possibly from all the input samples.

The reader may already be familiar with a few processing schemes. For example, computing a moving average is sometimes used as a means of reducing measurement uncertainty or noise in data. In a three-point symmetric scheme the output sequence is found by

$$y(n) = \frac{x(n-1) + x(n) + x(n+1)}{3}$$

Note that the output sequence in this case is a sum of products of the input sample values with certain coefficients. (In this case the coefficients all have the same value of  $1/3$ .)

To make some headway in analyzing digital filters, it is necessary to restrict in two ways the types of filters being considered. First, a given filter is restricted to being linear. This means that the response of the filter to a sum of inputs is the sum of the outputs corresponding to the inputs individually and that, if the input to the filter is scaled by a multiplicative factor, the output is

scaled by the same factor.

The second restriction placed on the types of filters being analyzed is that they be shift-invariant. This property states that for any given input  $x(n)$  producing output  $y(n)$ , the response of the filter to the shifted input  $x(n - n_o)$  produces the same output sequence of values shifted by the same amount, namely,  $y(n - n_o)$ . Note that the moving average processing scheme satisfies these restrictions. However, a much larger class of processing algorithms also falls into the category of linear shift-invariant filters.

The output of a digital filter to any input can be determined from a formula known as the *convolution sum*. To derive this relation, consider first the unit impulse sequence defined as

$$\delta(n) = \begin{cases} 1 & \text{for } n = 0 \\ 0 & \text{otherwise} \end{cases}$$

By use of this special sequence any discrete sequence can be written

$$x(n) = \sum_{m=-\infty}^{\infty} x(m)\delta(n - m)$$

Suppose this sequence were input to a linear shift-invariant digital filter. Since the filter is linear, the output will be a linear combination of the outputs resulting from shifted unit impulse inputs. Since the filter is shift-invariant, the outputs will also be shifted by the same amounts. Thus, if the output of the filter in response to a single unit impulse at  $n = 0$  is the sequence  $h(n)$ , the output of the filter to the input  $x(n)$  will be the linear combination of shifted  $h(n)$  sequences weighted with the coefficients of the  $x(n)$  sequence:

$$y(n) = \sum_{m=-\infty}^{\infty} x(m)h(n - m)$$

By a change of dummy index of summation, it is easily shown that this can also be written

$$y(n) = \sum_{m=-\infty}^{\infty} h(m)x(n - m)$$

These equations are known as the **convolution summation** and describe the output of the filter to any arbitrary input. Thus, in theory, the response of a given filter to any input can be computed from knowledge of the sequence  $h(n)$ , which is referred to as the *impulse response* of the filter. It is a sequence that is of extreme importance in digital filtering, since it completely describes the filter.

A digital filter is often conveniently described in terms of its frequency characteristics, which are given by the Fourier transform of its impulse response. The impulse response and frequency response make up the Fourier transform pair,

$$H(e^{j\omega}) = \sum_{n=-\infty}^{\infty} h(n)e^{-j\omega n}, \quad -\pi \leq \omega \leq \pi$$

$$h(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} H(e^{j\omega})e^{j\omega n} d\omega, \quad -\infty \leq n \leq \infty$$

where  $\omega$  is the digital radian frequency. The discrete-time Fourier transform is expressed as a function of  $e^{j\omega}$  rather than simply as a function of  $\omega$  to distinguish the discrete-time transform from its continuous-time counterpart. The radian frequency ranging from  $\omega = 0$  to  $\omega = \pi$  corresponds to the "real-world" frequency range from 0 to  $F_s/2$ , where  $F_s$  is the sample rate of the discrete-time data. For example, if the sample rate of data into a digital filter is 2 kHz, then the frequency 100 Hz corresponds to  $\omega = 0.1\pi$ .

Just as in the analysis of continuous-time systems, the operation of convolution is equivalent to the product of Fourier transforms in the frequency domain,  $Y(e^{j\omega}) = H(e^{j\omega})X(e^{j\omega})$ . Therefore,  $H(e^{j\omega})$  may be treated as the *transfer function* of the digital filter since it relates the input Fourier transform to the Fourier transform of the output, specifying how each frequency component in the filter input is altered by the filter.

Closely related to the Fourier transform of  $h(n)$  is the  $z$  transform defined by

$$H(z) = \sum_{n=-\infty}^{\infty} h(n)z^{-n}$$

$H(z)$  is referred to as the  $z$ -domain transfer function of the filter. The Fourier transform is then the  $z$  transform evaluated on the unit circle in the  $z$  plane ( $z = e^{j\omega}$ ). An important property of the  $z$  transform is that  $z^{-1}H(z)$  corresponds to  $h(n-1)$ , so  $z^{-1}$  represents a one-sample delay, termed a *unit delay*.

In this chapter the focus will be restricted to **filter design** and **filter implementation** of frequency-selective filters. These filters are intended to pass frequency components of the input sequence in a given band of the spectrum while blocking the rest. Typical frequency-selective filter types are low-pass, high-pass, band-pass, and band-reject filters. Other special-purpose filters exist; however, their design is an advanced topic that will not be addressed here. In addition, special attention is given to causal filters for which the impulse response is identically zero for negative  $n$  and which can thus be implemented in real time.

## 125.1 Finite Impulse Response Filter Design

---

The objective of **finite impulse response (FIR) digital filter** design is to determine  $N + 1$  coefficients

$$h(0), h(1), \dots, h(N)$$

so that the transfer function  $H(e^{j\omega})$  approximates a desired frequency characteristic  $H_d(e^{j\omega})$ . All other impulse response coefficients are zero. An important property of FIR filters for practical applications is that they can be designed to be *linear phase*; that is, the transfer function has the form

$$H(e^{j\omega}) = A(e^{j\omega})e^{-j\omega N/2}$$

where the amplitude  $A(e^{j\omega})$  is a real function of frequency. The desired transfer function can be similarly written

$$H_d(e^{j\omega}) = A_d(e^{j\omega})e^{-j\omega N/2}$$

where  $A_d(e^{j\omega})$  describes the amplitude of the desired frequency-selective characteristics. For example, the amplitude frequency characteristics of an ideal low-pass filter are given by

$$A_d(e^{j\omega}) = \begin{cases} 1 & \text{for } |\omega| \leq \omega_c \\ 0 & \text{otherwise} \end{cases}$$

where  $\omega_c$  is the *cutoff frequency* of the filter.

A linear phase characteristic ensures that a filter has a constant delay independent of frequency. Thus, all frequency components in the signal are delayed by the same amount, and the only signal distortion introduced is that imposed by the filter's frequency-selective characteristics.

Since an FIR filter can only approximate a desired frequency-selective characteristic, some measures of the accuracy of approximation are needed to describe the quality of the design. These are the *passband ripple*  $\delta_p$ , the *stopband attenuation*  $\delta_s$ , and the *transition bandwidth*  $\Delta\omega$ . These quantities are illustrated in Fig. 125.1 for a prototype low-pass filter. The passband ripple gives the maximum deviation from the desired amplitude (typically unity) in the region where the input signal spectral components are desired to be passed unattenuated. The stopband attenuation gives the maximum deviation from zero in the region where the input signal spectral components are desired to be blocked. The transition bandwidth gives the width of the spectral region in which the frequency characteristics of the transfer function change from the passband to the stopband values. Passband ripple and stopband attenuation are often specified in decibels, in which case their values are related to the quantities  $\delta_p$  and  $\delta_s$  by the following:

$$\begin{aligned} \text{Passband ripple in dB} &= P = -20 \log_{10} (1 - \delta_p) \\ \text{Stopband attenuation in dB} &= S = -20 \log_{10} \delta_s \end{aligned}$$

**Figure 125.1** Amplitude frequency characteristics of an FIR low-pass filter showing definitions of passband ripple  $\delta_p$ , stopband attenuation  $\delta_s$ , and transition bandwidth  $\Delta\omega$ . (Source: Dorf, R. C. (Ed.) 1993. *The Electrical Engineering Handbook*, p. 240. CRC Press, Boca Raton, FL. With permission.)

## FIR Filter Design by Windowing

The windowing design method is a computationally efficient technique for producing nonoptimal filters. Filters designed in this manner have equal passband ripple and stopband attenuation:

$$\delta_p = \delta_s = \delta$$

The method begins by finding the impulse response of the desired filter from

$$h_d(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} A_d(e^{j\omega}) e^{j\omega(n-N/2)} d\omega$$

For ideal low-pass, high-pass, band-pass, and band-reject frequency-selective filters, the integral can be solved in closed form. The impulse response of the filter is then found by multiplying this ideal impulse response with a window  $w(n)$  that is identically zero for  $n < 0$  and for  $n > N$ :

$$h(n) = h_d(n)w(n), \quad n = 0, 1, \dots, N$$

Some commonly used windows are defined as follows:

Rectangular (truncation)

$$w(n) = \begin{cases} 1 & \text{for } 0 \leq n \leq N \\ 0 & \text{otherwise} \end{cases}$$

Hamming

$$w(n) = \begin{cases} 0.54 - 0.46 \cos(2\pi n/N) & \text{for } 0 \leq n \leq N \\ 0 & \text{otherwise} \end{cases}$$

Kaiser

$$w(n) = \begin{cases} I_0 \left( \beta \sqrt{1 - [(2n - N)/N]^2} \right) / I_0(\beta) & \text{for } 0 \leq n \leq N \\ 0 & \text{otherwise} \end{cases}$$

In general, windows that slowly taper the impulse response to zero result in lower passband ripple and a wider transition bandwidth. Other windows (e.g., Hanning, Blackman) are also sometimes used, but not as often as those shown above.

Of particular note is the Kaiser window where  $I_0(\cdot)$  is the 0th-order modified Bessel function of the first kind, and  $\beta$  is a shape parameter. The proper choice of  $N$  and  $\beta$  allows the designer to meet given passband ripple, stopband attenuation, and transition bandwidth specifications. Specifically, using  $S$ , the stopband attenuation in dB, the filter order must satisfy

$$N = \frac{S - 8}{2.285 \Delta\omega}$$

Then the required value of the shape parameter is given by

$$\beta = \begin{cases} 0 & \text{for } S < 21 \\ 0.5842(S - 21)^{0.4} + 0.07886(S - 21) & \text{for } 21 \leq S \leq 50 \\ 0.1102(S - 8.7) & \text{for } S > 50 \end{cases}$$

Consider as an example of this design technique a low-pass filter with a cutoff frequency of  $\omega_c = 0.4\pi$ . The ideal impulse response for this filter is given by

$$h_d(n) = \frac{\sin[0.4\pi(n - N/2)]}{\pi(n - N/2)}$$

Choosing  $N = 8$  and a Kaiser window with shape parameter of  $\beta = 0.5$  yields the following impulse response coefficients:

$$\begin{aligned}
h(0) &= h(8) = -0.075\,682\,67 \\
h(1) &= h(7) = -0.062\,365\,96 \\
h(2) &= h(6) = 0.093\,548\,92 \\
h(3) &= h(5) = 0.302\,730\,70 \\
h(4) &= 0.400\,000\,00
\end{aligned}$$

## Design of Optimal FIR Filters

The accepted standard criterion for the design of optimal FIR filters is to minimize the maximum value of the error function

$$E(e^{j\omega}) = W_d(e^{j\omega})|A_d(e^{j\omega}) - A(e^{j\omega})|$$

over the full range of  $-\pi \leq \omega \leq \pi$ .  $W_d(e^{j\omega})$  is a desired weighting function used to emphasize specifications in a given frequency band. The ratio of the deviation in any two bands is inversely proportional to the ratio of their respective weighting.

A consequence of this optimization criterion is that the frequency characteristics of optimal filters are *equiripple*: Although the maximum deviation from the desired characteristic is minimized, it is reached several times in each band. Thus, the passband and stopband deviations oscillate about the desired values with equal amplitude in each band. Such approximations are frequently referred to as *mini-max* or *Chebyshev* approximations. In contrast, the maximum deviations occur near the band edges for filters designed by windowing.

Equiripple FIR filters are usually designed using the *Parks-McClellan* computer program [Antoniou, 1979], which uses the *Remez exchange algorithm* to determine iteratively the *extremal frequencies* at which the maximum deviations in the error function occur. A listing of this program along with a detailed description of its use is available in several references, including Parks and Burrus [1987] and DSP Committee [1979]. The program is executed by specifying as inputs the desired band edges, gain for each band (usually 0 or 1), band weighting, and filter impulse response length. If the resulting filter has too much ripple in some bands, those bands can be weighted more heavily and the filter redesigned. Details on this design procedure are discussed in Rabiner [1973] along with approximate design relationships that aid in selecting the filter length needed to meet a given set of specifications.

Although we have focused on the design of frequency-selective filters, other types of FIR filters exist. For example, the Parks-McClellan program will also design linear-phase FIR filters for differentiating broadband signals and for approximating the Hilbert transform of such signals.

For practice in the principles of equiripple filter design, consider an eighth-order low-pass filter with a passband  $0 \leq \omega \leq 0.3\pi$ , a stopband  $0.5\pi \leq \omega \leq \pi$ , and equal weighting for each band. The impulse response coefficients generated by the Parks-McClellan program are as follows:

$$\begin{aligned}
h(0) &= h(8) = -0.063\,678\,59 \\
h(1) &= h(7) = -0.069\,122\,76 \\
h(2) &= h(6) = 0.101\,043\,60 \\
h(3) &= h(5) = 0.285\,749\,90 \\
h(4) &= 0.410\,730\,00
\end{aligned}$$

These values can be compared to those for the similarly specified filter designed in the previous section using the windowing method.

## 125.2 Infinite Impulse Response Filter Design

---

An **infinite impulse response (IIR) digital filter** requires less computation to implement than an FIR digital filter with a corresponding frequency response. However, IIR filters cannot generally achieve a perfect linear phase response.

Techniques for the design of infinite impulse response analog filters are well established. For this reason the most important class of IIR digital filter design techniques is based on forcing a digital filter to behave like a reference analog filter. For frequency-selective filters this is generally done by attempting to match frequency responses. This task is complicated by the fact that the analog filter response is defined for an infinite range of frequencies ( $\Omega = 0$  to  $\infty$ ), whereas the digital filter response is defined for a finite range of frequencies ( $\omega = 0$  to  $\pi$ ). Therefore, a method for mapping the infinite range of analog frequencies,  $\Omega$ , into the finite range from  $\omega = 0$  to  $\pi$  that is termed the *bilinear transform* is employed.

Let  $H_a(s)$  be the Laplace transform transfer function of an analog filter with frequency response  $H_a(j\Omega)$  ( $\Omega$  in radians/s). The bilinear transform method obtains the digital filter transfer function  $H(z)$  from  $H_a(s)$  using the substitution

$$s = \frac{2}{T} \frac{1 - z^{-1}}{1 + z^{-1}}$$

That is,

$$H(z) = H_a(s) \Big|_{s=(2/T)(1-z^{-1})/(1+z^{-1})}$$

This transformation maps analog frequency  $\Omega$  to digital frequency  $\omega$  according to

$$\omega = 2 \tan^{-1} \left( \frac{\Omega T}{2} \right)$$

thereby warping the frequency response  $H_a(j\Omega)$  and forcing it to lie between 0 and  $\pi$  for  $H(e^{j\omega})$ . Therefore, to obtain a digital filter with a cutoff frequency of  $\omega_c$ , it is necessary to design an analog filter with cutoff frequency

$$\Omega_c = \frac{2}{T} \tan\left(\frac{\omega_c}{2}\right)$$

This process is referred to as *prewarping* the analog filter frequency response to compensate for the warping of the bilinear transform. Applying the bilinear transform substitution to this analog filter will then give a digital filter that has the desired cutoff frequency.

Analog filters and hence IIR digital filters are typically specified in a slightly different fashion than are FIR filters. Figure 125.2 illustrates how analog and IIR digital filters are usually specified. Notice by comparing to Fig. 125.1 that the passband ripple in this case never goes above unity, where in the FIR case the passband ripple is specified about unity.

**Figure 125.2** Frequency characteristics of an IIR digital low-pass filter showing definitions of passband ripple  $\delta_p$ , stopband attenuation  $\delta_s$ , and transition bandwidth  $\Delta\omega$ . (Source: Dorf, R. C. (Ed.) 1993. *The Electrical Engineering Handbook*, p. 244. CRC Press, Boca Raton, FL. With permission.)

Four basic types of analog filters are generally used to design digital filters: (1) Butterworth filters, which are maximally flat in the passband and decrease monotonically outside the passband, (2) Chebyshev filters, which are equiripple in the passband and decrease monotonically outside the passband, (3) inverse Chebyshev filters, which are flat in the passband and equiripple in the

stopband, and (4) elliptic filters, which are equiripple in both the passband and stopband. Techniques for designing these analog filters are covered elsewhere [see, for example, [Van Valkenberg \(1982\)](#)] and will not be considered here.

To illustrate the design of an IIR digital filter using the bilinear transform, consider the design of a second-order Chebyshev low-pass filter with 0.5 dB of passband ripple and a cutoff frequency of  $\omega_c = 0.4\pi$ . The sample rate of the digital filter is to be 5 Hz, giving  $T = 0.2$  seconds. To design this filter we first design an analog Chebyshev low-pass filter with a cutoff frequency of

$$\Omega_c = \frac{2}{0.2} \tan(0.2\pi) = 7.2654 \text{ rad/s}$$

This filter has a transfer function

$$H(s) = \frac{0.9441}{1 + 0.1249s + 0.01249s^2}$$

Substituting

$$s = \frac{2}{0.2} \frac{z - 1}{z + 1}$$

gives

$$H(z) = \frac{0.2665(z + 1)^2}{z^2 - 0.1406z + 0.2695}$$

Computer programs are available that accept specifications on a digital filter and carry out all steps required to design the filter, including prewarping the frequencies, designing the analog filter, and performing the bilinear transform. Two such programs are given in Parks and Burrus [1987] and Antoniou [1979].

## Notch Filters

An important special type of IIR filter is the notch filter. Such filters can remove a very narrow band of frequencies and are useful for applications like removing 60 Hz noise from data. The following second-order  $z$ -domain transfer function realizes a notch filter at frequency  $\omega_0$ :

$$H(z) = \frac{1 - 2 \cos \omega_0 z^{-1} + z^{-2}}{1 - 2r \cos \omega_0 z^{-1} + r^2 z^{-2}}$$

The parameter  $r$  is restricted to the range  $0 < r < 1$ . Substituting  $z = e^{j\omega}$ , multiplying the numerator and denominator by  $e^{j\omega}$ , and applying some trigonometric identities yields the following frequency response for the filter:

$$H(e^{j\omega}) = \frac{2 \cos \omega - 2 \cos \omega_o}{(1 + r^2) \cos \omega - 2r \cos \omega_o + j(1 - r^2) \sin \omega}$$

From this expression it can easily be seen that the response of the filter at  $\omega = \omega_o$  is exactly zero. Another property is that, for  $r \cong 1$  and  $\omega \neq \omega_o$ , the numerator and denominator are very nearly equal, and so the response is approximately unity. Overall, this is a very good approximation of an ideal notch filter as  $r \rightarrow 1$ .

## 125.3 Digital Filter Implementation

---

For FIR filters the convolution sum represents a computable process, and so filters can be implemented by directly programming the arithmetic operations

$$y(n) = h(0)x(n) + h(1)x(n-1) + \cdots + h(N)x(n-N)$$

However, for an IIR filter the convolution sum does not represent a computable process. Therefore, it is necessary to examine the general transfer function, which is given by

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\gamma_0 + \gamma_1 z^{-1} + \gamma_2 z^{-2} + \cdots + \gamma_M z^{-M}}{1 + \beta_1 z^{-1} + \beta_2 z^{-2} + \cdots + \beta_N z^{-N}}$$

where  $Y(z)$  is the  $z$  transform of the filter output,  $y(n)$ , and where  $X(z)$  is the  $z$  transform of the filter input,  $x(n)$ . The unit-delay characteristic of  $z^{-1}$  then gives the following **difference equation** for implementing the filter

$$y(n) = \gamma_0 x(n) + \gamma_1 x(n-1) + \cdots + \gamma_M x(n-M) - \beta_1 y(n-1) - \cdots - \beta_N y(n-N)$$

In calculations of  $y(0)$ , the values of  $y(-1), y(-2), \dots, y(-N)$  represent initial conditions on the filter. If the filter is started in an initially relaxed state, then these initial conditions are zero.

### Defining Terms

**Convolution summation:** A possibly infinite summation expressing the output of a digital filter in terms of the impulse response coefficients of the filter and present and past values of the input to the filter. For FIR filters this summation represents a way of implementing the filter.

**Difference equation:** An equation expressing the output of a digital filter in terms of present and past values of the filter input and past values of the filter output. For IIR filters a difference equation must be used to implement the filter since the convolution summation is infinite.

**Discrete data sequence:** A set of values constituting a signal whose values are known only at distinct sampled points.

**Filter design:** The process of determining the impulse response coefficients or coefficients of a difference equation to meet a given frequency or time response characteristic.

**Filter implementation:** The numerical method or algorithm by which the output sequence of a

digital filter is computed from the input sequence.

**Finite impulse response (FIR) digital filter:** A filter whose output in response to a unit impulse function is identically zero after a given bounded number of samples.

**Infinite impulse response (IIR) digital filter:** A filter whose output in response to a unit impulse function remains nonzero for indefinitely many samples.

## Further Information

The monthly journals *IEEE Transactions on Circuits and Systems II* and *IEEE Transactions on Signal Processing* routinely publish articles on the design and implementation of digital filters. The bimonthly journal *IEEE Transactions on Instrumentation and Measurement* also contains related information. The use of digital filters for integration and differentiation is discussed in the December 1990 issue (pp. 923–927).

Pulse Modulation • Multiplexing and Multiple Access • Spread-Spectrum Signaling • Sequences of Symbols • Implementation Issues

### H. Vincent Poor

*Princeton University*

A general model of an electrical communication system is shown in [Fig. 126.1](#). It consists of a *transmitting* side and a *receiving* side. The transmitting side includes an *information source* that produces an *input message*, a transducer that converts this input message to an electrical **message signal**, and a **transmitter** that couples the message signal to the communication **channel**. The receiving side consists of a **receiver** that converts the signal received from the channel back into a replica of the electrical message signal, which is in turn converted to an *output message* via an output transducer. The information source can be either continuous (i.e., analog) or discrete in nature. Typical continuous information sources include speech and video, whereas discrete information sources include computer data and text. In the model of [Fig. 126.1](#) the channel comprises all of the physical media affecting the transmitted signal. Depending on the type of communication system being modeled, these media could include coaxial cables, microwave links, telephone lines, optical fibers, the electronics in the receiver, and so forth. A communication channel has essentially two characteristics that affect the ability to transmit information through it: limited **bandwidth** and noise. The bandwidth of a channel describes the maximum rate of change in the input to which the channel can respond. Obviously, this quantity limits the signaling rate that the channel can accommodate. *Noise* refers to random distortion that the channel introduces into the transmitted signal. Such noise consists of atmospheric noises arising in the physical channel connecting the transmitter and receiver, internally generated thermal noises due to random electron motion in the receiver electronics, and other effects such as amplitude fading. In addition to bandwidth limitations and noise, some channels introduce other changes, such as nonlinear distortion, into the transmitted signal.

**Figure 126.1** A general model for an electrical communication system.

We focus here on two elements of the communication system shown in Fig. 126.1—namely, the transmitter and the receiver. In most communication systems the primary purpose of the transmitter is **modulation**, and the primary purpose of the receiver is **demodulation** (or **detection**).

*Modulation* refers to the impression of the message signal onto a **carrier** signal—that is, onto a signal that is well-suited to carry the message through the channel. There are several reasons why it may be desirable to impress the message signal onto a carrier. For example, in radio channels the carrier signal lies in a frequency range that is more easily radiated than is the message signal. Also, different carriers can be used to assign different messages to different channels, or modulation can be used to place multiple messages into the same channel. A further purpose of modulation is to reduce the effects of noise and interference by creating a transmitted signal that is less susceptible to these effects than is the message signal. Carrier signals are almost always sinusoids or signals related to sinusoids, and thus modulation involves modifying the amplitude, phase, or frequency of a sinusoidal carrier in concert with the message signal. *Demodulation* or *detection* refers to the extraction of the message signal from the modulated carrier after it has passed through the channel.

The following paragraphs give an overview of the basic techniques used for modulation and demodulation in electrical communication systems. This treatment is necessarily very brief, and a number of more detailed treatments to which the reader may refer are listed at the end of the chapter.

## 126.1 Analog Modulation and Detection

Many basic electrical communication systems involve *continuous-wave* or *analog* message signals. Such signals have amplitudes that can take on values in a continuum of real numbers, and they are defined for continuous time. In this section we consider modulation techniques and corresponding detection techniques for transmitting such signals via sinusoidal carriers. Thus, we consider a message signal  $m(t)$  that we wish to impress onto a sinusoidal carrier signal

$$A_c \sin(2\pi f_c t + \phi_c) \quad (126.1)$$

to produce a transmitted signal  $x(t)$ . In order to accomplish this transmission, the message signal can be used to modulate (i.e., to change) either the amplitude,  $A_c$ , the frequency,  $f_c$ , or the phase,  $\phi_c$ , of the carrier. The first of these three possibilities is termed **linear modulation** and the second two are termed **angle modulation** (or *exponential modulation*).

Before describing these methods, we first digress briefly to provide some necessary background material.

## Linear Filtering and Fourier Transforms

Analog modulation and demodulation techniques are often most easily described in the frequency domain via the *Fourier transform*, which is a way of representing a temporal signal in terms of sinusoids. The Fourier transform  $S(f)$  of a temporal signal  $s(t)$  is defined by

$$S(f) = \int_{-\infty}^{\infty} s(t) e^{-j\omega\pi ft} dt \quad (126.2)$$

where  $j$  denotes the imaginary unit  $\sqrt{-1}$ . The value of  $S(f)$  represents the component of  $s(t)$  at frequency  $f$ . This transform can be inverted via the formula

$$s(t) = \int_{-\infty}^{\infty} S(f) e^{j2\pi ft} df \quad (126.3)$$

which displays the representation of  $s(t)$  in terms of the (continuous) superposition of the sinusoids  $\{e^{j2\pi ft}\}$ . A key property of the Fourier transform is that the Fourier transform of a *real-valued* signal is even symmetric about  $f = 0$ ; that is,  $S(f) = S(-f)$ . In general, the Fourier transform is a complex-valued function. The magnitude and phase of  $S(f)$  as functions of frequency are known as the *amplitude spectrum* and *phase spectrum*, respectively, of  $s(t)$ .

The Fourier transform is particularly useful in describing the effects of time-invariant linear filtering on signals. In particular, if a signal  $s(t)$  is passed through a time-invariant linear filter with impulse response  $h(t)$  to form the output signal

$$s_o(t) = \int_{-\infty}^{\infty} h(t - \tau) s(\tau) d\tau \quad (126.4)$$

then the Fourier transform of the output is given simply in terms of the  $S(f)$  and  $H(f)$  [the Fourier transform of  $h(t)$ ] via

$$S_o(f) = H(f) S(f) \quad (126.5)$$

The function  $H(f)$  is known as the *transfer function* of the filter. [Figure 126.2](#) illustrates two types of filters of interest: an ideal *low-pass filter* of bandwidth  $2W$ , and an ideal *band-pass filter* of bandwidth  $2W$  and center frequency  $f_c$ . Note that these filters are idealizations of actual filters that can be used in practice. Practical filters must have a smoother transition between the *passband* [i.e., the set of frequencies for which  $|H(f)| = 1$ ] and the *stopband* [the set of frequencies for which  $|H(f)| = 0$ ].

**Figure 126.2** Transfer functions of idealized filters.

(a) Ideal lowpass filter with bandwidth  $2w$

(b) Ideal bandpass filter with bandwidth  $2w$  and center frequency  $f_c$

## Linear Modulation

There are several ways in which the amplitude of a sinusoidal carrier can be modulated by a message signal. The two most basic of these are:

*Double-sideband (DSB) modulation:*

$$x_{\text{DSB}}(t) = A_c m(t) \sin(2\pi f_c t + \phi_c) \quad (126.6)$$

*Amplitude modulation (AM):*

$$x_{\text{AM}}(t) = A_c [1 + km(t)] \sin(2\pi f_c t + \phi_c) \quad (126.7)$$

where the *modulation index*,  $k$ , satisfies  $0 < k \leq 1$  and where  $m(t)$  has been scaled to satisfy  $|m(t)| \leq 1$ .

These modulation techniques are illustrated in Fig. 126.3, and the resulting signals are illustrated in Fig. 126.4 for the case in which the message signal is also a sinusoid. (In this illustration  $k = 0.75$ .)

**Figure 126.3** Basic linear analog modulation techniques.

**Figure 126.4** Illustration of waveforms arising in DSB and AM.

The multiplication of the message signal by the sinusoidal carrier has the effect of translating the *baseband* power of the message signal (i.e., the power concentrated around zero frequency) up to

power centered around the carrier frequency. This is illustrated in Fig. 126.5, which shows the Fourier transforms of a baseband message signal and of DSB and AM signals created from this message signal. An impulse in the Fourier transform (represented by a vertical arrow) denotes the transform of a sinusoid. Thus, we note that the AM signal contains a residual of the carrier, as evidenced by the impulse in its transform at the carrier frequency. A basic DSB does not have this residual carrier, although a carrier is sometimes transmitted with DSB to aid in demodulation. For this reason the basic form of DSB defined in Eq. (126.6) is sometimes known as *suppressed carrier* DSB.

**Figure 126.5** Amplitude spectra in linear modulation.

**Figure 126.5** Amplitude spectra in linear modulation.

DSB can be demodulated by multiplying the received signal by a replica of the carrier and then

passing the result through a low-pass filter whose bandwidth includes the modulated signal. This type of demodulator—known as a *coherent* detector because it uses an exact replica of the carrier—is shown in Fig. 126.6(a). [Here,  $2W$  denotes the bandwidth of the message signal  $m(t)$ .] The essential difference between DSB and AM is that AM places the message signal in the *envelope* (i.e., in the magnitude of the instantaneous amplitude) of the carrier, and thus it can be demodulated without producing a replica of the carrier. In particular, an AM demodulator is illustrated in Fig. 126.6(b). The block marked **envelope detector** refers to a circuit that outputs the envelope of its input signal. Envelope detectors are usually implemented with a half-wave rectifier (e.g., a diode) followed by a low-pass filter.

**Figure 126.6** Demodulators of linearly modulated signals.

(a) Coherent demodulator for DSB

(b) Noncoherent demodulator for AM

Note that AM could also be demodulated coherently by using a DSB demodulator followed by a circuit that eliminates the direct current (DC) or constant part of the the linear modulation,  $[1 + km(t)]$ . However, the fact that AM can be demodulated via an envelope detector is its chief virtue, since it is less efficient than other forms of linear modulation. In particular, the addition of DC to the message signal before impressing it onto the carrier results in only a fraction of the electrical power contained in an AM signal being due to the message itself. This fraction, known as the *efficiency* of the modulation waveform, is given by

$$E = \frac{k^2 \langle m^2(t) \rangle}{1 + k^2 \langle m^2(t) \rangle} \quad (126.8)$$

where

$$\langle m^2(t) \rangle = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} [m(t)]^2 dt \quad (126.9)$$

is the average power in the message signal. The AM efficiency can never be greater than 1/2, and it can achieve this maximum only for very limited types of message signals.

Each of the demodulators of Fig. 126.6 is preceded by a band-pass filter, which passes only those frequencies contained in the modulated waveform. The purpose of this filter is to eliminate extraneous noise from the receiver, an issue that will be discussed later.

Two further types of linear modulation of interest are described as follows.

### Single-Sideband (SSB) Modulation

$$x_{\text{SSB}}(t) = \frac{A_c}{2} m(t) \cos(2\pi f_c t + \phi_c) \pm \frac{A_c}{2} \hat{m}(t) \sin(2\pi f_c t + \phi_c) \quad (126.10)$$

where  $\hat{m}(t)$  is the *Hilbert transform* of the message signal:

$$\hat{m}(t) = \int_{-\infty}^{\infty} \frac{m(\tau)}{t - \tau} d\tau \quad (126.11)$$

Taking the + in  $\pm$  in SSB yields lower-sideband (LSB) modulation, and taking the – yields upper-sideband (USB) modulation. The Fourier transforms of LSB and USB signals corresponding to the example of Fig. 126.5 are shown in Fig. 126.7. The basic motive behind SSB modulation is to remove redundancy that occurs in DSB due to inclusion of both positive and negative frequencies of the message signal. Since the message signal is real valued, the symmetry of its Fourier transform renders these two sidebands redundant. Thus, SSB can transmit the same information as DSB can while using only half as much bandwidth.

**Figure 126.7** SSB spectra.

(a) USB amplitude spectrum

(b) LSB amplitude spectrum

### Vestigial Sideband (VSB) Modulation

As seen from Fig. 126.7, SSB signals are DSB signals from which one of the sidebands has been removed. It is difficult to implement circuitry for removing these sidebands completely; an alternative is *VSB modulation*, in which a vestige of the unused sideband is also included in the modulated signal. This approach results in less stringent requirements on the hardware needed, while retaining most of the advantages of SSB modulation.

### Angle Modulation

There are two basic forms of continuous angle modulation.

*Phase modulation (PM):*

$$x_{\text{PM}}(t) = A_c \sin[2\pi f_c t + k_d m(t)] \quad (126.12)$$

Here, as before,  $A_c$  and  $f_c$  are the amplitude and frequency of carrier, and  $m(t)$  is the message signal. The constant  $k_d$  is a modulation index.

*Frequency modulation (FM):*

$$x_{\text{FM}}(t) = A_c \sin \left\{ 2\pi [f_c t + f_d \int^t m(u) du] \right\} \quad (126.13)$$

Here, the constant  $f_d$  is the *frequency deviation constant*, which quantifies the amount of frequency excursion that the carrier undergoes per unit of message signal amplitude.

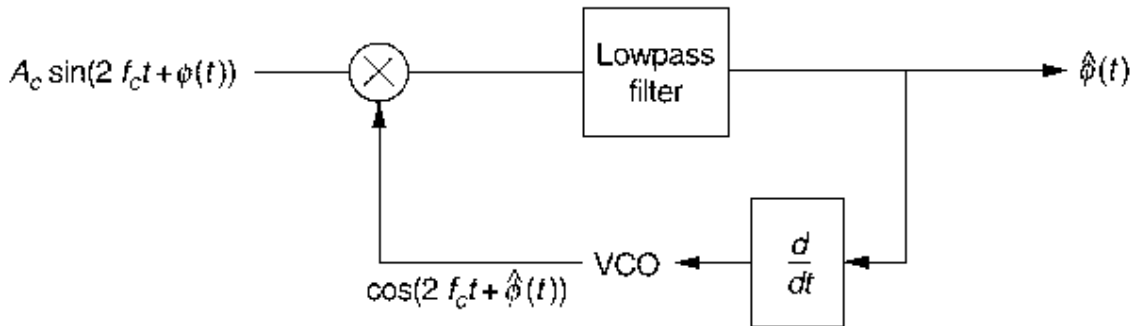

Note that PM and FM are essentially the same type of modulation, except that the frequency deviation of the carrier is proportional to the time derivative of the message signal in PM, and it is directly proportional to the message signal in FM.

A generic demodulator structure for angle modulation is shown in Fig. 126.8(a). The bandwidth  $B$  of the band-pass filter is the bandwidth of the angle-modulated signal, which can be significantly larger than the message bandwidth. The block labeled **phase detector** refers to a type of circuit that detects the instantaneous phase of its input. One such circuit is a *phase-lock loop* (PLL), which is shown in Fig. 126.8(b). The block labeled VCO refers to a *voltage-controlled oscillator*, which is a type of device that produces a sinusoidal signal whose frequency is proportional to the input voltage. Essentially, a PLL tracks the phase of a modulated sinusoid by applying feedback through a VCO. The low-pass filter in the PLL has bandwidth approximately equal to that of the phase signal  $\phi(t)$ , and the output signal  $\hat{\phi}(t)$  is an approximation of  $\phi(t)$ .

**Figure 126.8** Angle demodulation.

(a) Generic demodulator for angle-modulated signals

(b) Phase-lock loop

The Fourier transforms of angle-modulated signals are difficult to depict in generality because of the nonlinear way in which the message signal affects the carrier. However, it is generally true that,

for a given message bandwidth, angle-modulated signals typically require greater bandwidth than do linearly modulated signals. An empirical rule of thumb for the bandwidth required by FM is *Carson's rule*:

$$B \cong 2W(D + 1) \quad (126.14)$$

where  $B$  is the bandwidth of the modulated signal,  $2W$  is the bandwidth of the message signal, and  $D$  is the *deviation ratio*, given by

$$D = \frac{f_d}{W}M \quad (126.15)$$

where  $M$  is the maximum absolute value of the message signal  $m(t)$ . If  $D \ll 1$ , then  $B \cong 2W$  and the required bandwidth is approximately the same as that for DSB. Modulation of this type is called *narrowband* angle modulation. For large deviation ratios, however, angle modulation requires considerably more bandwidth than does linear modulation for the same message bandwidth. Angle modulation has advantages in defeating the nonideal effects of the channel. In particular, the fact that the transmission quality of angle modulation is unaffected by amplitude fluctuations is an advantage for channels in which there is amplitude fading. Also, the ability to spread the message over a larger bandwidth for transmission is useful in mitigating the effects of noise. This issue will be discussed further in the following section.

## Signal-to-Noise Ratio Analysis

In the preceding sections we commented on the bandwidth requirements and ease of demodulation of several modulation schemes. A further criterion differentiating such schemes is their performance in noisy channels. A measure of the quality of a waveform that consists of useful signal plus noise can be measured by the **signal-to-noise ratio (SNR)**, which is the ratio of the power contained in the useful signal to the power contained in the noise. SNR is typically expressed in *decibels* (dB), units that refer to  $10 \log_{10}$  of the actual ratio of powers.

The effectiveness of various modulation/demodulation schemes in combating noise can be compared by considering the SNR at the output of the demodulator relative to the *baseband SNR*, which is the SNR of a system that involves no modulation and demodulation. In order to compare modulation schemes on this basis, it is common to assume that the channel is corrupted by **additive white Gaussian noise (AWGN)**. AWGN is an additive random noise process that delivers a constant density (i.e., power per unit frequency) of power across all frequencies and whose amplitude statistics obey a normal (or Gaussian) probability distribution. This assumption provides a useful model for many types of noise-corrupting communication signals.

Relative SNRs for various demodulators in AWGN channels are shown in [Table 126.1](#). The values shown in this table for PM, FM, and envelope-detected AM are approximations valid only for large SNRs. From this table we see that DSB and SSB are superior to AM, whose relative SNR is twice the AM efficiency (and hence is never greater than 1). Also, DSB and SSB have

equivalent performance even though SSB requires only half the bandwidth required by DSB. It is also interesting that coherently detected AM and envelope-detected AM have identical performance for sufficiently large received SNR (greater than 10 dB). For received SNRs below 10 dB, the relative SNR of envelope detection is very poor. Similarly, note that for large received SNRs, the quality of demodulated FM signals can be made arbitrarily large at the expense of increased transmitted bandwidth (i.e., increased deviation ratio  $D$ ). As with AM, the performance of PM and FM degrades dramatically if the received SNR is not sufficiently high.

**Table 126.1** SNRs Relative to Baseband for Analog Modulation/Demodulation Techniques

Modulator/Demodulator	Relative SNR
DSB/SSB	1
Coherent AM	$\frac{k^2 \langle m^2(t) \rangle}{1 + k^2 \langle m^2(t) \rangle}$
Envelope-detected AM (large SNR)	$\frac{k^2 \langle m^2(t) \rangle}{1 + k^2 \langle m^2(t) \rangle}$
PM (large SNR)	$k_p^2 \langle m^2(t) \rangle$
FM (large SNR)	$3 \left( \frac{f_d}{W} \right)^2 \langle m^2(t) \rangle$

## 126.2 Digital Modulation and Detection

It is often advantageous to transmit messages as digital data. This approach allows greater flexibility in protecting the data from noise and other nonideal effects of the channel through the use of *error-control* (or channel) coding (see **Chapter 127**), and it also often allows greater efficiency in terms of usage of channel bandwidth through the use of *data compression* (or source coding). Some types of message sources, such as computer data or text, are inherently digital in nature. However, continuous information sources such as speech and images can be converted into digital data for transmission. This process involves *analog-to-digital* (A/D) conversion—that is, *time sampling* to convert the continuous-time message signal to a discrete-time message—and *amplitude quantization* to map the continuous amplitudes of the message signal into a finite set of values. In order to preserve the fidelity of the source, it is necessary that the sampling rate be sufficiently high to prevent loss of information and that the quantization be sufficiently fine to prevent undue distortion. [A minimum sampling rate to capture the message in discrete time is twice the bandwidth of the message (a rate known as the *Nyquist rate*).] Once the message is in digital form it can be converted to a sequence of binary words for transmission by encoding its discrete amplitude values. Modulation schemes that transmit analog messages in this way are known as *pulse code modulation* (PCM) schemes.

A number of forms of modulation can be used to transmit data through a communication channel. The most basic of these transmit a single binary digit (1 or 0) in each of a sequence of symbol intervals of duration  $T$ , where  $T$  is the reciprocal of the data rate (expressed in bits per second). To use such a scheme, the data sequence of binary words can be converted to a sequence

of bits via parallel-to-serial conversion. Most binary transmission schemes can be described in terms of two waveforms,  $x^{(0)}(t)$  and  $x^{(1)}(t)$ , where the transmitted waveform  $x(t)$  equals  $x^{(0)}(t)$  in a given symbol interval if the corresponding data bit is a 0, and  $x(t)$  equals  $x^{(1)}(t)$  if the corresponding data bit is a 1.

As with analog modulation, the basic manner in which most binary modulation procedures couple the data sequence to the channel is to impress it onto a sinusoidal carrier. Thus, we can have digital modulation schemes based on amplitude, phase, or frequency modulation, and the waveforms  $x^{(0)}(t)$  and  $x^{(1)}(t)$  are chosen accordingly to modify a basic carrier waveform  $A_c \sin(2\pi f_c t + \phi_c)$ , where  $A_c$ ,  $f_c$ , and  $\phi_c$  are, respectively, the amplitude, frequency, and phase of the carrier. Several fundamental techniques of this type are described in the following paragraphs.

## On-Off Keying (OOK)

OOK is the simplest type of binary modulation. It transmits the signal

$$x_{\text{OOK}}^{(1)}(t) = A_c \sin(2\pi f_c t + \phi_c) \quad (126.16)$$

in a given symbol interval if the corresponding data bit is a 1, and it transmits nothing, that is,

$$x_{\text{OOK}}^{(0)}(t) = 0 \quad (126.17)$$

if the corresponding data bit is a 0. An OOK waveform is illustrated in [Fig. 126.9](#). OOK is a form of *amplitude-shift keying* (ASK) since it "keys" (i.e., modulates) the carrier by shifting its amplitude by an amount depending on the polarity of the data bit. ASK waveforms other than the "on-off" version described here can also be used.

**Figure 126.9** Digital modulation waveforms for transmitting the bit sequence 101101 ( $T = 200$ ).

OOK can be demodulated either coherently (i.e., with knowledge of the carrier phase), as shown in Fig. 126.10 (a), or noncoherently (i.e., without knowledge of the carrier phase) as shown in Fig. 126.10(b). In either case the output of the detector (coherent or noncoherent) is sampled at the end of each symbol interval and compared with a threshold. If this output exceeds the threshold for a given sampling time, then the corresponding data symbol is detected as a 1; otherwise, this symbol is detected as a 0. (In a coherent detector, the integrator is "quenched"—that is, reset to 0—as it is sampled.) Errors occur in these systems because the noise in the channel can move the output of the detector to the incorrect side of the threshold. The proper choice of the threshold to minimize this effect, and the corresponding rate of bit errors, are discussed below.

**Figure 126.10** Demodulation of OOK.

(a) Coherent demodulator for OOK (and BPSK)

(b) Noncoherent demodulator for OOK

## Phase-Shift Keying (PSK)

As its name suggests, PSK uses the phase of the carrier to encode the binary data to be transmitted. The basic forms of PSK are described in the following sections.

### Binary PSK (BPSK)

This form of modulation uses the following waveforms:

$$x_{\text{BPSK}}^{(1)}(t) = A_c \sin(2\pi f_c t + \phi_c) \quad (126.18)$$

$$x_{\text{BPSK}}^{(0)}(t) = A_c \sin(2\pi f_c t + \phi_c + \pi) \equiv -A_c \sin(2\pi f_c t + \phi_c) \quad (126.19)$$

A BPSK waveform is illustrated in Fig. 126.9. This type modulation uses antipodal signaling [i.e.,  $x^{(0)}(t) = -x^{(1)}(t)$ ]. Note that BPSK is also a form of ASK, in which the two amplitudes are  $\pm 1$ .

Since the information in BPSK is contained in the carrier phase, it is necessary to use coherent detection in order to accurately demodulate BPSK. The demodulator of Fig. 126.10(a) can be used to perform this demodulation. In the case of BPSK the decision threshold can be taken to be zero due to the antipodal nature of the signaling.

### Differential PSK (DPSK)

The necessity of knowing the carrier for demodulation of BPSK is a disadvantage that can be overcome by the use of DPSK. In a given bit interval (say the  $k$ th one), DPSK uses the following

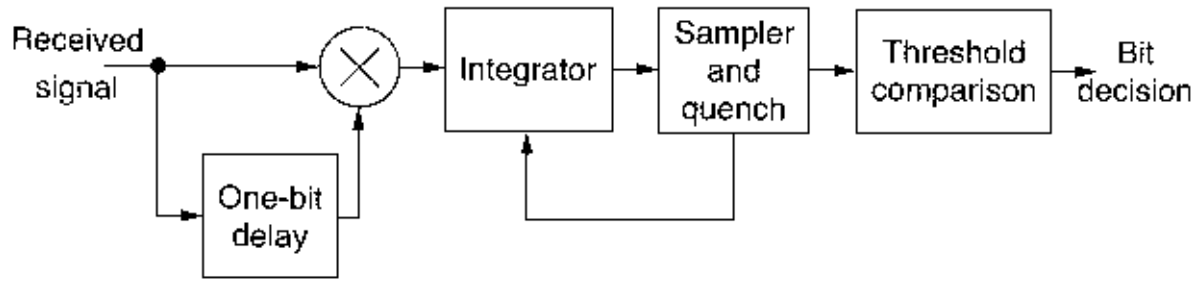

waveforms,

$$x_{\text{DPSK}}^{(1)}(t) = A_c \sin(2\pi f_c t + \phi_{k-1}) \quad (126.20)$$

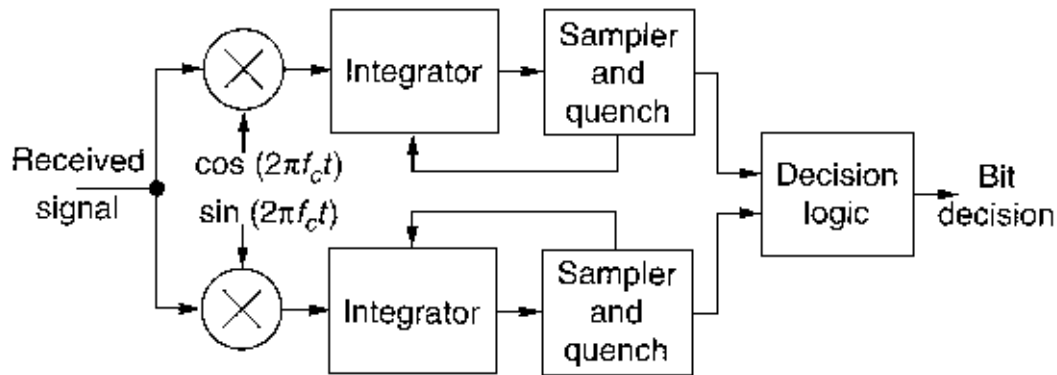

$$x_{\text{DPSK}}^{(0)}(t) = A_c \sin(2\pi f_c t + \phi_{k-1} + \pi) \quad (126.21)$$

where  $\phi_{k-1}$  denotes the phase transmitted in the *preceding* bit interval (i.e., the  $(k - 1)$  th bit interval). Thus, the information is encoded in the difference between the phases in succeeding bit intervals rather than in the absolute phase, as illustrated in Fig. 126.9. (DPSK requires an initial reference bit, which is taken to be 1 in the illustration.) This step allows for noncoherent demodulation of DPSK, as shown in Fig. 126.11.

**Figure 126.11** Demodulation of DPSK.

(a) Suboptimum demodulator for DPSK

(b) Optimum demodulator for DPSK

Note that the demodulator in Fig. 126.11(a) does not require knowledge of the carrier phase or frequency, whereas that in Fig. 126.11(b) requires knowledge of the carrier frequency but not its phase. The block marked "decision logic" in Fig. 126.11(b) makes each bit decision based on two successive pairs of outputs of the two channels that provide its inputs. In particular, the  $k$ th bit is

demodulated as a 1 if  $p_k p_{k-1} + q_k q_{k-1} > 0$  and as a 0 otherwise, where  $p_k$  and  $p_{k-1}$  are the outputs of the upper channel (known as *in-phase* channel) at the end of the  $k$ th and  $(k - 1)$  th bit intervals, respectively, and where  $q_k$  and  $q_{k-1}$  are the corresponding outputs of the lower channel (the *quadrature* channel). The second of these demodulators is actually optimum for demodulating DPSK and, as such, exhibits performance advantages over the first. This performance comes in exchange for the obvious disadvantage of requiring carrier-frequency reference signals at the receiver.

### Quadrature PSK (QPSK)

The bandwidth efficiency of BPSK can be improved by taking advantage of the fact that there is another pair of antipodal signals, namely,

$$A_c \cos(2\pi f_c t + \phi_c) \quad (126.22)$$

$$A_c \cos(2\pi f_c t + \phi_c + \pi) \quad (126.23)$$

that have the same frequency as the two signals used in BPSK [i.e.,  $x_{\text{BPSK}}^{(1)}(t)$  and  $x_{\text{BPSK}}^{(0)}(t)$  of Eqs. (126.18) and (126.19)] while being completely orthogonal to those signals. By using all four of these signals, two bits can be sent in each symbol interval, thereby doubling the transmitted bit rate. Such a signaling scheme is known as *QPSK* because it involves the simultaneous transmission of two BPSKs in quadrature (i.e., 90 degrees out of phase). Although the performance in terms of bit-error of rate of QPSK is the same as that for BPSK, QPSK has the advantage of requiring half the bandwidth needed by BPSK to transmit at the same bit rate. This situation is directly analogous to that involving DSB and SSB analog modulation, the latter of which uses two quadrature signals to transmit the same information as the former does, while using only half the bandwidth.

Note that QPSK is a form of  $M$ -ary signaling, in which  $\log_2 M$  bits are transmitted in each symbol interval by selecting among  $M$  possible waveforms,  $x^{(0)}(t), x^{(1)}(t), \dots, x^{(M-1)}(t)$ . In QPSK we have the case  $M = 4$  and the waveforms are four sinusoids having the same frequency and having phases separated by 90 degrees. QPSK can be generalized by allowing more than four separate phases and also by allowing modulation types other than PSK. Such techniques are widely used in modern digital communication systems such as high-speed data modems.

### Frequency-Shift Keying (FSK)

FSK transmits binary data by sending one of two distinct frequencies in each bit interval, depending on the polarity of the bit to be transmitted. This scheme can be described in terms of the two signaling waveforms,

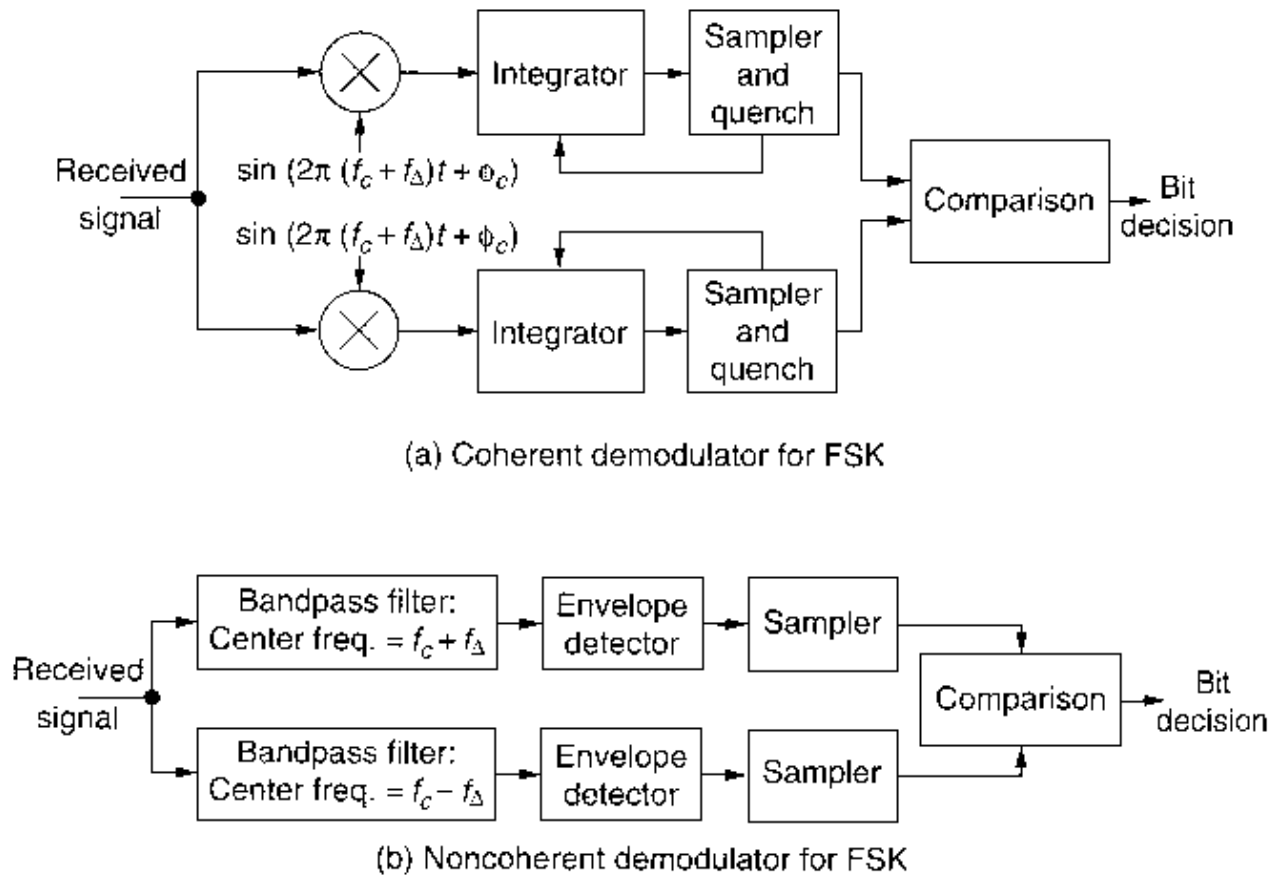

$$x_{\text{FSK}}^{(1)}(t) = A_c \sin(2\pi(f_c + f_\Delta)t + \phi_c) \quad (126.24)$$

$$x_{\text{FSK}}^{(0)}(t) = A_c \sin(2\pi(f_c - f_\Delta)t + \phi_c) \quad (126.25)$$

where  $f_\Delta$  is a constant. An FSK waveform is illustrated in Fig. 126.9.

FSK can be demodulated either coherently or noncoherently, as shown in Fig. 126.12. In these demodulators the block marked "comparison" chooses the bit decision as a 1 if the upper-channel output is larger than the lower-channel output and as a 0 otherwise. Note that, when noncoherent demodulation is to be used (as is very commonly the case), it is not necessary that the carrier phase be maintained from bit interval to bit interval. This simplifies the design of the modulator and makes noncoherent FSK one of the simplest types of digital modulation. It should be noted, however, that FSK generally requires greater bandwidth than do the other forms of digital modulation described above.

**Figure 126.12** Demodulation of FSK.

## Bit-Error Rates and Bandwidth Efficiency

The various binary modulation/demodulation types described above can be compared by analyzing

their **bit-error rates (BERs)** or bit-error probabilities—that is, the probabilities with which they incur errors in receiving bits. As in the analysis of analog modulation/demodulation, this comparison is commonly done by assuming that the channel is corrupted by AWGN. In this case and under the further assumption that the symbols 0 and 1 are equally likely to occur in the message, expressions for the bit-error probabilities of the various schemes described above are shown in [Table 126.2](#). These results are given as functions of the SNR parameter,  $E_b/N_0$ , where  $E_b$  is the signal energy received per bit and  $N_0/2$  is the spectral density of the AWGN. In some cases the expressions involve the function  $Q$ , which denotes the tail probability of a standard normal probability distribution:

$$Q(x) \triangleq \frac{1}{\sqrt{2\pi}} \int_x^{\infty} e^{-y^2/2} dy$$

The expressions for OOK assume that the decision threshold in the demodulators have been optimized. This optimization requires knowledge of the received SNR, which makes OOK the only one of these techniques that requires this information for demodulation. The expression for noncoherent OOK is an approximation that is valid for large SNRs. The result for DPSK corresponds to the optimum demodulator depicted in [Fig. 126.11\(b\)](#). The suboptimum DPSK demodulator of [Fig. 126.11\(a\)](#) requires approximately 2 dB higher values of  $E_b/N_0$  in order to achieve the same performance as the optimum demodulator.

**Table 126.2** Bit-Error Probabilities and Bandwidth Efficiencies for Digital Modulation/Demodulation Techniques

Modulator/Demodulator	Bit-Error Probability	Bandwidth Efficiency
BPSK	$Q(\sqrt{2E_b/N_0})$	1/2 (bits/s)/hertz
QPSK	$Q(\sqrt{2E_b/N_0})$	1
Optimum DPSK	$(1/2)e^{-E_b/N_0}$	1/2
Coherent OOK	$Q(\sqrt{E_b/N_0})$	1/2
Coherent FSK	$Q(\sqrt{E_b/N_0})$	1/3
Noncoherent OOK	$(1/2)e^{-E_b/2N_0}$	1/2
Noncoherent FSK	$(1/2)e^{-E_b/2N_0}$	1/3

The quantities of [Table 126.2](#) are plotted in [Fig. 126.13](#). From this figure we see that BPSK is the best performing of these schemes, followed, in order, by DPSK, coherent OOK and FSK, and noncoherent OOK and FSK. The superiority of BPSK is due to its use of antipodal signals, which can be shown to be an optimum choice in this respect for signaling through an AWGN channel. DPSK exhibits a small loss relative to BPSK, which is compensated for by its simpler demodulation. OOK and FSK are both examples of *orthogonal* signaling schemes (i.e., schemes in which  $\int x^{(0)}(t)x^{(1)}(t) dt = 0$ , where the integration is performed over a single bit interval), which explains why they exhibit the same performance. Orthogonal signaling is less efficient than antipodal signaling, which is evident from [Fig. 126.13](#). Finally, note that there is a small loss in performance for these two orthogonal signaling schemes when they are demodulated

noncoherently. Generally speaking, DPSK and noncoherent FSK are seen from this comparison to be quite utilitarian. They each require less than a single dB more of received SNR to achieve the same performance as the best antipodal and orthogonal signaling schemes, respectively, while allowing relatively simple demodulation. For these reasons these two schemes are quite commonly used in practice.

**Figure 126.13** Bit-error probabilities for digital communication systems.

In addition to bit-error rate, digital communication systems can also be compared in terms of bandwidth efficiency, which is often quantified in terms of the number of bits per second that can be transmitted per hertz of bandwidth. Bandwidth efficiencies for the various signaling schemes are also shown in [Table 126.2](#).

## 126.3 Further Issues

There are many types of modulation and demodulation used in practice other than those described

in the preceding sections. Some of these are discussed briefly in the following paragraphs.

## Pulse Modulation

A general class of modulation techniques that are used to transmit analog messages in discrete time are known as *pulse modulation* schemes. Such techniques convert an analog message signal into a discrete-time one by time sampling, and then transmit these time samples by using them to modulate the properties of a train of pulses. Techniques in this category include *pulse-amplitude modulation* (PAM), *pulse-width modulation* (PWM), and *pulse-position modulation* (PPM), whose characteristics can be inferred from their names.

Recall that we have already mentioned *pulse-code* modulation, in which the amplitudes of the time-sampled message are quantized and encoded for digital transmission. Two forms of PCM that are commonly used in practice are *delta* modulation (DM) and *differential* PCM (DPCM), which encode message samples by digitally representing the *change* in the message from sampling time to sampling time. This change can be measured in terms of a direct difference or, more commonly, as the difference between the sample at one time and a value of that sample predicted from past values through the use of a prediction algorithm. These techniques generally require fewer data bits to represent each message sample, at the expense of somewhat higher sampling rate requirements. Differential encoding techniques are particularly effective in transmitting speech signals, which contain considerable redundancy that can be removed through such encoding.

## Multiplexing and Multiple Access

As noted early in the chapter, one purpose of modulation is *multiplexing*, which refers to the simultaneous transmission of multiple message signals through a single channel (i.e., on a single carrier frequency). One form of multiplexing is *quadrature* multiplexing (QM), such as that employed in QPSK, in which two orthogonal carriers of the same frequency are employed. In addition to this form of multiplexing, there are two other basic types: *frequency-division* multiplexing (FDM) and *time-division* multiplexing (TDM). FDM involves the modulation of the message signals to be multiplexed onto distinct low-frequency carriers, which are then added to form a bulk baseband signal that is modulated onto the main carrier. The low-frequency carriers, known as *subcarriers*, must be spaced sufficiently far apart in frequency to prevent overlap of the various message signals when the bulk signal is formed. TDM involves, instead, the interlacing in time of samples from a group of (discrete-time) message signals to form a bulk baseband signal to be modulated onto the main carrier.

A process related to multiplexing is *multiple-access* transmission. Like multiplexing, multiple-access transmission involves the sharing of channel resources by multiple message sources, or *users*. However, whereas *multiplexing* usually refers to the situation in which the multiple messages are combined centrally for transmission, multiple-access transmission allows each message source to access the channel remotely and independently of the other sources. (An example of an application of multiple-access communications is a cellular telephony system.) Commonly used multiple-access techniques include *frequency-division* multiple access (FDMA)

and *time-division* multiple access (TDMA), which divide the channel among the users on the basis of frequency and time, respectively (analogous to FDM and TDM). A further basic type of multiple-access technique is code-division multiple access (CDMA), which divides the channel by encoding each user in a way that a receiver can distinguish it from the other users.

## Spread-Spectrum Signaling

CDMA is usually implemented through the use of *spread-spectrum signaling*, which refers to signaling techniques in which the bandwidth of the signal transmitted by a given user is much larger than the bandwidth required for the user's message signal. There are two basic ways in which spread spectrum can be implemented: *direct-sequence* spread spectrum (DSSS) and *frequency-hopping* spread spectrum (FHSS).

In DSSS the message signal to be transmitted by a given user is multiplied (before modulation onto the carrier) by a signal (known as a *pseudonoise* or PN signal) whose Fourier transform is constant over the entire bandwidth of the shared channel and whose amplitude is always  $\pm 1$ . The resulting transmitted signal uniformly occupies the entire bandwidth of the shared channel. A receiver knowing the PN signal can recover the original message signal by removing the carrier and multiplying the remaining signal by the PN signal. Since the amplitude of the PN signal is always 1, this multiplication removes the PN signal from the message signal, allowing the latter to be detected. In this way all users can in principle share all of the bandwidth of the channel all of the time. Interference among users is kept at a minimum by assigning a unique PN signal to each user in the channel and by choosing this set of PN signals appropriately. Although the use of this type of modulation does not, of course, create new bandwidth for message transmission, it does permit effective use of bandwidth in channels (such as cellular telephony channels) in which the traffic is sporadic or in which there is significant amplitude fading. DSSS signaling also offers other advantages over narrowband communication systems, including a greater degree of privacy and greater immunity to certain types of noise and interference.

As can be inferred from its name, FHSS performs spectrum spreading by changing the carrier frequency used by an individual user in a regular pattern while the user is transmitting its message. Each user's frequency "hops" from frequency to frequency in a distinct pattern, and the choice of the set of "hopping patterns" is used to prevent undue interference among the active users in the channel.

## Sequences of Symbols

The digital modulation and demodulation techniques described thus far involve the modulation and demodulation of a single symbol at a time. In some circumstances, though, it is desirable (or necessary) to modulate or to demodulate strings of symbols taken as a group. This can be done at the transmitter for the purposes of coding (resulting in *coded modulation*) or at the receiver for the purposes of correcting nonideal effects of the channel. Among techniques falling into this latter category is *equalization*, which is applied to undo the effects of symbol mixing in the channel [known as *intersymbol interference* (ISI)]. Discussions of these and other advanced methods can

be found in the sources cited at the end of the chapter.

## Implementation Issues

A further important issue that has not been discussed in this chapter, is the implementation of the various devices that comprise the modulators and demodulators described herein. For example, in general, none of the received carrier parameters (amplitude, frequency, and phase) can be assumed to be known at the receiver without special provision for determining them, since none of these parameters may coincide with their transmitted counterparts. Certainly the amplitude and phase of the carrier will be modified by the channel simply by attenuation and time delay, and the frequency may also be modified by Doppler shift if the transmitter and receiver are moving relative to one another. Likewise, the digital transmission the timing of the symbol sequence (which must be known for choosing the correct sampling times to detect the data) is not generally known in advance by the receiver. Thus, in order to employ any of this information in demodulation, it is necessary to provide means for acquiring it. Moreover, devices for performing carrier generation and multiplication, phase detection, envelope detection, and so forth require special consideration.

## Defining Terms

**Additive white Gaussian noise (AWGN):** An additive random noise process that delivers a constant density (i.e., power per unit frequency) of power across all frequencies and whose amplitude statistics obey a normal (or Gaussian) probability distribution.

**Angle modulation:** The impression of a message onto a sinusoidal carrier by varying the phase of the carrier. Types of angle modulation include phase modulation (PM), frequency modulation (FM), phase-shift keying (PSK), and frequency-shift keying (FSK).

**Bandwidth:** For a *channel*, the property of the channel that describes the maximum rate of change in the input to which the channel can respond. This quantity limits the signaling rate that the channel can accommodate. For a *signal*, the width of its amplitude spectrum in the frequency domain. For a *filter*, the width of its passband.

**Bit-error rate (BER):** The rate at which a digital communication system incurs bit errors.

**Carrier:** A signal onto which a message signal is impressed for the purposes of transmitting the message signal through a communication channel.

**Channel:** The medium through which a message is to be transmitted by a communication system.

**Demodulation/detection:** The process of extracting a message signal from a modulated carrier.

**Envelope detector:** A device whose output is the instantaneous magnitude of an input sinusoidal signal.

**Linear modulation:** The impression of a message onto a sinusoidal carrier by varying the amplitude of the carrier. Types of linear modulation include double sideband (DSB),

amplitude modulation (AM), single sideband (SSB), vestigial sideband (VSB), amplitude-shift keying (ASK), and on-off keying (OOK).

**Message signal:** A signal containing the information to be transmitted by a communication system.

**Modulation:** The process of impressing a message signal onto a carrier.

**Phase detector:** A device whose output is the instantaneous phase of an input sinusoidal signal.

**Receiver:** An element of a communication system that extracts the message signal from the signal received at the output of the channel.

**Signal-to-noise ratio (SNR):** A measure of the quality of a noisy signal, defined as the ratio of the power contained in the useful part of the signal to the power contained in the noise. SNR is typically expressed in *decibels* (dB), whose units refer to  $10 \log_{10}$  of the actual ratio of powers.

**Transmitter:** An element of a communication system that couples the message signal to the channel.

## Coding

---

### 127.1 Block Codes

### 127.2 Convolutional Codes

### 127.3 Trellis-Coded Modulation

**Scott L. Miller**

*University of Florida*

**Leon W. Couch II**

*University of Florida*

Error correction coding involves adding redundant symbols to a data stream in order to allow for reliable transmission in the presence of channel errors. Error correction codes fall into two main classes: block codes and convolutional codes. In block codes the code word is only a function of the current data input, whereas in convolutional codes the current output is a function of not only the current data input but also of previous data inputs. Thus a convolutional code has memory, whereas a block code is memoryless. Codes can also be classified according to their code rate, symbol alphabet size, error detection/correction capability, and complexity. The code rate determines the extra bandwidth needed and also the reduction in energy per transmitted symbol relative to an uncoded system. The alphabet size is usually either two (binary) or a power of two. When the alphabet size is binary, the symbol is called a bit. Codes can be made either to detect or to correct errors or some combination of both and also can be made to detect/correct either random errors or burst errors. The complexity of a code is usually a function of the decoding procedure that is used, so the most popular codes are those that can be decoded in a relatively simple manner and still provide good error correction capability.

## 127.1 Block Codes

---

An  $(n, k)$  block code is a mapping of a  $k$  symbol information word into an  $n$  symbol code word. The code is said to be systematic if the first  $k$  symbols in the code word are the information word. In an  $(n, k)$  code,  $n - k$  symbols are redundant and are often referred to as *parity symbols*. The code rate,  $R$ , is defined as  $R = k/n$ . An important parameter of a block code is its minimum distance,  $d_{\min}$ , which is defined as the minimum Hamming distance between any two code words. (Hamming distance is the number of places in which two code words disagree.) A code with a minimum distance of  $d_{\min}$  can guarantee to correct any pattern of  $t = \lfloor (d_{\min} - 1)/2 \rfloor$  or fewer

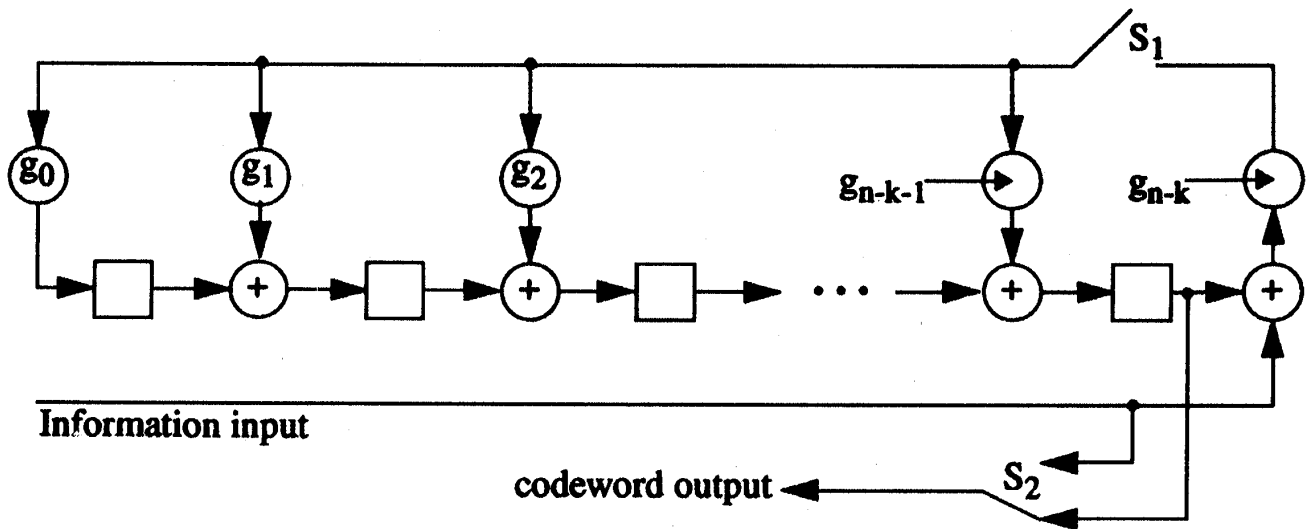

errors. Alternatively, the code can guarantee to detect any error pattern consisting of  $s = d_{\min} - 1$  or fewer errors. If simultaneous error detection and correction is desired, the minimum distance of the code must be such that  $d_{\min} \geq s + t + 1$ .

Most block codes used in practice are linear (or group) codes. In a linear code the set of code words must form a mathematical group. Most importantly, the sum of any two code words must itself be a code word. Encoding of linear block codes is accomplished by multiplying the  $k$  symbol information word by an  $n \times k$  matrix (known as a generator matrix) forming an  $n$  symbol code word. To decode, a received word is multiplied by an  $n \times (n - k)$  matrix (known as a *parity check matrix*) to form an  $n - k$  symbol vector known as the *syndrome*. A look-up table is then used to find the error pattern that corresponds to the given syndrome and that error pattern is subtracted from the received word to form the decoded word. The parity (redundant) symbols are then removed to form the decoded information word. In general, unless the number of parity symbols ( $n - k$ ) of a linear code is very small, syndrome decoding is too complicated and so codes with a simpler decoding procedure are used.

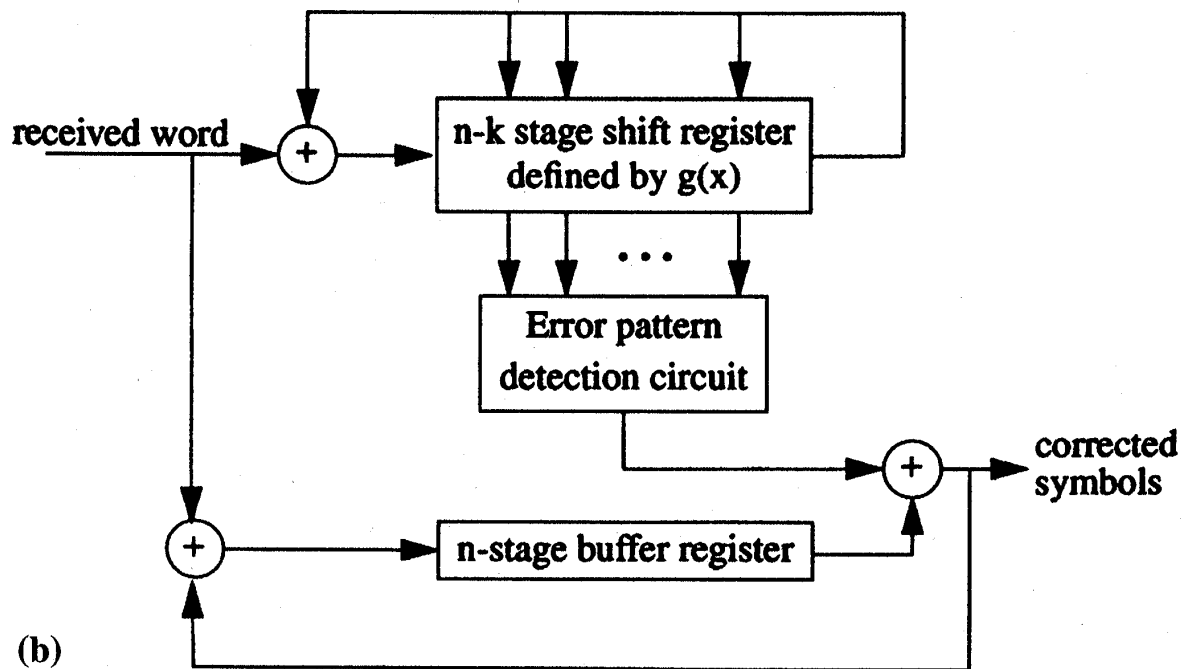

A cyclic code is a group code that has the additional property that any cyclic shift of a code word produces another code word. A cyclic code is specified by a generator polynomial, which is a polynomial of order  $n - k$  of the form  $g(x) = g_0 + g_1x + \cdots + g_{n-k}x^{n-k}$ , or by its parity check polynomial,  $h(x)$ , which is related to  $g(x)$  by  $g(x)h(x) = x^n - 1$ . The code is encoded with a division circuit (a linear feedback shift register) as shown in Fig. 127.1(a). In that circuit, switches  $S_1$  and  $S_2$  are in the closed and up positions, respectively, until the  $k$  data symbols are clocked in. After that, the two switches are flipped and the parity symbols are read out. The received sequence can be decoded using a similar circuit known as the *Meggitt decoder*, shown in Fig. 127.1(b). Most of the complexity of the decoder is in the error pattern detector, which must recognize all correctable error patterns with errors in the last position. For a single-error correcting code this can be implemented with a multiple-input AND gate, but for codes with large error correction capability the number of error patterns that must be recognized becomes unfeasible.

A technique known as *error-trapping decoding* can be used to simplify the error pattern detector of the Meggitt decoder, but again, this technique only works for short codes with low error correcting capability. Error trapping is quite effective for decoding burst error correcting codes and also works nicely on the well-known Golay code. When longer codes with high error correction capability are needed, it is common to consider various subclasses of cyclic group codes that lead to implementable decoding algorithms. One such subclass that is extremely popular comprises the BCH codes. Since BCH codes are cyclic codes, they can be encoded with the same general encoder shown in Fig. 127.1(a). In addition, a well-known technique called the *Berlekamp algorithm* can be used to decode BCH codes. The Berlekamp algorithm is fast and easy to implement, but it is not a maximum likelihood decoding technique, and so it does not always take advantage of the full error correcting capability of the code. In addition, it is often desirable for a demodulator to feed soft decisions on to the decoder. This will usually enable the decoder to make a more reliable decision about which symbols are in error. A demodulator is said to make soft decisions when it quantizes its output into an alphabet size larger than the size of the transmitted symbol set. All of the standard techniques for decoding block codes suffer from the fact that they cannot be used on soft decisions; this is the main reason why convolutional codes are often preferred.

**Figure 127.1** (a) Encoder for a cyclic group code; (b) Meggitt decoder for cyclic group codes.

(a)

(b)

For a memoryless channel with an error rate of  $p$ , the probability of decoding error,  $P_d$ , for an  $(n, k)t$ - error correcting code is given by

$$P_d = \sum_{i=t+1}^n \binom{n}{i} p^i (1-p)^{n-i} = 1 - \sum_{i=0}^t \binom{n}{i} p^i (1-p)^{n-i}$$

Finding exact expressions for the probability of a symbol error,  $P_s$  (i.e., probability of bit error or bit-error rate for the case of binary symbols), is generally not tractable, but the following bounds work quite well:

$$\frac{d_{\min}}{n} P_d \leq P_s \leq \sum_{i=t+1}^n \binom{n}{i} \frac{i+t}{n} p^i (1-p)^{n-i}$$

Another method of specifying the performance of an error correction coding scheme focuses on coding gain. Coding gain is the reduction in dB of required signal-to-noise ratio needed to achieve a given error rate relative to an uncoded system. Specifically, if an uncoded system needs an energy per bit of  $E_u(P_s)$  to achieve a symbol error rate of  $P_s$ , and a coded system requires  $E_c(P_s)$ , the coding gain is

$$\gamma(P_s) = 10 \log \{ [E_u(P_s)] / [E_c(P_s)] \} \text{ dB}$$

The asymptotic coding gain is the coding gain measured in the limit as  $P_s$  goes to zero and is given for a Gaussian noise channel by

$$\gamma = \lim_{P_s \rightarrow 0} \gamma(P_s) = 10 \log \left( \frac{k}{n} (t+1) \right) \text{ dB}$$

## 127.2 Convolutional Codes

---

In a convolutional code, as in a block code, for each  $k$  information symbols,  $n - k$  redundant symbols are added to produce  $n$  code symbols and the ratio of  $k/n$  is referred to as the code rate,  $R$ . The mapping, however, is not memoryless, and each group of  $n$  code symbols is a function of not only the current  $k$  input symbols but also the previous  $K - 1$  blocks of  $k$  input symbols. The parameter  $K$  is known as the *constraint length*. The parameters  $n$  and  $k$  are usually small and the code word length is arbitrary (and potentially infinite). As with block codes, the ability to correct errors is determined by  $d_{\min}$ , but in the case of convolutional codes this quantity is generally referred to as the *free distance*,  $d_{\text{free}}$ . Although the error correction capability,  $t$ , has the same relationship to  $d_{\text{free}}$  as in block codes, this quantity has little significance in the context of convolutional codes.

A convolutional code is generated using a feed-forward shift register. An example of the structure for the convolutional encoder is shown in Fig. 127.2(a) for a code with  $R = 1/2$  and  $K = 3$ . In general, for each group of  $k$  symbols input to the encoder,  $n$  symbols are taken from the output. A convolutional code can be described graphically in terms of a state diagram or a trellis diagram, as shown in Figs. 127.2(b) and 127.2(c) for the encoder of Fig. 127.2(a). The state diagram represents the operation of the encoder, whereas the trellis diagram illustrates all the possible code sequences. The states in both the state and trellis diagrams represent the contents of the shift register in the encoder, and the branches are labeled with the code output corresponding to that state transition.

**Figure 127.2** A rate  $1/2$ ,  $K = 3$  convolutional encoder.

The optimum (maximum likelihood) method for decoding convolutional codes is the Viterbi algorithm, which is nothing more than an efficient way to search through the trellis diagram for the most likely transmitted code word. This technique can be used equally well with either hard or soft channel decisions and has a complexity that is exponential in the constraint length. As a result the Viterbi algorithm can be used only on codes with a moderate constraint length (currently about  $K \leq 10$ ). For most applications this limit on  $K$  is not too severe and so Viterbi decoding is used almost exclusively. If a larger constraint length is needed, several suboptimal decoding algorithms exist whose complexities do not depend on the constraint length. Sequential decoding techniques such as the Stack and Fano algorithms are generally nearly optimum in terms of performance and faster than Viterbi decoding, whereas majority logic decoding is very fast, but generally gives substantially worse performance.

The performance of a convolutionally encoded system is specified in terms of the decoded symbol error probability or in terms of a coding gain, as defined in section 127.1. An exact result for the error probability cannot be easily found but a good upper bound is provided through the use of transfer functions. To find the transfer function for a given code, an augmented state diagram is

produced from the original state diagram of the code by splitting the all-zero state into a starting and ending state and labeling each branch with  $W^w I^i$ —where  $w$  is the Hamming weight of the output sequence on that branch,  $i$  is the Hamming weight of the input that caused that transition, and  $W$  and  $I$  are dummy variables. The transfer function of the code is then given by applying Mason's gain formula to the augmented state diagram. The augmented state diagram and the transfer function for the encoder in Fig. 127.2(a) are shown in Figs. 127.2(d) and 127.2(e). The probability of decoded symbol error can be found from the transfer function by

$$P_e \leq \frac{1}{k} \frac{\partial}{\partial I} T(W, I) \Big|_{I=1, W=Z}$$

The parameter  $Z$  that appears in this equation is a function of the channel being used. For a binary symmetric channel (BSC),  $Z = \sqrt{4p(1-p)}$ , where  $p$  is the crossover probability of the channel; for an additive white Gaussian noise (AWGN) channel with antipodal signaling,  $Z = \exp(-E_s/N_o)$ , where  $E_s$  is the average energy per symbol and  $N_o/2$  is the two-sided power spectral density of the noise.

Although the given bound is convenient because it is general, it is often not very tight. A tighter bound can be obtained for various channel models. For example, for the AWGN channel, a tighter bound is

$$P_e \leq \frac{1}{k} \exp\left(\frac{d_{\text{free}} E_s}{N_o}\right) Q\left(\sqrt{\frac{2d_{\text{free}} E_s}{N_o}}\right) \frac{\partial}{\partial I} T(W, I) \Big|_{I=1, W=\exp(-E_s/N_o)}$$

This bound generally gives a good estimate of the true error probability, at least for high values of  $E_s/N_o$ . For complex codes (long constraint length) calculating the transfer function can be tedious. In that case it is common to use a lower bound that involves just the first term in the Taylor series expansion of the transfer function, resulting in

$$P_e \geq \frac{B_{d_{\text{free}}}}{k} Q\left(\sqrt{\frac{2d_{\text{free}} E_s}{N_o}}\right)$$

where  $B_{d_{\text{free}}}$  is the sum of the input Hamming weights of all paths with an output Hamming weight of  $d_{\text{free}}$ . In many cases  $B_{d_{\text{free}}} = 1$ , and this can always be used as a lower bound. This expression can also be used to obtain the expression for asymptotic coding gain:

$$\gamma = 10 \log \left( \frac{k d_{\text{free}}}{2n} \right) \text{ dB}$$

This result is very similar to the expression for asymptotic coding gain for block codes.

Finally, Fig. 127.3 shows a performance comparison of the rate  $1/2$ ,  $K = 3$  convolutional code depicted in Fig. 127.2 with several block codes whose code rates are nearly equal to  $1/2$ . Bit-error rate is plotted as a function of  $E_b/N_o$  (energy per bit divided by noise spectral density). For all

cases the assumed modulation is BPSK. Note that even this simple convolutional code with soft decisions can perform as well as a fairly long (and hence complex) block code.

**Figure 127.3** Bit-error-rate comparison of block and convolutional codes.

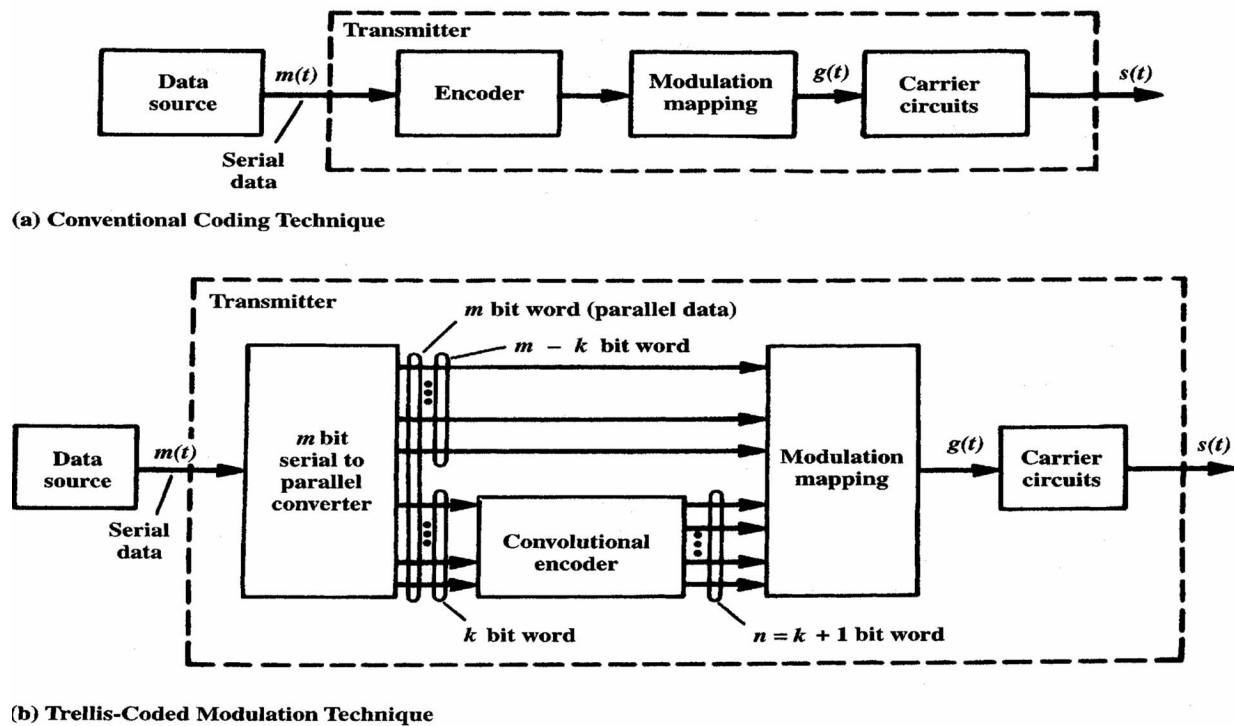

### 127.3 Trellis-Coded Modulation

In both block and convolutional coding a savings in power (coding gain) is obtained at the cost of extra bandwidth. In order to provide the redundancy, extra symbols are added to the information stream. Accommodating these symbols without sacrificing information rate requires a shorter symbol duration or, equivalently, a larger bandwidth. The bandwidth expansion relative to an uncoded system is equal to  $1/R = n/k$ . Thus, coding is used when power is at a premium but bandwidth is available—that is, a power-limited environment. When power savings is not so crucial and bandwidth is at a premium, (a bandwidth-limited environment), spectrum can be conserved by using a multilevel signaling scheme (some form of  $M$ -ary PSK or  $M$ -ary quadrature amplitude modulation is popular in this case). When both bandwidth and power are tightly constrained, trellis-coded modulation (TCM) provides power savings with no bandwidth expansion. Redundancy is added to the data stream through the expansion of the size of the signal set. For example, binary data could be sent using a QPSK signal set. Since a QPSK constellation has four points and thus could represent two bits, each QPSK signal would represent one data bit

and one parity bit (a rate  $1/2$  code). Alternatively, one could use 8-PSK with a rate  $2/3$  code and send two bits of information per symbol. As a general rule of thumb, if it is desired to send  $m$  bits of information per channel symbol, the size of the signal set is doubled and a rate  $m/(m+1)$  code is used.

A general block diagram of a TCM encoder is shown in Fig. 127.4. Data bits are grouped into  $m$  bit blocks. These blocks are then input to a rate  $m/(m+1)$  binary convolutional encoder. The  $m+1$  output bits are then used to select a signal from an  $M = 2^{m+1}$ -ary constellation. The constellation is usually restricted to being one- or two-dimensional in order to save bandwidth. The encoding is often done in a systematic manner as indicated in Fig. 127.4, where  $m-k$  of the input bits are left uncoded and the remaining  $k$  bits are encoded using a rate  $k/(k+1)$  encoder. As with convolutional codes, the TCM scheme is designed to maximize the free distance of the code, but in this case distance is measured as Euclidean distance in the signal constellation. Each path through the trellis diagram now represents a sequence of signals from the constellation, and performance is mainly determined by the minimum Euclidean distance between any two distinct sequences of signals.

**Figure 127.4** Block diagram of transmitter for TCM. (Source: Couch, L. W. 1993. *Digital and Analog Communication Systems*, 4th ed. Macmillan, New York. With permission.)

At the receiver, the received signal is demodulated using soft decisions and then decoded using the Viterbi algorithm. Performance is determined in a manner very similar to that for a convolutional code. Bounds on the bit-error rate can be found using transfer function techniques, although the method to obtain these transfer functions can be more complicated if the signal constellation does not exhibit a great deal of symmetry. Also, a coding gain relative to an uncoded system can be calculated as

$$\gamma = 20 \log \left( \frac{d_{\text{free}}}{d_{\text{uncoded}}} \right) \text{ dB}$$

**Figure 127.5** Free distance of binary convolution codes with 4-PSK modulation, and TCM with a variety of two-dimensional modulation schemes. (Source: Ungerboeck, G. 1987. ## TELEGRAPH SIGNS

*Samuel F. B. Morse*

*Patented June 20, 1840*

*#1,647*

An excerpt:

*To all whom it may concern:*

Be it known that I, the undersigned, SAMUEL F. B. MORSE, of the city, county, and State of New York, have invented a new and useful machine and system of signs for transmitting intelligence between distant points by the means of a new application and effect of electro-magnetism in producing sounds and signs, or either, and also for recording permanently by the same means, and application, and effect of electro-magnetism any sign thus produced and representing intelligence, transmitted as before named between distant points; and I denominate said invention the "American Electro-Magnetic Telegraph,"...

This was the Telegraph that opened interstate and international commerce as well as the frontier west. The compact system of dots and dashes representing letters and numerals known as the Morse Code was also developed and is still used in radio communications. (©1992, DewRay Products, Inc. Used with permission.)

## Defining Terms

**Block code:** A memoryless mapping from  $k$  input symbols to  $n$  output symbols.

**Code rate:** The ratio of the number of input symbols to the number of output symbols for a block or convolutional encoder.

**Constraint length:** The number of input blocks that affect a current output block in a convolutional encoder. It is also a measure of the complexity of the code.

**Convolutional code:** A mapping from  $k$  input symbols to  $n$  output symbols that is not memoryless. The current output depends on current and past inputs.

**Cyclic code:** A block code for which every cyclic shift of a code word produces another code word.

**Group Code:** A block code for which any linear combination of two code words produces another code word. Also known as a *linear code*.

**Trellis-coded modulation:** A combination of traditional modulation and convolutional coding techniques whereby redundancy is added through the expansion of the size of the signal constellation.

## **Further Information**

A good tutorial presentation of traditional coding techniques can be found in the article by Bhargava. For full details the book by Lin and Costello gives a good presentation of both block and convolutional coding techniques.

For information on trellis-coded modulation the reader is referred to the tutorial article by Ungerboeck, which is quite readable. The text by Biglieri *et al.* is the only one known to the authors completely devoted to TCM.

For the latest developments in the area of coding, the reader is referred to the *IEEE Transactions on Information Theory* and the *IEEE Transactions of Communications*.

### John N. Daigle

*University of Mississippi*

The last several years have indeed been exciting times in the brief history of computer communication networks. Over this period of time we have seen the explosive growth of the Internet, a worldwide interconnection of computer communication networks that allows low-latency person-to-person communications on a global basis. So-called **firewall** technology has been developed to the point where more private companies are able to connect to the internet with significantly reduced fear of compromising their important private information. Significant steps have been taken to extend networking services to the mobile information user.

The potential for using networking technology as a vehicle for delivering multimedia—voice, data, image, and video—presentations, and, indeed, multiparty, multimedia conferencing service, is being demonstrated, and the important problems that must be solved in order to realize this potential are rapidly being defined and focused upon. And, perhaps more importantly, user-friendly applications that facilitate navigation within the **World Wide Web** have been developed and made available to networking users on a nonfee basis via network servers, thus facilitating virtually instantaneous search and retrieval of information on a global basis.

By definition, a **computer communication network** is a collection of applications hosted on separate machines and interconnected by an infrastructure that provides communications among the communicating entities. Although the applications are generally understood to be computer programs, the generic model includes the human being as an application.

This chapter summarizes the major characteristics of computer communication networks. Its objective is to provide a concise introduction that will allow the reader to gain an understanding of the key distinguishing characteristics of the major classes of networks that exist today and some of the issues involved in the introduction of emerging technologies.

There are a significant number of well-recognized books in this area. Among these are the excellent texts by Schwartz [1987] and Spragins [1991], which have enjoyed wide acceptance both by students and practicing engineers and cover most of the general aspects of computer communication networks. Other books that have been found especially useful by many practitioners are those by Rose [1990] and Black [1991].

The latest developments are, of course, covered in the current literature, conference proceedings, and the notes of standards meetings. A pedagogically oriented magazine that specializes in computer communications networks is *IEEE Network*, but *IEEE Communications* and *IEEE Computer* often contain interesting articles in this area. *ACM Communications Review*, in addition to presenting pedagogically oriented articles, often presents very useful summaries of the latest standards activities. Major conferences that specialize in computer communications include the IEEE INFOCOM and ACM SIGCOMM series, which are held annually. It is becoming common at this time to have more and more discussion about personal communication systems, and the mobility issues involved in communication networks are often discussed in *IEEE Network* and a new magazine, *IEEE Personal Communication Systems*.

We begin our discussion with a brief statement of how computer networking came about and a capsule description of the networks that resulted from the early efforts. Networks of this generic class, called **wide-area networks** (WANs) are broadly deployed today, and there are still a large number of unanswered questions with respect to their design. The issues involved in the design of those networks are basic to the design of most networks, whether wide area or otherwise. In the process of introducing these early systems, we describe and contrast three basic types of communication switching: circuit, message, and packet.

We next turn to a discussion of computer communication **architecture**, which describes the structure of communication-oriented processing software within a communication-processing system. Our discussion is limited to the **International Standards Organization/Open Systems Interconnection (ISO/OSI) reference model** (ISORM) because it provides a framework for discussion of some of the modern developments in communications in general and communication networking in particular. This discussion is necessarily simplified in the extreme, thorough coverage requiring on the order of several hundred pages, but we hope our brief description will enable the reader to appreciate some of the issues.

Having introduced the basic architectural structure of communication networks, we next turn to a discussion of an important variation on this architectural scheme: the **local-area network** (LAN). Discussion of this topic is important because it helps to illustrate what the reference model is and what it is not. In particular, the architecture of LANs illustrates how the ISO/OSI reference model can be adapted for specialized purposes. Specifically, early network architectures anticipate networks in which individual node pairs are interconnected via a single link, and connections through the network are formed by concatenating node-to-node connections.

LAN architectures, on the other hand, anticipate all nodes being interconnected in some fashion over the same communication link (or medium). This, then, introduces the concept of adaption layers in a natural way. It also illustrates that, if the services provided by an architectural layer are carefully defined, the services can be used to implement virtually any service desired by the user, possibly at the price of some inefficiency.

We conclude with a brief discussion of the status of two recent developments in communication networking: frame relay and asynchronous transfer mode (ATM) technology, which is a part of the larger **broadband integrated services digital network** (BISDN) effort. These technologies are likely to be important building blocks for the computer communication networks of the future.

## 128.1 General Networking Concepts

---

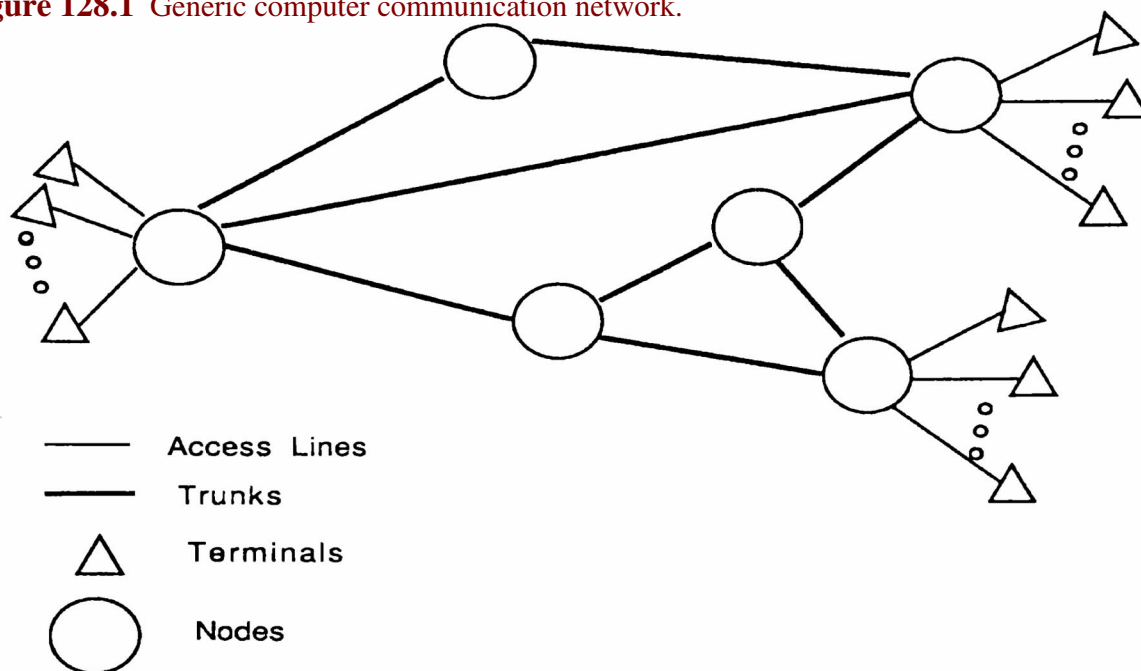

Data communication networks have existed since about 1950. The early networks existed primarily for the purpose of connecting users of a large computer to the computer itself, with additional capability to provide communications between computers of the same variety and

having the same operating software. The lessons learned during the first 20 or so years of operation of these types of networks have been valuable in preparing the way for modern networks. For the purposes of our current discussion, however, we think of communication networks as being networks whose purpose is to interconnect a set of applications that are implemented on hosts manufactured by possibly different vendors and managed by a variety of operating systems. Networking capability is provided by software systems that implement standardized interfaces specifically designed for the exchange of information among heterogeneous computers.

The earliest effort to develop large-scale, general purpose networking capability based on packet switching was led by the Advanced Research Projects Agency (ARPA) of the Department of the Army in the late 1960s; this effort resulted in the computer communication network called the ARPANET. The end results of the ARPA networking effort, its derivatives, and the early initiatives of many companies such as AT&T, DATAPOINT, DEC, IBM, and NCR have been far reaching in the extreme. We will concentrate on the most visible product of these efforts, which is a collection of programs that allows applications running in different computers to intercommunicate. Before turning to our discussion of the software, however, we shall provide a brief description of a generic computer communication network.

Figure 128.1 shows a diagram of a generic computer communication network. The most visible components of the network are the *terminals*, the **access lines**, the **trunks**, and the **switching nodes**. Work is accomplished when the users of the network, the terminals, exchange messages over the network.

**Figure 128.1** Generic computer communication network.

The terminals represent the set of communication-terminating equipment communicating over the network. Equipment in this class includes, but is not limited to, user terminals, general purpose computers, and database systems. This equipment, either through software or through human interaction, provides the functions required for information exchange between pairs of application programs or between application programs and people. The functions include, but are not limited to, call setup, session management, and message transmission control. Examples of applications include electronic mail transfer, terminal-to-computer connection for time sharing or other purposes, and terminal-to-database connections.

Access lines provide for data transmission between the terminals and the network switching nodes. These connections may be set up on a permanent basis or they may be switched connections, and there are numerous transmission schemes and protocols available to manage these connections. The essence of these connections, however, from our point of view, is a channel that provides data transmission at some number of bits per second (bps), called the *channel capacity*,  $C$ . The access line capacities may range from a few hundred bps to in excess of millions of bps, and they are usually not the same for all terminating equipments of a given network. The actual information-carrying capacity of the link depends upon the protocols employed to effect the transfer; the interested reader is referred to Bertsekas and Gallager [1987], especially chapter 2, for a general discussion of the issues involved in transmission of data over communication links.

Trunks, or internodal trunks, are the transmission facilities that provide for transmission of data between pairs of communication switches. These are analogous to access lines and, from our point of view, they simply provide a communication path at some capacity, specified in bps.

There are three basic switching paradigms: circuit, message, and packet switching. **Circuit switching** and **packet switching** are transmission technologies while **message switching** is a service technology. In circuit switching a call connection between two terminating equipments corresponds to the allocation of a prescribed set of physical facilities that provide a transmission path of a certain bandwidth or transmission capacity. These facilities are dedicated to the users for the duration of the call. The primary performance issues, other than those related to quality of transmission, are related to whether or not a transmission path is available at call setup time and how calls are handled if facilities are not available.

**Message switching** is similar in concept to the postal system. When a user wants to send a message to one or more recipients, the user forms the message and addresses it. The message-switching system reads the address and forwards the complete message to the next switch in the path. The message moves asynchronously through the network on a message switch-to-message switch basis until it reaches its destination. Message-switching systems offer services such as mailboxes, multiple-destination delivery, automatic verification of message delivery, and bulletin boards. Communication links between the message switches may be established using circuit or packet-switching networks, as is the case with most other networking applications. Examples of message-switching protocols that have been used to build message-switching systems are Simple Mail Transfer Protocol (SMTP) and the International Telegraph and Telephone Consultative Committee (CCITT) X.400 series. The former is much more widely deployed, whereas the latter has significantly broader capabilities, but its deployment is plagued by having two incompatible versions (1984 and 1988) and other problems. Many commercial vendors offer message-switching services based either on one of the above protocols or a proprietary protocol.

In the circuit-switching case, there is a one-to-one correspondence between the number of trunks between nodes and the number of simultaneous calls that can be carried. That is, a trunk is a facility between two switches that can service exactly one call, and it does not matter how this transmission facility is derived. Major design issues include the specification of the number of trunks between node pairs and the routing strategy used to determine the path through a network in order to achieve a given call-blocking probability. When blocked calls are queued, the number of calls that may be queued is also a design question.

A packet-switched communication system exchanges messages between users by transmitting sequences of packets comprising the messages. That is, the sending terminal equipment partitions a message into a sequence of packets, the packets are transmitted across the network, and the receiving terminal equipment reassembles the packets into messages. The transmission facility interconnecting a given node pair is viewed as a single trunk, and the transmission capacity of this trunk is shared among all users whose packets traverse both nodes. Whereas the trunk capacity is

specified in bps, the packet-handling capacity of a node pair depends on both the trunk capacity and the nodal processing power.

In many packet-switched networks the path traversed by a packet through the network is established during a call setup procedure, and the network is referred to as a *virtual circuit packet-switching network*. Other networks provide datagram service, a service that allows users to transmit individually addressed packets without the need for call setup. Datagram networks have the advantage of not having to establish connections before communications take place, but have the disadvantage that every packet must contain complete addressing information. Virtual circuit networks have the advantage that addressing information is not required in each packet, but have the disadvantage that a call setup must take place before communications can occur. Datagram is an example of **connectionless service**, whereas virtual circuit is an example of **connection-oriented service**.

Prior to the late 1970s signaling for circuit establishment was in-band. That is, in order to set up a call through the network, the call setup information was sent sequentially from switch to switch using the actual circuit that would eventually become the circuit used to connect the end users. In an extreme case this process amounted to trying to find a path through a maze, sometimes having to retrace steps before finally emerging at the destination or simply giving up when no path could be found. This system had two negative characteristics: First, the rate of signaling information transfer was limited to the circuit speed, and, second, the circuits that could have been used for accomplishing the end objective were being consumed simply to find a path between the end points. These limitations resulted in tremendous bottlenecks on major holidays, which were solved by virtually disallowing alternate routes through the toll switching network.

An alternate out-of-band signaling system, usually called **common channel interoffice signaling** (CCIS), was developed primarily to solve this problem. Signaling now takes place over a signaling network that is partitioned from the network that carries the user traffic. This principle is incorporated into the concept of integrated services digital networks (ISDNs), which is described thoroughly in Helgert [1991]. The basic idea of ISDN is to offer to the user some number of 64 kbps access lines, plus a 16 kbps access line through which the user can describe to an ISDN how the user wishes to use each of the 64 kbps circuits at any given time. The channels formed by concatenating the access lines with the network interswitch trunks having the requested characteristics are established using an out-of-band signaling system, the most modern of which is Signaling System #7 (SS#7).

In either virtual circuit or *datagram networks*, packets from a large number of users may simultaneously need transmission services between nodes. Packets arrive at a given node at random times. The switching node determines the next node in the transmission path and then places the packet in a queue for transmission over a trunk facility to the next node. Packet arrival processes tend to be bursty—that is, the number of packet arrivals over fixed-length intervals of time has a large variance. Because of the burstiness of the arrival process, packets may experience significant delays at the trunks. Queues may also build due to the difference in transmission capacities of the various trunks and access lines, and delays result. Processing is also a source of delay; the essence of packet-switching technology is to trade delay for efficiency in resource utilization.

Protocol design efforts, which seek to improve network efficiencies and application performance, are frequent topics of discussion at both general conferences in communications and those specialized to networking. The reader is encouraged to consult the proceedings of the conferences mentioned earlier for a better appreciation of the range of issues and the diversity of the proposed solutions to the issues.

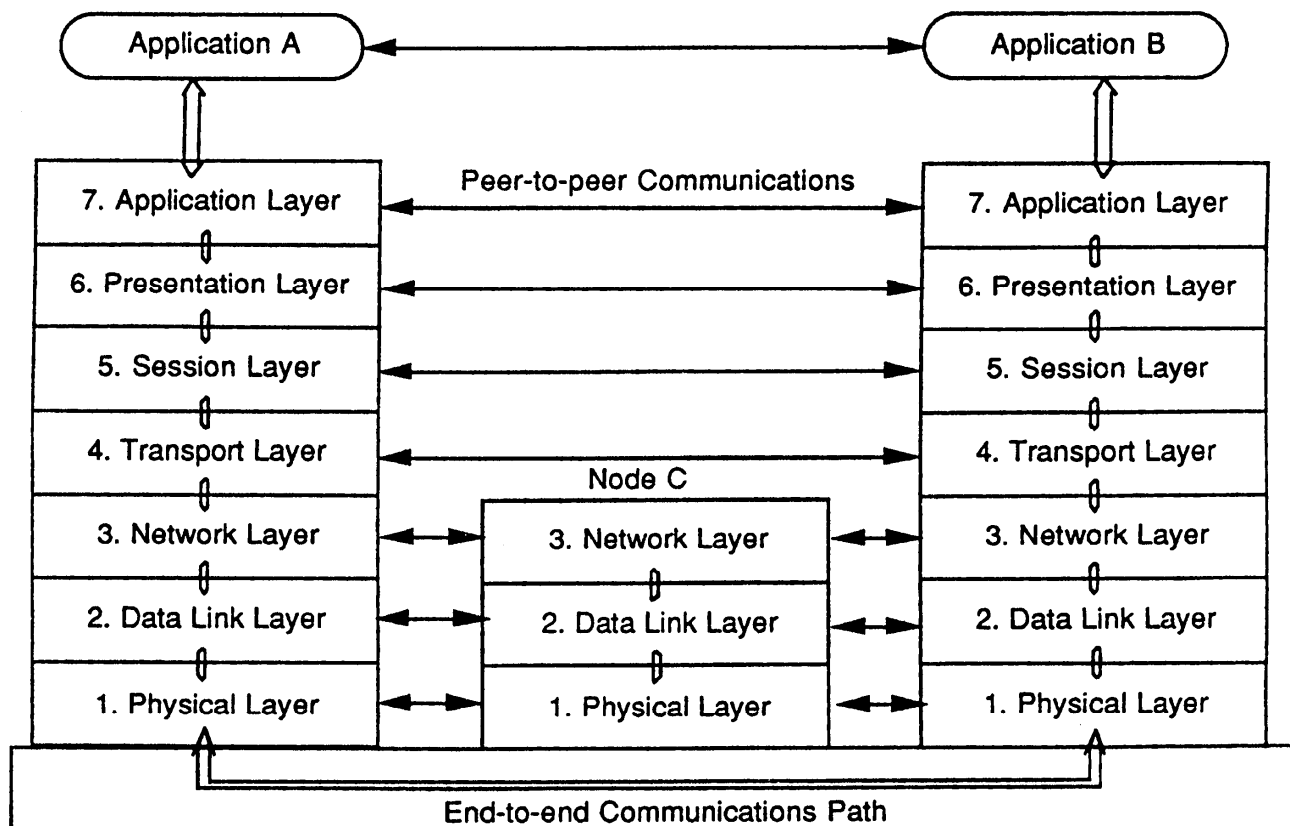

## 128.2 Computer Communication Network Architecture

In this section we begin with a brief, high-level definition of the ISORM, which is discussed in significant detail in Black [1991]. There is significant debate over whether the efforts of the ISO/OSI community are leading to the best standards, but we choose to base our discussion on the ISORM because it is very useful for discussing network architecture principles, and these principles apply across the board.

The reference model has seven layers, none of which can be bypassed conceptually. In general, a layer is defined by the types of services it provides to its users and the quality of those services. For each layer in the ISO/OSI architecture the user of a layer is the next layer up in the hierarchy—except for the highest layer, for which the user is an application. Clearly, when a layered architecture is implemented under this philosophy, the quality or service obtained by the end user, the application, is a function of the quality of service provided by all of the layers.

Figure 128.2, adapted from Spragins [1991], shows the basic structure of the OSI architecture and how this architecture is envisaged to provide for exchange of information between applications. As shown in the figure, there are seven layers: application, presentation, session, transport, network, data link, and physical. Brief definitions of the layers are now given, but the reader should bear in mind that substantial further study will be required to develop an understanding of the practical implications of the definitions.

**Figure 128.2** Layered architecture for ISO/OSI reference model. (Adapted from Spragins, J. D. 1991. *Telecommunications: Protocols and Design*. Addison-Wesley, Reading, MA.)

*Physical layer.* Provides electrical, functional, and procedural characteristics to activate, maintain, and deactivate physical data links that transparently pass the bit stream for communication between data link entities.

*Data link layer.* Provides functional and procedural means to transfer data between network entities. Provides for activation, maintenance, and deactivation of data link connections; character and frame synchronization; grouping of bits into characters and frames; error control, media access control; and flow control.

*Network layer.* Provides switching and routing functions to establish, maintain, and terminate network layer connections and transfer data between transport layers.

*Transport layer.* Provides host-to-host, cost-effective, transparent transfer of data; end-to-end flow control; and end-to-end quality of service as required by applications.

*Session layer.* Provides mechanisms for organizing and structuring dialogues between application processes.

*Presentation layer.* Provides for independent data representation and syntax selection by each communicating application and for conversion between selected contexts and the internal architecture standard.

*Application layer.* Provide applications with access to the ISO/OSI communication stack and certain distributed information services.

As mentioned previously, a layer is defined by the types of services it provides to its users. In the

case of a request or a response, these services are provided via invocation of **service primitives** of the layer in question by the layer that wants the service performed. In the case of an indication or a confirm, these services are provided via invocation of service primitives of the layer in question by the same layer that wants the service performed.

This process is not unlike a user of a programming system calling a subroutine from a scientific subroutine package in order to obtain a service, for instance, matrix inversion or memory allocation. For example, a request is analogous to a CALL statement in a FORTRAN program, and a response is analogous to the RETURN statement in the subroutine that has been CALLED. The requests for services are generated asynchronously by all of the users of all of the services, and these join (typically prioritized) queues along with other requests and responses while awaiting servicing by the processor or other resource such as a transmission line.

The service primitives fall into four basic types, which are as follows: request, indication, response, and confirm. These types are defined as follows:

*Request.* A primitive sent by layer  $(N + 1)$  to layer  $N$  to request a service.

*Indication.* A primitive sent by layer  $N$  to layer  $(N + 1)$  to indicate that a service has been requested of layer  $N$  by a separate layer  $(N + 1)$  entity.

*Response.* A primitive sent by  $(N + 1)$  to layer  $N$  in response to an *indication primitive*.

*Confirm.* A primitive sent by layer  $N$  to layer  $(N + 1)$  to indicate that a response to an earlier *request* primitive has been received.

In order to be more specific about how communication takes place, we now turn to a brief discussion of layer 2, the data link layer. The primitives provided by the ISO data link layer are as follows [Stallings, 1990a].

- DL\_CONNECT.request
- DL\_RESET.request
- DL\_CONNECT.indication
- DL\_RESET.indication
- DL\_CONNECT.response
- DL\_RESET.response
- DL\_CONNECT.confirm
- DL\_RESET.confirm
- DL\_DATA.request
- DL\_DISCONNECT.request
- DL\_DATA.indication
- DL\_DISCONNECT.indication
- DL\_DATA.response
- DL\_UNITDATA.request
- DL\_DATA.confirm
- DL\_UNITDATA.indication

Each *primitive* has a set of **formal parameters**, which are analogous to the formal parameters of a procedure in a programming language. For example, the parameters for the DLCONNECT.request primitive are the called address, the calling address, and the quality-of-service parameter set. These three parameters are used in the establishment of data link

(DL) connections. The called address and the calling address are analogous to the telephone numbers of two parties of a telephone call, whereas the quality-of-service parameter set allows for the negotiation of various agreements, such as throughput (measured in bits per second).

All four DLCONNECT primitives are used to establish a data link. An analogy to an ordinary phone call is now drawn so that the basic idea of the primitives can be better appreciated. DLCONNECT.request is equivalent to picking up the phone and dialing. The phone ringing at the called party's end is represented by DLCONNECT.indication. DLCONNECT.response is equivalent to the called party lifting the receiver and answering, and DLCONNECT.confirm is equivalent to the calling party hearing the response of the called party.

In general, communications take place between peer layer protocols by the exchange of **protocol data units** (PDUs), which contain all of the information required for the receiving protocol **entity** to provide the required service. In order to exchange PDUs entities at a given layer use the services of the next lower layer. The data link primitives listed include both connection-mode primitives and connectionless mode primitives. For connection mode communications a connection must be established between two peer entities before they can exchange PDUs.

For example, suppose a network layer entity in host A wishes to be connected to a network layer entity in host B, as shown in [Fig. 128.2](#). Then the connection would be accomplished by the concatenation of two data link connections: one between A and C, and one between C and B. In order to establish the connection, the network layer entity in host A would issue a DLCONNECT.request to its associated data link entity, providing the required parameters. This data link entity would then transmit this request to a data link entity in C, which would issue a DLCONNECT.indication to a network entity in C. The network entity in C would then analyze the parameters of the DLCONNECT.indication and realize that the target destination is B. This network layer entity would then reissue the DLCONNECT.request to its data link entity, which would transmit the request to a data link entity in B. The data link entity in B would send a DLCONNECT.indication to a network layer entity in B, and this entity would issue a DLCONNECT.response back to the data link entity in B. This DLCONNECT.response would be relayed back to the data link entity in A following the same sequence of events as in the forward paths. Eventually, this DLCONNECT.response would be converted to a DLCONNECT.confirm by the data link entity in A and passed to the network entity in A, thus completing the connection.

Once the connection is established, data exchange between the two network layer entities can take place; that is, the entities can exchange PDUs. For example, if a network layer entity in host A wishes to send a PDU to a network layer entity in host B, the network layer entity in host A would issue a DLDATA.request to the appropriate data link layer entity in host A. This entity would package the PDU together with appropriate control information into a data link service data unit (DLSDU) and send it to its peer at C. The peer at C would deliver it to the network entity at C, which would forward it to the data link entity in C providing the connection to host B. This entity would then send the DLSDU to its peer in host B, and this data link entity would pass the PDU to host B network entity via a DLDATA.indication. Now, network layer PDUs are called *packets* and DL layer PDUs are called *frames*. But, the data link layer does not know that the information it is transmitting is a packet; to the DL layer entity, the packet is simply user information. From the perspective of a data link entity, it is not necessary to have a network layer. The network layer exists to add value for the user of the network layer to the services provided by the DL layer. In the

example given, value was added by the network layer by providing a relaying capability since hosts A and C were not directly connected. Similarly, the DL layer functions on a hop-by-hop basis, each hop being completely unaware that there are any other hops involved in the communication. We will see later that the data link need not be limited to a single physical connection.

The philosophy of the ISO/OSI architecture is that, in addition to the software being layered, implementations are not allowed to bypass entire layers; that is, every layer must appear in the implementation. This approach was developed after the approach defined for the ARPANET project, which is hierarchical, was fully developed. In the hierarchical approach the layer interfaces are carefully designed, but any number of layers of software can be bypassed by any application (or other higher-layer protocol) that provides the appropriate functionality. These two approaches have been hotly debated for a number of years, but as the years pass, the approaches are actually beginning to look more and more alike for a variety of reasons that will not be discussed here.

The ISO/OSI layered architecture described would appear to be very rigid, not allowing for any variations in underlying topology or variations in link reliability. However, as we shall see, this is not necessarily the case. For example, ISO 8348, which developed as a result of the X.25 project, provides only connection-oriented service, and it was originally intended as the only network layer standard for ISO/OSI. However, ISO 8473, or ISO-IP—which is virtually identical to the Department of Defense (DoD) internet protocol (DoD-IP) developed in the ARPANET project—has since been added to the protocol suite to provide connectionless service as well as internet service.

The ISO/OSI protocol suite is in a constant state of revision as new experience reveals the need for additional capabilities and flexibility. Some of this additional flexibility and functionality is being provided through the use of so-called **adaption sublayers**, which enhance the capabilities of a given layer so that it can use the services of a lower layer with which it was not specifically designed for compatibility.

Interestingly, the use of adaption sublayers is only a short step away from using adaption layers that would allow applications to directly interface with any ISO layer. This would result in a hierarchical rather than layered architecture; to wit, ISORM becomes DoDRM. Meanwhile, the severe addressing limitations of DoD-IP—together with the emergence of high-performance multimedia networking applications, which require service quality guarantees—have led to a significant effort in the internet community to rethink the service requirements and implementation features of the internetworking layer. Many features of the ISO protocols have been considered for incorporation into the next generation of IP. Fundamental changes in the national (and worldwide) communications infrastructure appear to be leading naturally in the hierarchical direction, and this fact has been recognized by the U.S. government, which has recently relaxed its requirements for compliance with ISO standards in networking products.

We now turn to a discussion of LANs, which have inherent properties that make the use of sublayers particularly attractive.

## 128.3 Local-Area Networks and Internets

---

In this section we discuss the organization of communications software for LANs. In addition, we

introduce the idea of **internets**, which were brought about to a large extent by the advent of LANs. We discuss the types of networks only briefly and refer the reader to the many excellent texts on the subject. Layers 4 and above for local-area communications networks are identical to those of wide-area networks. However, because the hosts communicating over an LAN share a single physical transmission facility, the routing functions provided by the network layer, layer 3, are not necessary. Thus, the functionality of a layer 3 within a single LAN can be substantially simplified without loss of utility. On the other hand, a DL layer entity must now manage many simultaneous DL layer connections because all connections entering and leaving a host on a single LAN do so over a single physical link. Thus, in the case of connection-oriented communications, the software must manage several virtual connections over a single physical link.

There were several basic types of transmission schemes in use in early local-area networks. Three of these received serious consideration for standardization: the **token ring**, **token bus**, and **carrier sense multiple access** (CSMA). All three of these access methods became IEEE standards (IEEE 802) and eventually became ISO standards (ISO 8802 series) because all merited standardization. On the other hand, all existed for the express purposes of exchanging information among peers, and it was recognized at the outset that the upper end of the data link layer could be shared by all three access techniques. The decision to use a common logical link control (LLC) sublayer for all of the LAN protocols and develop a separate sublayer for each of the different media apparently ushered in the idea of adaption sublayers, in this case, the **media access control** (MAC) sublayer. This idea has proven to be valuable as new types of technologies have become available. For example, the new fiber-distributed digital interface (FDDI) uses the LLC of all other LAN protocols, but its MAC is completely different from the token ring MAC even though FDDI is a token ring protocol. A thorough discussion of FDDI and related technologies is given in Jain [1994].

One of the more interesting consequences of the advent of local-area networking is that many traditional computer communication networks became internets overnight. LAN technology was used to connect stations to a host computer, and these host computers were already on a WAN. It was then a simple matter to provide a relaying, or bridging, service at the host in order to provide wide-area interconnection of station to LANs to each other. In short, the previously established WANs became networks for interconnection of LANs; that is, they were interconnecting networks rather than stations. Internet performance suddenly became a primary concern in the design of networks; a new business developed vending specialized equipment, routers, to provide interconnection among networks.

Metropolitan-area networks (MANs) have been deployed for the interconnection of LANs within a metropolitan area. The primary media configuration for MANs is a dual-bus configuration, and it is implemented via the distributed queue, dual-bus (DQDB) protocol, also known as IEEE 802.6. The net effect of this protocol is to use the dual-bus configuration to provide service approaching the FCFS service discipline to the traffic entering the FDDI network, which is remarkable considering that the LANs being interconnected are geographically dispersed. Interestingly, DQDB concepts have recently also been adapted to provide wide-area communications. Specifically, structures have been defined for transmitting DQDB frames over standard DS-1 (1.544 megabits per second) and DS-3 (6.312 megabits per second) facilities, and these have been used as the basis for a service offering called *switched multimegabit data*

services (SMDS).

Over the last few years, wireless LANs—which are local-area networks in which radio or photonic links serve as cable replacements—have been marketed. Wireless LAN technology is viewed by many as crucial to the evolution of personal communication networks, but deployment has been far less than anticipated up to this time. Part of the reason for this fact is the continued improvement in Ethernet innovations, such as Ethernet bridges, which continue to add value to the installed base. Thus, in order to achieve a market niche, added values of wireless LANs must continue to be improved. This is, of course, typical in product life cycle.

## 128.4 Some Additional Recent Developments

---

In this section we describe two recent developments of significant interest in communication networking: *frame relay* (FR) technology, which is described in Braun [1994], and **asynchronous transfer mode** (ATM) technology, which is described in McDysan and Spohn [1994]. We also comment briefly on personal communication services.

As mentioned previously, there is really no requirement that the physical media between two adjacent data link layers be composed of a single link. In fact, if a path through the network is initially established between two data link entities, there is no reason that DLC protocols need to be executed at intermediate nodes. Through the introduction of adaption layers and an elementary routing layer at the top of the DL layer, DLC frames can be relayed across the physical links of the connection without performing the error checking, flow control, and retransmission functions of the DLC layer on a link-by-link basis. The motivation is that, since link transmission is becoming more reliable, extensive error checking and flow control is not needed across individual links; an end-to-end check should be sufficient. Meanwhile, the savings in processing due to not processing at the network layer can be applied to frame processing, which allows interconnection of the switches at higher line speeds. Since bit-per-second costs decrease with increased line speed, service providers can offer savings to their customers through FRNs. Significant issues are frame loss probability and retransmission delay. Such factors will determine the retransmission strategy deployed in the network. The extensive deployment of FR technology at this time suggests that this technology provides improvements over standard packet technology.

Another recent innovation is the ATM, usually associated with BISDN. The idea of ATM is to partition a user's data into many small segments, called cells, for transmission over the network. Independent of the data's origin, the cell size is 53 octets, of which five octets are for use by the network itself for routing and error control. Users of the ATM are responsible for segmentation and reassembly of their data. Any control information required for this purpose must be included in the 48 octets of user information in each cell. In the usual case these cells would be transmitted over networks that would provide users with 135 Mbps and above data transmission capacity (with user overhead included in the capacity).

The segmentation of units of data into cells introduces tremendous flexibility for handling various types of information—such as voice, data, image, and video—over a single transmission facility. As a result, there has been a tremendous investment in developing implementation agreements that will enable a large number of vendors to independently develop interoperable equipment. This effort is focused primarily in the ATM Forum, a private, not-for-profit consortium

of over 500 companies, of which more than 150 are principal members and active contributors.

LANs, WANs, and MANs based on the ATM paradigm are being designed and, indeed, deployed. A significant portion of the early deployment activity was part of a national test bed program under joint sponsorship of the National Science Foundation (NSF) and the Advanced Research Projects Agency (ARPA). But significant quantities of ATM equipment are already deployed in various private test bed efforts and, indeed, in various commercial networks. For example, ATM is an excellent technology for providing worldwide Ethernet LAN interconnection at the full rate of ten megabits per second. Not surprisingly, numerous vendors are planning to have ATM capabilities at the back plane in much the same way that Ethernet is provided today.

There are numerous possibilities for connection of hosts to ATM networks, but they all share a common architecture, which consists of three sublayers: the ATM adaption layer (AAL), the ATM layer, and the physical media-dependent (PMD) layer. It is convenient, for the purposes of this discussion, to think of services as falling into two categories: circuit mode and packet mode, where a circuit mode service, such as voice, is a service that is naturally implemented over a circuit-switched facility, and a packet-mode service, such as E-mail, is a service that is more naturally implemented over a packet-switched connection. From many perspectives it is natural to implement circuit-mode services directly over ATM, whereas it is more natural to implement packet-mode services at the internet (or packet) layer.

The implication of this partitioning of service types is that any service that has been developed for deployment over an IP network could naturally be deployed over an ATM network by simply using the ATM network as a packet delivery network. Each packet would traverse the network as a sequence of cells over an end-to-end virtual connection. If the flow control and resource management procedures can be worked out, the net effect of this deployment strategy would be, for example, that an application designed to be deployed over an Ethernet segment could be deployed on a nationwide (or even global) network without a noticeable performance degradation. The implications of this type of capability are obvious as well as mind-boggling.

At the present time, end-to-end connections at the ATM level are expected to be connection oriented. As cells traverse the network, they are switched on a one-by-one basis, using information contained in the five ATM overhead octets to follow the virtual path established during the ATM call setup. Typically, cells outbound on a common link are statistically multiplexed, and, if buffers are full, cells are dropped. In addition, if one or more errors are found in a cell, then the cell is dropped.

In the case of data transmission a lost cell will result in an unusable frame unless the data are encoded to guard against cell loss prior to transmission. Coding might be provided by the AAL, for example. The trade-offs involved in coding and retransmission and their impact upon network throughput, delay, and complexity are not well understood at the time of this writing. Part of the reason for this uncertainty is that cell loss probability and the types of traffic that are likely to use the network are not thoroughly understood at this time. Resolution of these issues accounts for a significant portion of the research activity in computer communication networking at this time. The relevant ANSI and CCITT documents are frequently updated to include the results.

The accomplishment of deploying ATM technology would be unexciting in terms of reaching the potential pointed out in the previous paragraph if application development for communication networking were at a standstill. Fortunately, this is far from true. In addition, the last few years

have witnessed a tremendous increase in attention to the problem of providing access to networking service to the mobile user, and this has resulted in significant advances both in wireless data-networking technology and in telecommunication network control infrastructure. Computer communication networking, pronounced dead about ten years ago, has never been more alive than it is today.

## Defining Terms

**Access line:** A communication line that connects a user's terminal equipment to a switching node.

**Adaption sublayer:** Software that is added between two protocol layers to allow the upper layer to take advantage of the services offered by the lower layer in situations where the upper layer is not specifically designed to interface directly to the lower layer.

**Architecture:** The set of protocols defining a computer communication network.

**Asynchronous transfer mode (ATM):** A mode of communication in which communication takes place through the exchange of tiny units of information called *cells*.

**Broadband integrated services digital network (B-ISDN):** A generic term that generally refers to the future network infrastructure that will provide ubiquitous availability of integrated voice, data, imagery, and video services.

**Carrier sense multiple access:** A random access method of sharing a bus-type communications medium in which a potential user of the medium listens before beginning to transmit.

**Circuit switching:** A method of communication in which a physical circuit is established between two terminating equipments before communication begins to take place. This is analogous to an ordinary phone call.

**Common channel interoffice signaling:** Use of a special network, dedicated to signaling, to establish a path through a communication network, which is dedicated to the transfer of user information.

**Computer communication network:** Collection of applications hosted on different machines and interconnected by an infrastructure that provides intercommunications.

**Connectionless service:** A mode of packet switching in which packets are exchanged without first establishing a connection. Conceptually, this is very close to message switching, except that if the destination node is not active, then the packet is lost.

**Connection-oriented service:** A mode of packet switching in which a call is established prior to any information exchange taking place. This is analogous to an ordinary phone call, except that no physical resources need be allocated.

**Entity:** A software process that implements a part of a protocol in a computer communication network.

**Fast packet networks:** Networks in which packets are transferred by switching at the frame layer rather than the packet layer. Such networks are sometimes called *frame relay networks*. At this time it is becoming popular to think of frame relay as a service, rather than transmission, technology.

**Firewall:** Computer communication network hardware and software introduced into an internet at the boundary of a public network and a private network for the purpose of protecting the confidential information and network reliability of the private network.

**Formal parameters:** The parameters passed during the invocation of a service primitive; similar to the arguments passed in a subroutine call in a computer program.

**International Standards Organization reference model:** A model, established by ISO, that organizes the functions required by a complete communication network into seven layers.

**Internet:** A network formed by the interconnection of networks.

**Local-area networks:** A computer communication network spanning a limited geographic area, such as a building or college campus.

**Media access control:** A sublayer of the link layer protocol whose implementation is specific to the type of physical medium over which communication takes place and controls access to that medium.

**Message switching:** A service-oriented class of communication in which messages are exchanged among terminating equipments by traversing a set of switching nodes in a store-and-forward manner. This is analogous to an ordinary postal system. The destination terminal need not be active at the same time as the originator for the message exchange to take place.

**Metropolitan-area networks:** A computer communication network spanning a limited geographic area, such as a city; sometimes features interconnection of LANs.

**Packet switching:** A method of communication in which messages are exchanged between terminating equipments via the exchange of a sequence of fragments of the message called *packets*.

**Protocol data unit:** The unit of exchange of protocol information between entities. Typically, a protocol data unit (PDU) is analogous to a structure in C or a record in Pascal; the protocol is executed by processing a sequence of PDUs.

**Service primitive:** The name of a procedure that provides a service; similar to the name of a subroutine or procedure in a scientific subroutine library.

**Switching node:** A computer or computing equipment that provides access to networking services.

**Token bus:** A method of sharing a bus-type communications medium that uses a token to schedule access to the medium. When a particular station has completed its use of the token, it broadcasts the token on the bus, and the station to which the token is addressed takes control of the medium.

**Token ring:** A method of sharing a ring-type communications medium that uses a token to schedule access to the medium. When a particular station has completed its use of the token, it transmits the token on the bus, and the station that is physically next on the ring takes control.

**Trunk:** A communication line between two switching nodes.

**Wide-area network:** A computer communication network spanning a broad geographic area, such as a state or country.

**World Wide Web:** A collection of hypertext-style servers interconnected via internet services.

## Further Information

There are many conferences and workshops that provide up-to-date coverage in the computer communications area. Among these are the IEEE INFOCOM and ACM SIGCOMM conferences and the IEEE Computer Communications Workshop, which are specialized to computer communications and are held annually. In addition, IEEE GLOBCOM (annual), IEEE ICC (annual), IFIPS ICC (biannual), and the International Telecommunications Congress (biannual) regularly feature a substantial number of paper and panel sessions in networking.

The *ACM Communications Review*, a quarterly, specializes in computer communications and often presents summaries of the latest standards activities. *IEEE Network*, a bimonthly, specializes in tutorially oriented articles across the entire breadth of computer communications and includes a regular column on books related to the discipline. Additionally, *IEEE Communications* and *IEEE Computer*, monthly magazines, frequently have articles on specific aspects of networking. Also, see *IEEE Personal Communication Systems*, a quarterly magazine, for information on wireless networking technology.

For those who wish to be involved in the most up-to-date activities, there are many interest groups on the internet, a worldwide TCP/IP-based network, that specialize in some aspect of networking. Searching for information on the Internet has become greatly simplified with the advent of the World Wide Web and publicly available software to support access. *The User's Directory of Computer Networks*, Digital Press, T. L. LaQuey (ed.) provides an excellent introduction to the activities surrounding internetworking and advice on how to obtain timely information.

## 129.1 Communications Satellite Services and Frequency Allocation

---

An agency of the United Nations, the International Telecommunications Union (ITU) issues the radio regulations that have treaty status among the ITU members. The services of interest in satellite communications include: the fixed satellite service, the mobile satellite service (including maritime, aeronautical, and land mobile vehicles), broadcast satellite service, and intersatellite service. Most commercial communications satellites operating in the fixed satellite service use the C band (6 GHz up, 4 GHz down) or the Ku band (14 GHz up, 12 GHz down). The mobile satellite services operate primarily in the L band (1.6 GHz up, 1.5 GHz down). Exact frequencies and permitted signal characteristics are contained in the radio regulations and tables of frequency allocations issued by the ITU in Geneva, Switzerland.

## 129.2 Information Transfer and Link Margins<sup>3/4</sup>Ground to Space (Up-Link)

---

A transmitter with an output power of  $P_t$ , transmitting through an antenna with a gain of  $G_t$ , will provide a power-flux density,  $\phi$ , at a range of  $r_u$ , according to the formula

$$\phi = \frac{P_t G_t}{4\pi r_u^2} \quad (129.1)$$

The satellite receiver antenna with an effective aperture of  $A_r$  located at a range from the ground transmitter will have a received power level,  $P_r$ , given by

$$P_r = \phi A_r = \frac{\phi G_u \lambda_u^2}{4\pi} \quad (129.2)$$

where  $\lambda_u$  is the wavelength of the up-link, and  $G_u$  is the gain of the receiving antenna.

The signal is received in the presence of thermal noise from the receiver plus external noise. The total noise power density is  $N_0 = kT_s$ , where  $k = 1.38 \cdot 10^{-23}$  J/K (joules per kelvin) is Boltzmann's constant and  $T_s$  is the system temperature. The noise power in the radio frequency (rf) transmission bandwidth,  $B$ , is  $N = N_0 B$ .

The up-link signal-to-noise power ratio is

$$P_u/N_u = (P_t G_t G_u / kT_s B) (\lambda / 4\pi r_u)^2 \quad (129.3)$$

In decibels,

$$\begin{aligned} P_u/N_u = & 10 \log P_t G_t - 20 \log (\lambda / 4\pi r_u) - 10 \log B \\ & + 10 \log (G/T) - 10 \log k \end{aligned} \quad (129.4)$$

The terms of this equation represent the earth station *effective isotropic radiated power* (EIRP) in dBW, the *free space loss* in dB, the rf channel bandwidth in dB Hz, the satellite  $G/T$  ratio in dB/K, and Boltzmann's constant, which is  $-228.6$  dBW/Hz K.

Similarly, the signal-to-noise power ratio of the space-to-earth link, or *down-link* ( $P_d/N_d$ ), yields

$$P_d/N_d = (P_s G_s G_e / kT_e B) (\lambda_d / 4\pi r_d)^2 \quad (129.5)$$

where  $P_s$  is the power of the satellite transmitter,  $G_s$  is the gain of the satellite transmitting antenna,  $G_e$  is the gain of the earth station receiving antenna,  $k$  is Boltzmann's constant,  $T_e$  is the temperature of the earth station receiver,  $B$  is the bandwidth,  $\lambda_d$  is the wavelength of the down-link, and  $r_d$  is the range of the down-link.

The overall system power-to-noise ratio ( $P_s/N_s$ ) is given by

$$\frac{1}{P_s/N_s} = \frac{1}{P_u/N_u} + \frac{1}{P_d/N_d} \quad (129.6)$$

Signals relayed via communications satellites include voice channels (singly, or in groups or supergroups), data channels, and video channels. Signals from multiple sources are multiplexed

onto a composite baseband signal. The techniques used to modulate these signals so that they can be kept separate use a physical domain such as frequency, time, space (separate antenna beams), or encoding. Access can be preassigned or assigned on demand. The three principal modes of multiple access include the following:

*Frequency-demand multiple access* (FDMA) isolates signals by filtering different frequencies.

*Time-Demand Multiple access* (TDMA) isolates signals by switching time slots.

*Code-Division Multiple access* (CDMA) isolates signals by correlation.

## 129.3 Communication Satellite Orbits

---

Earth-orbiting satellite trajectories are conic sections with the earth's center of mass located at one focus. The simplest orbit is circular, wherein the centrifugal force on the satellite is balanced by the gravitational force:

$$F_c = F_g \quad (129.7)$$

$$\frac{mv^2}{r} = \frac{GMm}{r^2} \quad (129.8)$$

where  $v$  is the satellite's velocity,  $r$  is the distance from the earth's center to the satellite,  $m$  is the satellite's mass,  $M$  is the earth's mass, and  $G$  is the constant of universal gravitation. Solving for  $v$  gives

$$v = \sqrt{\frac{GM}{r}} \quad (129.9)$$

$$(GM = 3.9858 \cdot 10^5 \text{ km}^3/\text{s}^2) \quad (129.10)$$

If the satellite is in an elliptical orbit, with the semimajor axis of the ellipse given by  $a$ , the velocity at any point is given by the "vis-viva" equation:

$$v = \sqrt{GM \left( \frac{2}{r} - \frac{1}{a} \right)} \quad (129.11)$$

The maximum distance from the earth's center is known as the *apogee radius* ( $A$ ), and the minimum distance is known as the *perigee radius* ( $P$ ). The eccentricity ( $e$ ) of the ellipse is given by

$$e = \frac{A - P}{A + P} \quad (129.12)$$

The velocity at apogee  $v_A$  is given by

$$v_A = \sqrt{\frac{GM}{A}(1 - e)} \quad (129.13)$$

and at perigee

$$v_P = \sqrt{\frac{GM}{P}(1 + e)} \quad (129.14)$$

The orbit period ( $T$ ) is given by

$$T = 2\pi\sqrt{\frac{a^3}{GM}} \quad (129.15)$$

Most communications satellites are in geostationary orbits, which are in the equatorial plane with a period equal to one (sidereal) day, which is approximately four minutes shorter than a solar day. These satellites have an altitude of approximately 36000 km.

Geostationary satellites appear to be stationary to observers (and antennas) on earth. The antennas are not required to track such a stationary target. Low-gain antennas with broad beams do not need to track satellites, and many of the satellites designed to operate with small mobile terminals use orbits with lower altitudes than the geostationary satellites. These orbits usually have high inclinations to the equatorial plane to provide coverage of the earth's surface to high latitudes.

## 129.4 Launch Vehicles

---

Launch services that were once the province of government organizations have become commercial enterprises. Practically all of the commercial launches to date have been to the geostationary orbit.

Recently, the most popular launch provider has been Arianespace, with launches from Kourou, French Guiana, on the Atlantic coast of South America. Three launch vehicles used for commercial launches in the U.S. are McDonnell Douglas's Delta and Martin Marietta's Atlas and Titan. In the U.S. all eastward launches are conducted from Cape Canaveral; the polar and near-polar launches use Vandenberg Air Force Base in California. Russia provides launches using the Proton and Zenit launch vehicles from Baikonur (Tyuratam) in Kazakhstan and from Plesetsk in Russia. China's Great Wall Trading Co. provides launches on the Long March launch vehicle from Xichang, China. Japan launches from Tanegashima, Japan, using the H-1 and H-2 launch vehicles. Locations of these launch sites are given in [Table 129.1](#).

**Table 129.1** Launch Site Locations

Site	Latitude	Longitude
Kourou, French Guiana	5°N	53°W
Cape Canaveral, Florida	28°N	81°W
Vandenberg Air Force Base, California	35°N	121°W
Baikonur (Tyuratam), Kazakhstan	46°N	63°E
Plesetsk, Russia	63°N	35°E
Xiachang, People's Republic of China	28°N	102°E
Tanegashima, Japan	30°N	131°E

The velocity increment ( $v$ ) gained by a launch vehicle when a propellant is burned to depletion is given by the equation

$$v = c \log_e M \quad (129.16)$$

The term  $c$  is the characteristic velocity of the propellants and is often expressed as

$$c = I_{sp}g \quad (129.17)$$

where  $I_{sp}$  is the specific impulse of the propellants (typically,  $I_{sp} = 300$  s for lox/kerosene propellants in space) and  $g$  is the acceleration due to gravity. The mass ratio ( $M$ ) can be expressed as

$$M = \frac{\text{Propellents} + \text{structure} + \text{payload}}{\text{Structure} + \text{payload}} \quad (129.18)$$

This velocity increment assumes that the vehicle doesn't change altitude appreciably during the propellant burn or experience significant aerodynamic drag.

## 129.5 Spacecraft Design

The primary subsystem in a communications satellite is the payload, which is the communications subsystem. The supporting subsystems include structure; electrical power; thermal control; attitude control; propulsion; and the telemetry, tracking, and control (TT&C).

The communications subsystem includes the receiving antennas, receivers, transponders, and transmitting antennas. This payload makes up 35 to 60% of the mass of the spacecraft. The communications capability of the satellite is measured by the antenna gain ( $G$ ), receiver sensitivity ( $T_r$ ), transmit power ( $P_t$ ), and signal bandwidth ( $B$ ). The sensitivity is often expressed as  $G_r/T_r$ , and the radiated power (EIRP) as  $G_t P_t$ .

Early models of communications satellites used antennas with broad beams and little directivity. These beams were spread over the whole earth and required large, highly directional antennas on

the ground to pick up the weak satellite signals.

Improvements in the satellite attitude control subsystems and in launch vehicle capabilities have enabled satellites to carry large antennas with multiple feeds to provide narrow beams that "spotlight" the desired coverage area ("footprint") on earth. These footprints can be focused and contoured to cover designated areas on earth. The narrow beams also permit multiple reuse of the same frequency allocations.

Antenna gain  $G$  is given by

$$G = 4\pi A\eta/\lambda^2 \quad (129.19)$$

where  $A$  is the effective cross-sectional area,  $\eta$  is the antenna efficiency (typically 55 to 80%), and  $\lambda$  is the wavelength. At the Ku-band down-link (12 GHz), where  $\lambda = 2.5$  cm, a 1 m diameter antenna can provide a gain of 40 dB. The half-power beam width in degrees  $\theta$  is given approximately by

$$\theta \approx 21/fD \quad (129.20)$$

where  $f$  is the frequency in gigahertz and  $D$  is the antenna diameter in meters. In this example the beam width  $\theta = 1.75^\circ$ . Using the same antenna reflector on the Ku band up-link (14 GHz), the beam width would be slightly narrower ( $1/5^\circ$ ) if the reflector is fully illuminated.

Transponders are satellite-borne microwave repeaters. A typical C-band transponder is composed of filters and low-noise amplifiers to select and amplify the received (6 GHz) signal. Local oscillators are fed into mixers along with the incoming signal to produce intermediate frequency (IF) signals, which are further amplified before mixing with another local oscillator to produce the down-link signal. This signal is fed to a high-power amplifier (HPA). Traveling wave tubes (TWTs) were used originally as HPAs but have been replaced by solid-state power amplifiers (SSPAs) at C-band. The amplified signal is fed to the transmitting antenna for transmission to earth on the down-link (4GHz).

Geostationary communications satellites operating at C band usually carry 24 transponders with 40 MHz separation between them. Dual polarizations permit double use of the 500 MHz frequency allocation.

Without onboard processing the transponders are usually "transparent," in that they receive the incoming (up-link) signals, amplify them, and change the carrier frequency before transmitting the down-link signals. Transparent transponders provide no signal processing other than amplification and changing the carrier frequency (heterodyning). These transponders can relay any signals that are within the transponders' bandwidth. Other types of transponders can demodulate the incoming signals and remodulate them on the down-link carrier frequencies.

The *spacecraft structure* must support the payload and the subsystems through the propulsion phases as well as in orbit. The accelerations can be as high as 6–8 g during the launch phases. On orbit the structure must permit deployment and alignment of solar cell arrays and antenna reflectors. The spacecraft utilization factor,  $U$ , is defined as

$$U = \frac{M_u}{M} \quad (129.21)$$

where  $M_u$  is the mass of the communications payload and power subsystems, and  $M$  is the total spacecraft mass in orbit.

Representative values of  $U$  range from 0.35 to 0.60. Typical large geostationary communications satellites have a mass of 2000 kg on orbit.

The *electric power subsystem* uses solar cell arrays to provide electric power. The transmitters of the communications subsystem consume most of this power. Increasing demands for electric power led to large deployable solar arrays composed of silicon solar cells. Typically, power demand is for 2 kW of 28 V DC power. Power-conditioning units maintain the voltage levels within prescribed specifications. Rechargeable batteries (nickel-cadmium or nickel-hydrogen) provide power in emergencies and during solar eclipses.

The *thermal control subsystem* must maintain the specified temperature for all components of the spacecraft. Heat sources include incident sunlight and internal electrical heat sources (especially the HPAs). The only way to eliminate heat is to radiate it to space. The Stefan-Boltzmann law of radiation gives the radiated heat ( $q$ ) as  $q = \varepsilon A \sigma T^4$  where  $\varepsilon$  is the emissivity, which is between 0 and 1 (a black body has  $\varepsilon = 1$ ),  $A$  is the surface area;  $\sigma$  is the Stefan-Boltzmann constant ( $= 5.760 \pm 0.007 \cdot 10^{-8} \text{ W/m}^2 \text{ K}^4$ ); and  $T$  is the absolute temperature.

The temperature of a passive black sphere in geostationary orbit around the earth in sunlight is between 275 and 280 K. The incident solar flux density ( $S$ ) is approximately  $1.37 \text{ kW/m}^2$ . To prevent absorption of this heat energy requires the spacecraft to have a low absorptivity ( $\alpha$ ). A designer can control the temperature by controlling the absorptivity/emissivity ratio and by using spacecraft radiators.

The satellite's average temperature is given by

$$T = \frac{1}{\sigma} \left( \frac{\alpha a S}{\varepsilon A} + \frac{Q}{\varepsilon A} \right) \quad (129.22)$$

where  $a$  is the projected area (facing the sun),  $A$  is the total surface area, and  $Q$  is the internal heat dissipation.

Satellites need *attitude control and station-keeping subsystems* to maintain their orientation so that the antenna beams will illuminate the desired coverage areas on earth, so that the solar arrays will intercept the sun's rays, and so that velocity increments from the onboard propulsion subsystem will keep the satellite in its desired location.

Onboard sensors can be used to detect the earth's horizon, the sun, and reference stars. Radio-frequency sensors are also used to detect beacons from earth stations.

Inertial measurements from on-board gyroscopes are used to detect attitude changes. These changes can be made using onboard reaction wheels, which transfer angular momentum between the spacecraft and the wheel, or by the reaction jets on the attitude control system.

Communications satellites are usually held to accuracies of approximately  $0.1^\circ$  or less in all three

axes (yaw, pitch, and roll). The onboard propulsion system can provide velocity for the initial insertion in orbit and subsequent station-keeping velocity increments, as well as attitude control.

A typical communications satellite has propellant tanks containing monopropellant hydrazine ( $\text{N}_2\text{H}_4$ ). On command, this fuel will flow through a valve to a thruster that contains a catalyst bed, a combustion chamber, and a nozzle. The resulting force from the thruster is used for the velocity corrections needed for station keeping or for attitude control. This force is given by

$$F = \dot{W} I_{\text{sp}} \quad (129.23)$$

where  $\dot{W}$  is the propellant weight flow rate, and  $I_{\text{sp}}$  is the specific impulse, which is about 230 s for the example described.

By using electrically heated thrusters and bipropellant systems, the specific impulse can be raised to 300 s or more. Some communications satellites have such large propellant tanks that velocity increments of several km/s can be achieved.

*Telemetry, tracking, and command (TT&C) subsystems* are provided for satellites in order to determine the status, performance, position, and velocity of the satellite; to control it; and to provide commands. Data from onboard sensors are transmitted by the telemetry transmitters to the ground control for monitoring the status of the satellite. Beacons are tracked in range and angle to determine the position and velocity. Ground commands are received, demodulated, and processed by the command receivers onboard the satellite. TT&C subsystems include high-power transmitters and omnidirectional antennas that can provide communications even if attitude control is lost and the spacecraft is tumbling. Link margins are similar to those described for the communications payload, but with more robust signal-to-noise ratios.

## 129.6 Propagation

---

Free space is transparent to electromagnetic waves; however, waves undergo refraction and absorption when passing through the troposphere and the ionosphere. The most important effect upon satellite communications is the clear sky attenuation caused by the molecular resonance absorption bands. The clear sky attenuation per km is plotted versus frequency in [Fig. 129.1](#). The resonance of the water vapor molecules reaches 0.15 dB/km at 25 GHz. During heavy rainstorms, this attenuation can increase significantly, as shown in [Fig. 129.1](#).

**Figure 129.1** Atmospheric path losses at sea level.

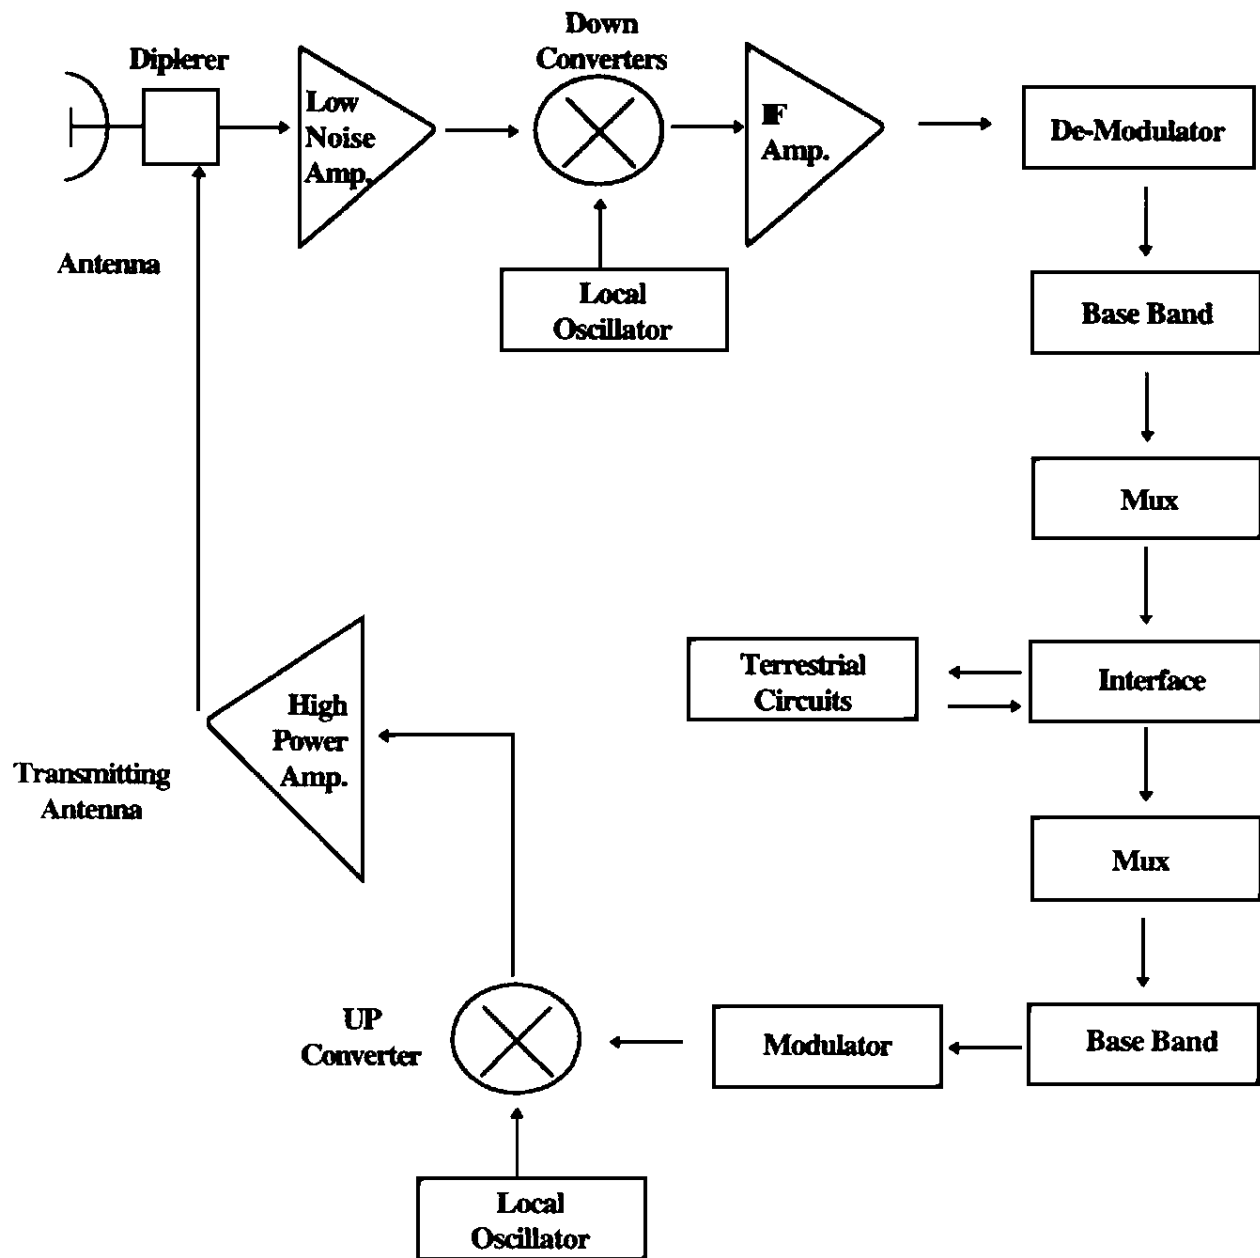

Below 10 GHz the atmosphere is transparent, but the resonant peaks shown for various molecules in the atmosphere can cause serious attenuation in the K band. The use of this band may be hampered by heavy rainstorms, which can cause depolarization as well as attenuation. One technique used to overcome this problem is to use diversity ground stations, spaced 5 to 10 km apart, to avoid transmission through localized thunderstorms.

## 129.7 Earth Stations

Earth stations are located on the ground segment of satellite communications systems. They provide communications with the satellites and interconnections to the terrestrial communications systems. A simplified block diagram is shown in [Fig. 129.2](#).

**Figure 129.2** Earth station block diagram.

The antennas, the most prominent subsystems, focus the beams to enhance the sensitivity of the receivers, to enhance the radiated power of the transmitters, and to discriminate against radio interference from transmitters located outside the narrow antenna beam.

Mobile radio communication systems transport information using electromagnetic waves to provide a viable communication link between a transmitter and receiver, either or both of which may be in motion or stationary at arbitrary locations. A variety of mobile radio systems are in use today, and the industry is experiencing rapid growth. In the U.S. alone, for example, the number of cellular telephone users grew from 25000 in 1984 to about 15 million in 1994. In Sweden, cellular telephones are already used by over 10% of the population. This growth is expected to continue worldwide at an even greater pace during the next decade.

Mobile radio transmission systems may be classified as *simplex*, *half-duplex*, or *full-duplex*. In simplex systems communication is possible in only one direction. Paging systems, in which

messages are received but not acknowledged, are simplex systems. Half-duplex radio systems allow two-way communication but use the same radio channel for both transmission and reception. This means that at any given time a user can only transmit or receive information. Constraints like "push to talk" and "release to listen" are fundamental features of half-duplex systems. Full-duplex systems, on the other hand, allow simultaneous radio transmission and reception by providing two separate channels or time slots for communication to and from the user. The channel used to convey traffic to the mobile user is called the *forward channel*, whereas the channel used to carry traffic from the mobile user is called the *reverse channel*. Full-duplex mobile radio systems provide many of the capabilities of the standard telephone, with the added convenience of mobility.

Modern mobile communication systems are networked through a central switching system, called a *mobile telephone switching office* (MTSO) or a *mobile switching center* (MSC), and typically provide coverage throughout a large metropolitan area. Many mobile radio systems are connected to the *public switched telephone network* (PSTN), which enables the full-duplex connection of mobile users to any telephone throughout the world. In order to utilize the available spectrum and radio equipment efficiently, these networked systems rely on **trunking**, so that a limited number of frequencies can accommodate a large number of mobile users on a statistical demand basis. Trunking exploits the fact that not every user requires service at a particular time; hence it is possible for a large number of users to share a relatively small number of radio channels. When a subscriber in a trunked system engages in a call, the system searches for a free channel and allocates it to the subscriber. If all the channels are already in use, the user is *blocked*, or denied access to the system. The process of allocating a channel in a trunked radio system requires a dedicated control channel, called the *control* or *call setup* channel.

Multiple-access techniques such as *frequency-division multiple access* (FDMA), *time-division multiple access* (TDMA), and *code-division multiple access* (CDMA) are employed to provide simultaneous access to many users without causing mutual interference. In FDMA separate users are allocated separate frequency bands (channels) for their exclusive use for the entire duration of a call. In TDMA several users share the same radio channel but are assigned unique time slots in which they communicate. In CDMA every user transmits at the same frequency and at the same time, and interference is avoided by the use of specialized codes that are unique to each user and uncorrelated between users. [Figure 130.1](#) illustrates the three multiple-access techniques.

Handheld walkie-talkies, paging receivers (pagers), cordless telephones, and cellular telephones are examples of mobile radio systems that are commonly used today. The complexity, performance, required infrastructure, and types of services offered by each of these systems are vastly different. In this chapter a variety of modern mobile radio systems are described with an emphasis placed on modern cellular radio systems. The chapter concludes with a summary of all major mobile radio system standards in use throughout the world.

**Figure 130.1** Illustration of the three multiplexing techniques, and how multiple channels are provided without interfering with each other: (a) FDMA, (b) TDMA, and (c) CDMA.

(c) CDMA

## 130.1 Paging Systems

Paging systems are simplex communication systems that can be used to send brief messages to a subscriber. Depending on the type of service, the message can be a numeric message, an alphanumeric message, or a voice message. Paging systems are typically used to notify a subscriber of the need to call a particular telephone number or to travel to a known location to receive further instructions. Anyone may send a message to a paging subscriber by dialing the paging system number (usually a toll-free telephone number) and using a telephone keypad or modem to issue a message, called a *page*. The paging system then transmits the page throughout the service area using base stations which broadcast the page on a radio carrier.

Paging systems vary widely in their complexity and coverage area. Whereas simple paging systems may only cover a limited range of 2–5 km, wide-area paging systems may provide worldwide coverage. Though paging receivers are simple and inexpensive, the transmission system required can be quite sophisticated. Wide-area paging systems consist of a network of telephone lines, large radio towers, satellite links, and powerful transmitters and simultaneously dispatch a page to many transmitters (this is called *simulcasting*), which may be located within the same service area or in different cities or countries. Paging systems are designed to provide reliable communication to subscribers wherever they are—whether inside buildings, driving on a highway, or in an airplane. This necessitates large transmitter powers (on the order of kilowatts) and low data rates (a few thousand bits per second) for maximum coverage. Figure 130.2 shows a diagram of a wide-area paging system.

**Figure 130.2** Example of a wide-area paging system. The paging control center dispatches pages received from the PSTN throughout several cities at the same time.

## 130.2 Cordless Telephone Systems

---

Cordless telephone systems are full-duplex communication systems that use radio to connect a handset to a dedicated base station. The base unit is connected to a dedicated telephone line with a specific telephone number. In first-generation cordless telephone systems (manufactured in the 1980s), the portable unit communicates only to the dedicated base unit, and only over distances of a few tens of meters. Early cordless telephones operate as extension telephones to a **transceiver** connected to a subscriber line on the PSTN and were developed primarily for in-home use. Second-generation cordless telephones have recently been introduced that allow subscribers to use their handsets at many outdoor locations within urban centers, such as London or Hong Kong. Modern cordless telephones are sometimes combined with paging receivers so that a subscriber may first be paged and then respond to the page using the cordless telephone. Cordless telephone systems provide the user with limited range and limited mobility, as it is usually not possible to maintain a call if the user travels outside the range of the base station. Typical second-generation base stations provide coverage ranges of a few hundred meters.

## 130.3 Cellular Telephone Systems

---

A cellular telephone system provides wireless access to the PSTN for any user located within the radio range of the system. Cellular systems accommodate a large number of users over a large geographic area, within a limited frequency spectrum. Cellular radio systems provide high-quality service, often comparable to that of landline telephone systems. High capacity is achieved by limiting the coverage of each transmitter to a small geographic area so that the same radio channels can be reused by another transmitter located a small distance away. A sophisticated switching technique called a **handoff** enables a call to proceed uninterrupted when the user moves from one area to another.

[Figure 130.3](#) shows a basic cellular system that consists of **mobile stations**, **base stations**, and a **mobile telephone switching office (MTSO)**. Each user communicates via radio with one of the base stations and may be handed off to any number of base stations throughout the duration of a call. The mobile station contains a transceiver, an antenna, and a control unit and can be mounted in a vehicle or handheld package. The base stations consist of several transmitters and receivers and generally have towers that support several transmitting and receiving antennas. The base station serves as a bridge between all mobile users in a geographic area and is connected via telephone lines or microwave links to the MTSO. The MTSO coordinates the activities of all the base stations and connects the entire cellular system to the PSTN.

**Figure 130.3** An illustration of a cellular system. The towers represent base stations that provide radio access between mobile users and the mobile telephone switching office (MTSO).

Communication between the base station and the mobile takes place over four distinct channels. The channel used for voice transmission from base station to mobile is called the *forward voice channel (FVC)*, and the channel used for voice transmission from mobile to base station is called the *reverse voice channel (RVC)*. The other two channels are the forward and reverse *control channels*. Control channels transmit and receive data messages that carry call initiation and service requests. Control channels are always monitored by mobiles that do not have an active call in progress.

Most cellular systems provide a special service called *roaming*, which allows subscribers to move into service areas other than the one from which service is subscribed. Once a mobile enters

a city or geographic area that is different from its home service area, it is registered as a roamer in the new service area. Roaming mobiles are allowed to receive and place calls from wherever they happen to be.

## 130.4 Personal Communications System (PCS)

---

In the mid-1990s the worldwide demand for cellular telephone service led to the development of the personal communication system (PCS). PCS offers personal wireless communications and advanced data networking using the cellular radio concept. PCS has been allocated the radio spectrum in the 1.8–2.0 GHz band in many countries throughout the world. Under the auspices of the International Telecommunications Union (ITU), an international consortium is developing a universal standard for PCS, so that the same equipment may be used throughout the world. This consortium, called the Future Public Land Mobile Telecommunications System (FPLMTS), and recently renamed IMT-2000, is considering local, regional, national, and international networking using cellular and satellite radio communication.

## 130.5 The Cellular Concept and System Fundamentals

---

The need to grow a mobile subscriber population within a limited radio spectrum led to the development of systems based on the cellular concept [MacDonald, 1979]. The key to providing capacity in a cellular system is a technique called **frequency reuse**.

### Frequency Reuse

Cellular radio systems rely on an intelligent allocation and reuse of channels throughout a coverage region. A subset of channels is assigned to a small geographic area called a *cell*. Each cell is served by a base station that uses the assigned channel group. The power radiated by a base station is deliberately kept low, and antennas are located so as to achieve coverage within the particular cell. By limiting the coverage area within a cell, the same group of channels can be used to cover various cells that are separated from one another by distances large enough to keep the cochannel interference level within tolerable limits.

Figure 130.4 shows a cellular layout where cells labeled with the same letter use the same group of channels. Due to random propagation effects, actual cell coverage areas are amorphous in nature. However, for system design purposes it is useful to visualize cells as hexagons.

**Figure 130.4** Illustration of the cellular concept. Cells labeled with the same letter use the same set of frequencies. A cell cluster is outlined in bold and is replicated over the coverage area. In this example the cluster size,  $N$ , is equal to 7, and each cell contains  $1/7$  of the total number of available channels.

To understand the frequency reuse concept, consider a cellular system that has a total of  $S$  duplex channels available for use. If each cell is allocated a group of  $k$  channels ( $k < S$ ), and if the  $S$  channels are divided among  $N$  cells into unique and disjoint channel groups with the same number of channels, the total number of available radio channels can be expressed as

$$S = kN \quad (130.1)$$

The factor  $N$  is called the *cluster size* and is typically equal to 7 or 4. The  $N$  cells that use the complete set of frequencies are collectively called a *cluster*. If a cluster is replicated  $M$  times within the system, the total number of duplex channels,  $C$ , available to the system is given by

$$C = MkN = MS \quad (130.2)$$

As seen from Eq. (130.2), the capacity of a cellular system is directly proportional to the number of times a cluster is replicated in a given service area. If the cluster size  $N$  is reduced, more clusters are used to cover a given area and hence more capacity (larger value of  $C$ ) is achieved. The choice of  $N$  depends on the cochannel interference level that can be tolerated, as discussed later.

## Channel Assignment and Handoff Strategies

For efficient utilization of the radio spectrum, a frequency reuse scheme that is consistent with the objectives of increasing capacity and minimizing interference is required. Channel assignment strategies can be classified as either fixed or dynamic. The particular type of channel assignment employed affects the performance of the system, particularly in how calls are managed when a mobile user travels from one cell to another [Tekinay and Jabbari, 1991].

In a fixed channel assignment strategy, each cell is allocated a predetermined set of channels. Any call attempt within the cell can be served only by the unoccupied channels in that particular cell. If all the channels in that cell are occupied, the call is blocked and the subscriber does not receive service. In dynamic channel assignment, channels are not allocated to various cells permanently. Instead, each time a call is attempted, the cell base station requests a channel from the MTSO, which allocates a channel based on an algorithm that minimizes the cost of channel allocation.

Since neighboring cells use separate channels, when a mobile passes into a separate cell while a conversation is in progress, it is required to transfer the connection to the new cell base station automatically. This handoff operation not only involves identifying a new base station, but also requires that the voice and control signals be allocated to channels associated with the new base station.

Processing handoffs is an important task in any cellular mobile system. Many system designs prioritize handoff requests over call initiation requests. It is required that every handoff be performed successfully and that they happen as infrequently and imperceptibly as possible. In cellular systems the signal strength on either the forward or reverse channel link is continuously monitored and, when the mobile signal begins to decrease (e.g., when the reverse channel signal

### THE ENVOY

The Envoy wireless communicator is creating a whole new industry by enabling mobile professionals to exchange Internet messages, send faxes, check flight schedules, and manage appointments, addresses, and other personal information from wherever they happen to be—even an airport lounge. This handheld device uses Motorola two-way wireless communications and thus requires no phone lines or external connection to access information. Wireless products, like the Envoy, will enable millions of travelling workers to have the same tools as those workers who are at their desks. (Courtesy of Motorola.)

strength drops to below between  $-90$  dBm and  $-100$  dBm at the base station), a handoff occurs. In first-generation analog cellular systems, the MTSO monitor(s) the signals of all active mobiles at frequent intervals to determine a rough estimate of their location and decide if a handoff is necessary. In second-generation systems that use digital TDMA technology, handoff decisions are mobile assisted. In a **mobile-assisted handoff (MAHO)** the mobile stations make measurements of the received power from several surrounding base stations and continually report the results of these measurements to the base station in use, which initiates the handoff. The MAHO method enables faster handoff than in first-generation analog cellular systems since the MTSO is not burdened with additional computation.

## 130.6 System Capacity and Performance of Cellular Systems

---

Interference is the major limiting factor in the capacity and performance of cellular radio systems. The source of interference may be from an adjacent channel in the same cell, a signal from other base stations operating in the same frequency band, or signals from cochannel mobiles. Interference caused by signals from adjacent channels is called *adjacent channel interference*, and the interference between signals from different cells using the same frequency is called *cochannel interference*. Adjacent channel interference occurs due to imperfect receiver filtering, especially when an undesired transmitter is significantly closer to a receiver than the desired source. Adjacent channel interference is reduced by maximizing the frequency separation between channels in each cell through careful frequency planning in the cellular system.

### Radio Interference and System Capacity

Cochannel interference is the major bottleneck for increasing capacity. Unlike noise, cochannel interference cannot be combated by simply increasing the carrier power. This is because an increase in carrier transmit power increases the interference as well. To reduce cochannel interference, cells using the same set of frequencies (cochannel cells) must be separated to provide sufficient isolation.

When the size of each cell in a cellular system is roughly the same, cochannel interference is independent of the transmitted power and is an increasing function of a parameter  $Q$ , called the **cochannel reuse ratio**. The value of  $Q$  is related to the cluster size  $N$  and is defined for a hexagonal geometry as

$$Q = \frac{D}{R} = \sqrt{3N} \quad (130.3)$$

where  $R$  is the major radius of the cells and  $D$  is the separation between cochannel cells as shown in Fig. 130.5. A small value of  $Q$  provides larger capacity for a particular geographic coverage region, whereas a large value of  $Q$  improves the transmission quality, due to a smaller level of cochannel interference. A trade-off is made between these two objectives in actual cellular design.

**Figure 130.5** Illustration of the first tier of cochannel cells for a cluster size of  $N = 7$ .

If  $i_0$  is the number of cochannel interfering cells, the signal to interference ratio ( $S/I$ ) at a receiver on the forward link can be expressed as

$$\frac{S}{I} = \frac{S}{\sum_{i=1}^{i_0} I_i} \quad (130.4)$$

where  $S$  is the desired signal from the desired base station and  $I_i$  is the interference caused by the  $i$ th outlying cochannel cell base station. If the signal levels of cochannel cells are known, then the  $S/I$  ratio for the reverse link can be found using Eq. (130.4).

Propagation measurements in a mobile radio channel show that the average received power at any point decays exponentially with respect to distance of separation between the transmitter and the receiver. The average received power  $P_r$  at a distance  $d$  from the transmitting antenna is approximated by either of the following:

$$P_r = P_0 \left( \frac{d_0}{d} \right)^n \quad (130.5)$$

$$P_r(\text{dBm}) = P_0(\text{dBm}) - 10n \log_{10} \frac{d}{d_0} \quad (130.6)$$

where  $P_0$  is the power received at a close-in reference point in the far-field region of the antenna at a distance  $d_0$  from the transmitting antenna, and  $n$  is the path loss exponent. Therefore, if  $D_i$  is the distance of the  $i$ th interferer from the mobile, the received power at a given mobile due to the  $i$ th interfering cell will be proportional to  $(D_i)^{-n}$ . The path loss exponent typically ranges between 2 and 4 in urban cellular systems [Rappaport and Milstein, 1992].

Assuming that the transmit power of each base station is equal and the path loss exponent is the same throughout the coverage area, the  $S/I$  ratio can be approximated as

$$\frac{S}{I} = \frac{R^{-n}}{\sum_{i=1}^{i_0} (D_i)^{-n}} \quad (130.7)$$

Considering only the first layer of interfering cells, if all the interfering base stations are equidistant from the desired base station and if this distance is equal to the distance  $D$  between cell centers, then Eq. (130.7) simplifies to

$$\frac{S}{I} = \frac{(D/R)^n}{i_0} = \frac{(\sqrt{3N})^n}{i_0} \quad (130.8)$$

Equation (130.8) relates  $S/I$  to the cluster size  $N$ , which in turn determines the overall capacity of the system. Hence, it is clear that cochannel interference determines the capacity of cellular systems.

## Grade of Service

Cellular systems rely on **trunking** to allow a large population of users to share a finite number of

radio channels. The quality of service in any trunked system is often measured using a benchmark called the **grade of service** (GOS). The grade of service is a measure of the ability of a particular user to access a trunked system during the busiest hour. GOS is typically given as the likelihood that a call is blocked or the likelihood of a call experiencing a delay greater than a certain queuing time.

The GOS for a trunked system that provides no queuing for blocked calls is given by the Erlang B formula,

$$\Pr[\text{blocking}] = \frac{A^C / C!}{\sum_{k=0}^C (A^k / k!)} \quad (130.9)$$

where  $C$  is the number of channels offered by the cell and  $A$  is the total traffic offered. The total offered traffic  $A$  is measured in erlangs, where one erlang represents the load over a channel that is completely occupied at all times. For a system containing  $U$  users, the total offered traffic can be expressed as

$$A = U\mu H \quad (130.10)$$

where  $\mu$  is the average number of call requests per unit time and  $H$  is the average duration of a typical call.

For trunked systems in which a queue is provided to hold calls that are blocked, the likelihood of a call not having immediate access to a channel is determined by the Erlang C formula:

$$\Pr[\text{delay} > 0] = \frac{A^C}{A^C + C![1 - (A/C)] \sum_{k=0}^{C-1} (A^k / k!)} \quad (130.11)$$

The GOS for a queued system is measured as the probability that a call is delayed greater than  $t$  seconds and is given by the probability that a call is delayed by a nonzero duration of time, multiplied by the conditional probability that the delay is greater than  $t$  seconds, as shown in Eq. (130.12):

$$\begin{aligned} \Pr[\text{delay} > t] &= \Pr[\text{delay} > 0] \Pr[\text{delay} > t \mid \text{delay} > 0] \\ &= \Pr[\text{delay} > 0] \exp[-(C - A)t/H] \end{aligned} \quad (130.12)$$

## 130.7 Mobile Radio Systems Around the World

Numerous mobile radio systems and services are in use around the world. There is a repertoire of standards that have been developed for the operation of these mobile radio systems, and many more are likely to emerge. [Tables 130.1, 130.2, and 130.3](#) provide listings of the most common paging, cordless, and cellular telephone standards in North America, Europe, and Japan.

**Table 130.1** Mobile Radio Standards in North America

Standard	Type	Year of Introduction	Multiple Access	Frequency Band	Modulation	Channel Bandwidth
AMPS	Cellular	1983	FDMA(FDD)	824–894 MHz	FM	30 kHz
NAMPS	Cellular	1992	FDMA	824–894 MHz	FM	10 kHz
USDC	Cellular	1991	TDMA(FDD)	824–894 MHz	$\pi/4$ -DQPSK	30 kHz
IS-95	Cellular	1993	CDMA	824–894 MHz	O-QPSK	1.25 MHz
GSC	Paging	1970s	Simplex FDM	Several	FSK	12.5 kHz
POCSAG	Paging	1970s	Simplex FDM	Several	FSK	12.5 kHz
FLEX	Paging	1993	Simplex FM	Several	4-FSK	15 kHz
PACS	Cordless/PCS	1993	TDMA/FDM A	1.8–2.2 GHz	$\pi/4$ -QPSK	300 kHz

**Table 130.2** Mobile Radio Standards in Europe

Standard	Type	Year of Introduction	Multiple Access	Frequency Band	Modulation	Channel Bandwidth
E-TACS	Cellular	1985	FDMA	900 MHz	FM	25 kHz
NMT-450	Cellular	1981	FDMA	450–470 MHz	FM	25 kHz
NMT-900	Cellular	1986	FDMA	890–960 MHz	FM	12.5 kHz
GSM	Cellular	1990	TDMA	890–960 MHz	GMSK	200 kHz
C-450	Cellular	1985	FDMA	450–465 MHz	FM	20 kHz/10kHz
ERMES	Paging	1993	FDMA	Several	4-FSK	25 kHz
CT-2	Cordless	1989	FDMA/(TDD)	864–868 MHz	GFSK	100 kHz
DECT	Cordless	1993	TDMA/(TDD)	1880–1900 MHz	GFSK	1.728 MHz
DCS-1800	Cordless	1993	TDMA	1710–1880 MHz	GMSK	200 kHz

**Table 130.3** Mobile Radio Standards in Japan

Standard	Type	Year of Introduction	Multiple Access	Frequency Band	Modulation	Channel Bandwidth
JTACS	Cellular	1988	FDMA	860–925 MHz	FM	25 kHz
JDC	Cellular	1992	TDMA	810–1513 MHz	$\pi/4$ -DQPSK	25 kHz
NTT	Cellular	1979	FDMA	400–800 MHz	FM	25 kHz
NTACS	Cellular	1993	FDMA	843–925 MHz	FM	12.5 kHz
NTT	Paging	1979	FDMA	280 MHz	FSK	12.5 kHz
NEC	Paging	1979	FDMA	Several	FSK	10 kHz
PHS	Cordless	1993	TDMA	1895–1907 MHz	$\pi/4$ -DQPSK	300 kHz

The two most common paging standards are the POCSAG (Post Office Code Standard Advisory Group), and GSC (Golay Sequential Code) paging standards. POCSAG was developed by British Post Office in the late 1970s and supports binary FSK signaling at 256 bps, 512 bps, 1200 bps, and 2400 bps. GSC is a Motorola paging standard that uses 300 bps for the pager address and 600 bps binary FSK for message transmission. New paging systems, such as FLEX and ERMES, will provide up to 6400 bps transmissions by using 4-level modulation.

The CT-2 and DECT standards developed in Europe are the two most popular cordless telephone standards throughout Europe and Asia. The CT-2 system makes use of microcells that cover small distances, usually less than 100 m, using base stations with antennas mounted on street lights or at low heights. The CT-2 system uses battery efficient frequency-shift keying along with a 32 kbps ADPCM speech coder for high-quality voice transmission. Handoffs are not supported in CT-2, as it is intended to provide short-range access to the PSTN. The DECT system accommodates data and voice transmissions for office and business users. In the U.S. the PACS standard, developed by Motorola and Bellcore, is likely to be used inside office buildings as a wireless voice and data telephone system.

The world's first cellular system was implemented by NTT in Japan. The system was deployed in 1979 and uses 600 FM duplex channels (25 kHz per one-way channel) in the 800 MHz band. In Europe the Nordic Mobile Telephone system (NMT450) was developed in 1981 for the 450 MHz band and uses 25 kHz channels. The Extended European Total Access Cellular System (ETACS) was deployed in 1985 and enjoys about 15% of the market share in Europe. In Germany a cellular standard called C-450 was introduced in 1985. The first-generation European cellular systems are generally incompatible with one another because of the different frequencies and communication protocols used. These systems are now being replaced by the Pan-European digital cellular standard GSM (Global System Mobile), which was first deployed in 1990. The GSM standard is gaining worldwide acceptance as the first digital cellular standard.

Unlike the incompatible first-generation cellular systems in Europe, the Advanced Mobile Phone System (AMPS) was introduced in the U.S. in 1983 as a nationwide standard ensuring that all cellular telephones are compatible with any cellular radio base station within the country. AMPS, like other first-generation cellular systems, uses analog FM modulation and frequency-division multiple access. As the demand for services continues to increase, cellular radio systems using more efficient digital transmission techniques are being employed. A U.S. TDMA-based digital standard called U.S. Digital Cellular (USDC or IS-54) has been in operation since 1991. In order to be compatible with the existing analog system, the IS-54 standard requires that the mobiles be capable of operating in both analog AMPS and digital voice channels. TDMA systems are able to provide capacity improvements of the order of 5–10 times that of analog FM without adding any new cell sites [Raith and Uddenfeldt, 1991]. Using bandwidth efficient  $\pi/4$ -DQPSK modulation, the IS-54 standard offers a capacity of about 50 erlangs/km<sup>2</sup>.

A CDMA-based cellular system has been developed by Qualcomm, Inc., and standardized by the Telecommunications Industry Association (TIA) as an interim standard (IS-95). This system supports a variable number of users in 1.25 MHz wide channels. Whereas the analog AMPS system requires that the signal be at least 18 dB above the interference to provide acceptable call quality, CDMA systems can operate with much larger interference levels because of their inherent

interference-resistant properties. This fact allows CDMA systems to use the same set of frequencies in every cell, which provides a large improvement in capacity. Unlike other digital cellular systems, the Qualcomm system uses a variable rate vocoder with voice activity detection, which considerably reduces the effective data rate and also the battery drain.

## Defining Terms

**Base station:** A station in the cellular radio service used for radio communication with mobile stations. They are located either in the center or edges of every cell and consist of transmitting and receiving antennas mounted on towers.

**Cochannel reuse ratio:** The ratio of the radius of a cell to the distance between the centers of two nearest cochannel cells.

**Frequency reuse:** The use of radio channels on the same carrier frequency to cover various areas that are separated from one another so that cochannel interference is not objectionable.

**Grade of service:** Likelihood that a call is blocked or delayed in a trunked system.

**Handoff:** The process of transferring a mobile station from one channel to another.

**Mobile-assisted handoff (MAHO):** A process in which a mobile, under directions from a base station, measures signal quality of specified RF channels. These measurements are forwarded to the base station upon request to assist in the handoff process.

**Mobile station:** A station in the cellular radio service intended to be used while in motion at unspecified locations. They could be either handheld personal units or units installed in vehicles.

**Mobile telephone switching office (MTSO):** Switching center that coordinates the routing of cellular calls in a service area. The MTSO connects the cellular base stations and mobiles to the PSTN.

**Transceiver:** A device capable of both transmitting and receiving radio signals.

**Trunking:** Method of accommodating a large number of users using a small number of radio channels by allocating them on a demand basis.

## 131.1 Optical Communications Systems Topologies

### 131.2 Fibers

### 131.3 Other Components

### 131.4 Signal Quality

## Joseph C. Palais

Arizona State University

Electronic communications over conducting wires or by atmospheric radio transmission began in the latter part of the 19th century and was highly developed by the middle part of the 20th century. Widespread communication via beams of light traveling over thin glass fibers is a relative newcomer, beginning in the 1970s, reaching acceptance as a viable technology in the early 1980s, and continuing to evolve since then [Chaffee, 1988]. Fibers now form a major part of the infrastructure for a national telecommunications information highway in the U.S. and elsewhere.

The fundamentals of optical communications are covered in many textbooks [e.g., Palais, 1992; Keiser, 1991], which elaborate on the information presented in this chapter.]

*Optical communications* refers to the transmission of messages over carrier waves that oscillate at optical frequencies. The frequency spectrum of electromagnetic waves can range from DC to beyond  $10^{21}$  Hz. (A tabulation of units and prefixes used in this chapter appears in Tables 131.1 and 131.2.) Optical waves oscillate much faster than radio waves or even microwaves. Their characteristically high frequencies (on the order of  $3 \cdot 10^{14}$  Hz) allow vast amounts of information to be carried. An optical channel utilizing a bandwidth of just one percent of this center frequency would have an enormous bandwidth of  $3 \cdot 10^{12}$  Hz. Numerous schemes exist for taking advantage of the vast bandwidths available. These include **wavelength-division multiplexing (WDM)** and **optical frequency-division multiplexing (OFDM)**, which allocate various information channels to bands within the optical spectrum.

**Table 131.1** Units Used in Optical Communications

1 Unit	Symbol	Measure
1 Meter	m	Length
1 Second	s	Time
1 Hertz	Hz	Frequency
1 Bits per second	b/s	Data rate
1 Watt	W	Power

**Table 131.2** Commonly Used Prefixes

1 Prefix	Symbol	Multiplication Factor
1 Giga	G	$10^9$
1 Mega	M	$10^6$
1 Kilo	k	$10^3$
1 Milli	m	$10^{-3}$
1 Micro	$\mu$	$10^{-6}$
1 Nano	n	$10^{-9}$

For historical reasons optical waves are usually described by their wavelengths rather than their frequencies. The two characteristics are related by

$$\lambda = c/f \quad (131.1)$$

where  $f$  is the frequency in hertz,  $\lambda$  is the wavelength, and  $c$  is the velocity of light in empty space ( $3 \cdot 10^8$  m/s). A frequency of  $3 \cdot 10^{14}$  Hz corresponds to a wavelength of  $10^{-6}$  meters (or  $1 \mu\text{m}$ , often called a *micron*). Wavelengths of interest for optical communications are on the order of a micron.

The Gaussian beam profile is common in optical systems. Its intensity pattern in a plane transverse to the direction of wave travel is described by

$$I = I_0 e^{-2(r/w)^2} \quad (131.2)$$

where  $r$  is the polar radial coordinate and the factor  $w$  is called the *spot size*. This is the light pattern emitted by many lasers and is (approximately) the intensity distribution in a **single-mode fiber**.

Optical transmission through the atmosphere is possible, but it suffers serious liabilities. A fundamental limit is imposed by diffraction of the light beam as it propagates away from the transmitting station. The full divergence angle of a Gaussian beam is given by

$$\theta = 2\lambda/\pi w \quad (131.3)$$

Because of the continual beam enlargement with propagation distance, the amount of light captured by a finite receiving aperture diminishes with increasing path length. The resultant low received power limits the distances over which atmospheric optical systems are feasible.

The need for an unobstructed line-of-sight connection between transmitter and receiver and a clear atmosphere also limits the practicality of atmospheric optical links. Although atmospheric applications exist, the vast majority of optical communications is conducted over glass fiber.

A key development leading to fiber communications was the demonstration of the first **laser** in 1960. This discovery was quickly followed by plans for numerous laser applications. Progress on empty space optical systems in the 1960s laid the groundwork for fiber communications in the 1970s. The first low-loss optical waveguide, the glass fiber, was produced in 1970. Soon after, multimode fiber transmission systems were being designed, tested, and installed. The mass-production commercialization of the single-mode fiber in 1983 brought about the fiber revolution in the communications industry. Fibers are practical for a range of path lengths, from under a meter to as long as required on the earth's surface and beneath its oceans (e.g., almost 10000 kilometers for transpacific links).

Fiber systems are limited in length by the bandwidth of their components (a fiber's bandwidth decreases with length) and by component losses (a fiber's loss increases with length). Loss is usually expressed in the decibel scale, which compares two power levels and is defined by

$$\text{dB} = 10 \log P_2/P_1 \quad (131.4)$$

## 131.1 Optical Communications Systems Topologies

---

Fibers find their greatest use in telephone networks, local-area networks, and cable television networks. They are also useful for short data links, closed-circuit video links, and elsewhere.

A block diagram of a point-to-point fiber optical communications system appears in [Fig. 131.1](#). This diagram represents the architecture typical of the telephone network. The fiber telephone network is digital, operating at levels indicated in [Table 131.3](#). Fiber systems often transmit at multiples of the rates listed in the table. For example, rates in the range of 2.5 Gb/s are commonplace. At this rate, several thousand digitized voice channels (each operating at 64 kb/s) can be transmitted along a single fiber using time-division multiplexing (TDM). Higher-rate fiber systems (tens of gigabits per second) will be developed as technology evolves.

**Figure 131.1** Point-to-point fiber transmission system.

**Table 131.3** Digital Transmission Rates

Designation	Data Rate (Mb/s)
DS-1	1.5444
DS-3	44.736
DS-4	274.175
OC-1	51.84
OC-3	155.52
OC-12	622.08
OC-24	1244.16
OC-48	2488.32

The DS levels refer to U.S. telephone signaling rates, whereas the OC levels are those of the SONET standard.

Because fiber cables may contain more than one fiber (in fact, some cables contain hundreds of fibers), a single cable may carry hundreds of thousands of voice channels.

Telephone applications may be broken down into several distinct areas: transmission between telephone exchanges, long-distance links, undersea links, and distribution in the local loop (i.e., to subscribers). Although similarities exist between these systems, the requirements are somewhat different. Between telephone exchanges, large numbers of calls must be transferred over moderate distances. Because of the moderate path lengths, optical amplifiers or regenerators are not required.

Long-distance links, such as between major cities, require signal boosting of some sort (either regenerators or optical amplifiers). Undersea links (such as transatlantic or transpacific) require multiple boosts in the signal because of the long path lengths involved [Thiennot *et al.*, 1993].

Fiber-to-the-home (for broadband services, such as cable television distribution) does not involve long path lengths but does include division of the optical power in order to share fiber transmission paths over all but the last few tens of meters into the subscriber's premises. In many subscriber networks, the fibers terminate at optical-to-electrical conversion units located close to the subscriber. From that point, copper wires transmit the signals over the remaining short distance to the subscriber. Because of the power division, optical amplifiers are needed to keep the signal levels high enough for proper reception.

Cable television distribution remained mostly coaxial cable based for many years, which was partly due to the distortion produced by optical analog transmitters. Production of highly linear laser diodes [such as the distributed feedback (DFB) laser diode] permitted the design of practical television fiber distribution links.

Some applications, such as local-area networks (LANs), require distribution of the signals over shared transmission fiber. Topologies include the passive star, the active star, and the ring network [Hoss, 1990]. The passive star and the active ring are illustrated in Figs. 131.2 and 131.3. LANs are *broadcast systems* that allow all terminals to receive messages sent from any one transmitting terminal.

**Figure 131.2** Star topology. Blocks T and R are, respectively, the optical transmitter and optical receiver.

**Figure 131.3** Ring topology. Blocks T and R are, respectively, the optical transmitter and optical receiver.

The star coupler distributes optical signals from any input port to all output ports. Its loss is simply

$$L = 10 \log (1/N) \quad (131.5)$$

where  $N$  is the number of output ports on the star coupler.

In the ring each node acts as a regenerator. The ring is simply a series of connected point-to-point networks.

The major components found in optical communications systems are modulators, light sources, fibers, photodetectors, connectors, splices, star couplers, regenerators, and optical amplifiers.

## 131.2 Fibers

Silica glass fibers make up the majority of optical transmission lines. The wavelength regions around 0.85, 1.3, and 1.55  $\mu\text{m}$  have been heavily utilized because of their low losses. These regions are called, respectively, the *first*, *second*, and *third windows*. Properties of fibers in these windows are tabulated in Table 131.4.

**Table 131.4** Typical Fiber Properties

Window	Wavelength (nm)	Loss (dB/km)	Dispersion (ps/nm · km)
First	800–900	3	120
Second	1290–1330	0.4	Nearly zero
Third	1520–1570	0.25	15

**Dispersion** causes pulse spreading, leading to intersymbol interference. This interference limits the fiber's allowable data rate. The amount of pulse spreading is given by

$$\Delta\tau = ML\Delta\lambda \quad (131.6)$$

where  $M$  is the dispersion (values are given in Table 131.4),  $L$  is the fiber length, and  $\Delta\lambda$  is the spectral width of the light source emission. Dispersion is created by the material and the waveguide structure, both of which have a wavelength-dependent pulse velocity.

Multimode fibers allow many modes to simultaneously traverse the fiber. This produces *multimode distortion* (resulting in additional pulse spreading) because the various modes travel at different speeds. For this reason multimode fibers can only be used for applications in which the product of data rate (or modulation frequency) and path length is not high.

Because single-mode fibers eliminate multimode spreading, they have larger bandwidths and are used for all long-distance, high-rate links.

Multimode fibers have relatively high loss and large dispersion in the 850 nm first window region. Applications are, therefore, restricted to moderately short path lengths (typically less than a kilometer). Components in this window tend to be cheaper than those operating in the 1300 nm and 1550 nm windows.

The 1300 nm second window exhibits low losses and nearly zero dispersion. Single-mode, nonrepeated paths up to 70 km or so are attainable in this window. Here, multimode fiber is feasible for modest lengths required by local-area networks and campus-based networks and single-mode fiber for longer point-to-point links.

Fiber systems operating in the 1550 nm third window cover the highest rates and longest unamplified, unrepeated distances. Unamplified lengths over 100 km are possible. Typically, only single-mode fibers are used in this region.

## 131.3 Other Components

---

Most systems utilize semiconductor **laser diodes** (LD) or **light emitting diodes** (LED) for the light source. These sources are typically modulated by controlling their driving currents. The conversion from current,  $i$ , to optical power,  $P$ , is given by

$$\begin{aligned} P &= a_1(i - I_{th}), & i > I_{th} \\ P &= 0, & i < I_{th} \end{aligned} \quad (131.7)$$

where  $a_1$  is a constant and  $I_{th}$  is the turn-on threshold current for the diode. The threshold current for LEDs is zero and in the range of a few milliamperes to a few tens of milliamperes for LDs. For example,  $a_1$  may be 0.1 mW/mA. Thus, the optical power waveform is a replica of the modulation current if the light source is operated above its threshold current.

Laser diodes are more coherent (i.e., they have smaller spectral widths) than LEDs and thus produce less dispersion. In addition, LDs can be modulated at higher rates (above 10 GHz), whereas LEDs are limited to rates of just a few hundred MHz. LEDs have the advantage of lower cost and simpler circuitry requirements.

The photodetector converts the light beam back into an electrical signal. Semiconductor **PIN photodiodes** and **avalanche photodiodes** are normally used. The conversion for the PIN diode is given by the linear equation

$$i = \rho P \quad (131.8)$$

where  $i$  is the detected current,  $P$  is the incident optical power, and  $\rho$  is the photodetector's *responsivity*. Typical values of the responsivity are on the order of 0.5 A/W. The avalanche photodiode response follows this same equation but includes an amplification factor that can be as high as several hundred.

## 131.4 Signal Quality

---

Signal quality is measured by the **signal-to-noise ratio** (S/N) in analog systems and by the **bit-error rate** (BER) in digital links. High-quality analog video links may require signal-to-noise ratios on the order of a hundred thousand (50 dB) or more. Good digital systems operate at error rates of  $10^{-9}$  or better.

In a thermal noise-limited system the probability of error,  $P_e$ , (which is the same as the bit-error rate) is

$$P_e = 0.5 - 0.5 \operatorname{erf} (0.354\sqrt{S/N}) \quad (131.9)$$

where erf is the error function, tabulated in many references. An error rate of  $10^{-9}$  requires a signal-to-noise ratio of nearly 22 dB ( $S/N = 158.5$ ).

## Defining Terms

**Avalanche photodiode:** Semiconductor photodetector having internal gain.

**Bit-error rate:** Probability of error.

**Dispersion:** Wavelength-dependent pulse group velocity caused by the material and the fiber structure. Results in pulse spreading due to the nonzero spectral emission widths of the light source.

**Laser:** Source producing highly coherent light.

**Laser diode:** Semiconductor laser. Spectral emission widths typically in the range of 1 to 5 nm. Special devices available with spectral widths of 0.1 nm or less.

**Light emitting diode:** Semiconductor emitter having spectral emission widths much larger than those of the laser diode. Typical emission widths are in the range of 20 to 100 nm.

**Optical frequency-division multiplexing (OFDM):** Transmission of closely spaced carrier wavelengths (a few tenths of a nm, or less) along a single fiber. Demultiplexing usually requires an optical coherent receiver.

**PIN photodiodes:** Semiconductor photodetector.

**Signal-to-noise ratio:** Ratio of signal power to noise power.

**Single-mode fiber:** Fiber that allows only one mode to propagate; has larger bandwidth, allowing greater data rate, than do multimode fibers.

**Wavelength-division multiplexing (WDM):** Transmission of multiple-carrier wavelengths simultaneously to increase the capacity of a single fiber. Typically, the individual carriers are widely spaced (from a few tens of nm to several hundred nm), permitting just a few independent channels on the fiber.

A COMPUTER IS A SYSTEM capable of solving various scientific and nonscientific problems; storing, retrieving, and manipulating data; communicating and sharing data; controlling processes; and interacting with the surrounding environment.

Today a typical computer consists of a complex electronic system containing a massive amount of components which are very highly integrated. Even the simplest computer today is far more complex than the computers from the not-so-distant past and may contain millions or hundreds of millions of transistors.

Computers emerged from complex digital systems and controllers in areas where the behavioral specification for such a system could be satisfied with some sort of general-purpose digital system. One of the first minicomputers (18-bit PDP-4) was built as a generalization of an atomic plant controller. The first microprocessor, Intel 4004 (S. Shima), was originally commissioned as a generalized calculator chip.

Because of the computers versatility and general-purpose orientation, there is hardly any place today that does not contain a computer in some form. There are two reasons for this:

1. The computer's structure and organization is general, and therefore it can be easily customized in many different forms.
2. Because of their general structure, computers can be mass-produced, which keeps their cost down.

The 4- and 8-bit microcontrollers, which represent over 90% of the microprocessors sold, generally sell for well under a dollar, which is due to the fact that they can be produced in very large quantities.

Based on their power, computers are traditionally classified in four major categories: personal computers, midrange or workstations, mainframes, and supercomputers; however, the boundaries between these categories are blurred. The reason is that the same technology is being used for all four categories, although mainframes and supercomputers are resorting to bipolar and gallium arsenide. Therefore, the performance increases are being achieved mainly through the improvements in technology. The performance is roughly doubling every two years, as shown in Fig. 1. This is not the result of changes in the architecture because the architecture issue has been settled around RISC, which has clearly demonstrated its advantage over CISC (RISC stands for Reduced Instruction Set Computer, while CISC stands for Complex Instruction Set Computer). RISC is characterized by simple instructions in the instruction set, which is constructed to fit the machine pipeline in such a way that one instruction can be issued in every cycle. CISC is characterized by complex instructions which have grown mainly out of the microprogramming design style of the computer.

The performance of leading RISC processors has increased steadily at a rate of about 55% per year since 1986. The gap between the trend lines for RISC and CISC performance is now slightly more than 2× and is increasing very slowly. (Reprinted with permission from the 1/23/95 issue of *Microprocessor Report*. Copyright 1995 MicroDesign Resources, Sebastopol, CA.)

The so-called supercomputers are the ones that have been driving all of the advanced concepts in architecture as well as driving the technology to its limits. Though several computers were designated as "supercomputers" in the past, such as IBM-Stretch, IBM System 360 Model 91, and Control Data's CDC 6600, the real era of supercomputers started with CRAY-1, engineered and designed by Seymour Cray. Probably the best description of a supercomputer is a design where performance is the prime objective and the cost is ignored. They are manufactured in small numbers for very special customers requiring very high performance who are willing to pay a

premium cost for that performance. CRAY-1 was introduced in 1976 and had a clock cycle of 12.5 n. The latest CRAY is the CRAY-4, built in gallium arsenide technology with a cycle time of 1 n and capable of achieving 256 gigaflops in a 128-processor configuration. CRAY-4 is truly state of the art in almost all aspects of engineering.

Today, typical high-performance computer systems employ multiple processors in various arrangements. There has been an ongoing effort to parallelize the execution of the programs and use a number of the relatively inexpensive processors in order to achieve a high processing rate. These efforts have achieved limited success. A number of parallel machines have been introduced with varying degrees of success. Although they can be divided in several categories, most of the machines introduced fall into one of two structures: SIMD and MIMD. SIMD, which stands for Single Instruction Multiple Data, is characterized by the execution of one instruction at a time, operating on an array of data elements in parallel. A typical example of SIMD architecture is the so-called Connection Machine, CM-1, introduced by Connection Machines of Cambridge, MA, in the first half of 1984. This machine is characterized by an array of up to 64K processors divided in four quadrants containing 16K processors each. CM-1 has been superseded by CM-2, 3, and CM-5. The operations of the processors are controlled by the same instruction issued from the central instruction unit. Another example of parallel SIMD architecture is the IBM GF-11 machine, capable of a peak execution rate of 11 billion floating-point operations per second.

The current trend is toward distributed computing on a large, even global, scale. This involves a network of workstations connected via high-bandwidth, low-latency networks acting as a computing platform. The goal is to take advantage of a large resource pool of workstations comprising hundreds of gigabytes of memory, terabytes of disk space, and hundreds of gigaflops of processing power that is often idle. This new paradigm in computing is expected to impact the fundamental design techniques for large systems and their ability to solve large problems, serve a large number of users, and provide a computing infrastructure.

## 132.1 Instruction Set

Addressing Modes • Data Representation Formats

## 132.2 RISC Architecture

**Vojin G. Oklobdzija**

*University of California, Davis*

On 7 April 1964 the term **computer architecture** was first defined by Amdahl, Blaauw, and Brooks of IBM Corporation in the paper announcing the IBM System/360 computer family [1964]. On that day IBM Corporation introduced, in the words of an IBM spokesman, "the most important product announcement that this corporation has made in its history." There were six models introduced originally, ranging in performance from 25 to 1. Six years later this performance range was increased to about 200 to 1. This was the key feature that prompted IBM's effort to design an architecture for a new line of computers that are to be code-compatible with each other. The recognition that architecture and **computer implementation** could be separated and that one need not imply the other led to establishment of a common System/360 machine architecture implemented in the range of models.

In their milestone paper Amdahl, Blaauw, and Brooks identified three interfaces: architecture, implementation, and realization. They defined computer *architecture* as the attributes of a computer seen by the machine language programmer, as described in the **principles of operation**. IBM referred to the principles of operation as a definition of the machine that enables the machine language programmer to write functionally correct, time-independent programs that run across a number of implementations of that particular architecture. Therefore, the architecture specification covers all functions of the machine that are observable by the program [Siewiorek *et al.*, 1982]. On the other hand, the principles of operation are used to define the functions that the implementation should provide. In order to be functionally correct the implementation must conform to the principles of operation. Accordingly, for the first time in the history of computer development, IBM has separated *machine definition* from *machine implementation*, thus enabling them to bring several machine implementations in a wide price and performance range that has reached—22 years after the introduction of System/360—2000 to 1.

The principles of operation define computer architecture, which includes:

- Instruction set
- Instruction format
- Operation codes

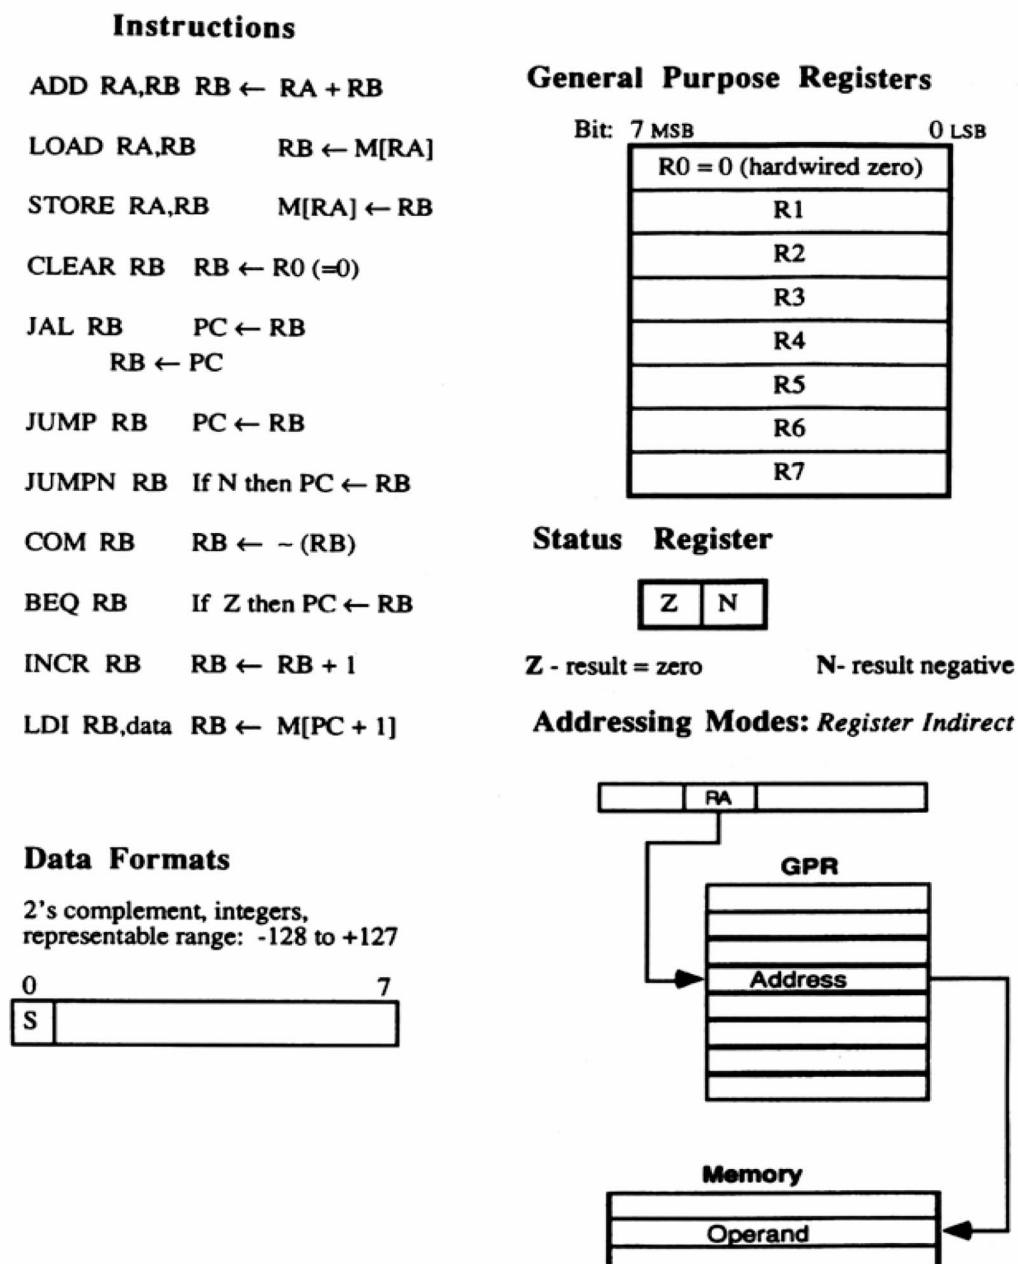

- Addressing modes
- All registers and memory locations that may be directly manipulated or tested by a machine language program
- Formats for data representation

**Machine implementation** was defined as the actual system organization and hardware structure encompassing the major functional units, data paths, and control. **Machine realization** includes issues such as logic technology, packaging, and interconnections.

An example of simple architecture of an 8-bit processor that uses 2s complement representation to represent integers and contains 11 instructions is shown in Fig. 132.1. The figure contains all of the necessary information for the architecture to be defined.

**Figure 132.1** Example of a minimal architecture: PRISC.

Separation of the machine architecture from implementation enables several embodiments of the same architecture to be built. Operational evidence proved that architecture and implementation could be separated and that one need not imply the other. This separation made it possible to transfer programs routinely from one model to another and expect them to produce the same result, which defined the notion of **architectural compatibility**. Implementation of the whole line of computers according to a common architecture requires unusual attention to details and some new procedures, which are described in the architecture control procedure. The design and control of system architecture is an ongoing process whose objective is to remove ambiguities in the definition of the architecture and, in some cases, to adjust the functions provided.

Definition of an architecture facilitated future development and introduction of not only new models but new **upwardly compatible architectures**. The architecture is upwardly compatible if the user's programs written for the old architecture run efficiently on the new models without modifications to the program. The limitations to upward compatibility are (1) that new systems have the same or equivalent facilities, and (2) that the programs have no time dependence, use only model-independent functions defined in the principles of operation, and do not use unassigned formats and operation codes [Case and Padegs, 1978]. An example of upward compatibility is IBM System/360, introduced in June 1970.

## 132.1 Instruction Set

---

Instruction set defines a basic set of operations, as specified by the architecture, that a particular implementation of that architecture is required to perform. An *instruction* of the instruction set defines an atomic operation that may alter data or the machine state or may perform an I/O operation. In terms of the operation performed, instructions of the instruction set are broadly classified in one of the four general categories:

1. Instructions performing transformation of data
2. Instructions altering the program flow
3. Instructions performing data movement
4. System instructions

The first category includes instructions performing arithmetic and logical operations. The operations can be arithmetic, string, logical, or floating point. They are performed in the appropriate functional units of the particular implementation of the architecture.

Instructions affecting the flow of the program and/or machine state are branches, calls, and returns as well as loop control instructions.

The third category of instructions performs data movement across various functional units of the machine. Examples of such instructions are the load instruction, which loads a content of a memory location to a particular register in the general purpose register file (GPR), and the store instruction, which does the opposite. The move instruction moves a block of data from one memory location to another, or to and from the Stack or GPR.

The system instructions change the system's mode and are not generally visible by the programmer that programs in the *problem state*. Problem state is the domain of the machine visible to a programmer executing a general purpose program—as opposed to the *system state*, which is visible to the operating system.

An example of the instruction set specified in the IBM System/360 architecture is given in [Fig. 132.2](#).

SL = SINGLE LOGICAL U = UNNORMALIZED D = DOUBLE

We can further classify instructions in terms of the number of *explicit operands*, *operand locations*, and *type* and *size* of the operands.

Instruction architecture that specifies no explicit operands is better known as *stack architecture*. In stack architecture all operations are performed on the data that are on the top of the stack. Examples of stack architecture are HP 3000/70 by Hewlett-Packard and B5500 by Burroughs. In the **accumulator architecture** all of the operations are performed between the operand specified in the instruction and the *accumulator*, which is a special register. An example of accumulator architecture is the PRISC processor shown in [Fig. 132.1](#). One of the well-known accumulator-based architectures is PDP-8, by Digital Equipment Corporation. Almost all of the modern machines have a repertoire of available general purpose registers whose numbers range from 16 to 32 and in some cases even more than 32 (SPARC). The number of operands explicitly specified in the instructions of a modern architecture today can be two or three. In the case of three operands an instruction explicitly specifies the location of both operands and the location where the result is to be stored. In some architectures (IBM System/360) only two operands are *explicitly specified* in order to save the bits in the instruction. As a consequence, one of the operands is always replaced by the result and its content is destroyed. This type of instruction is sometimes referred to as *diadic instruction*.

In terms of the operand locations, instructions can be classified as:

Register to register (or R-R) instructions

Memory to register (R-M) instructions

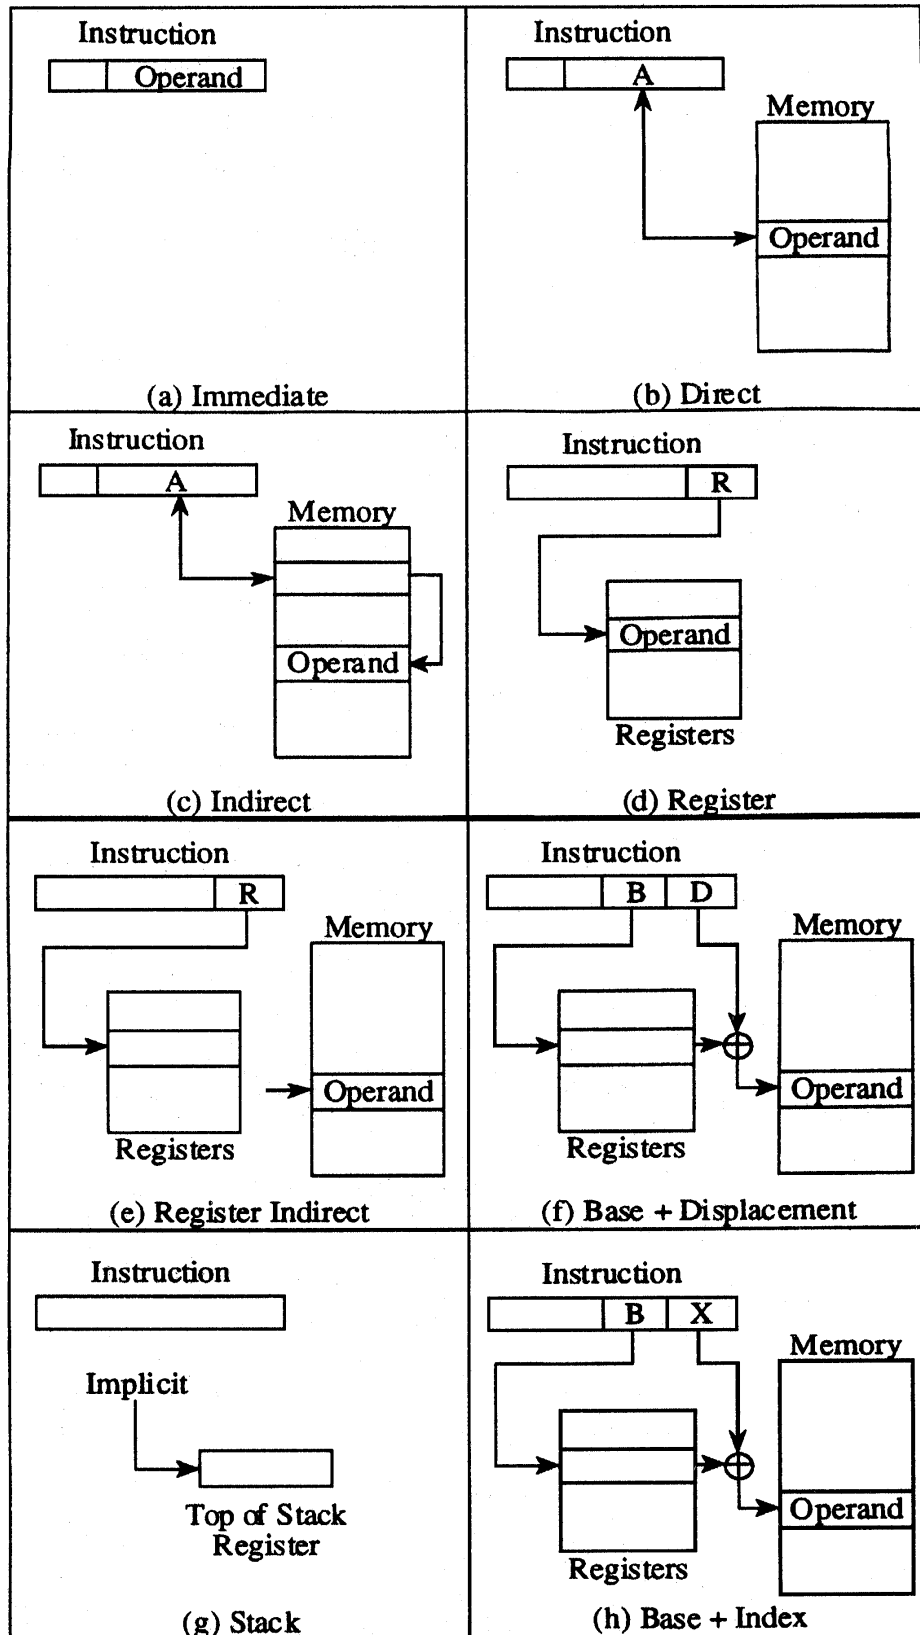

Memory to memory (M-M) instructions

The addresses of the operands are specified within the instruction. From the information contained in the particular operand field of the instruction, the address of the particular operand can be formed in various ways, described in the section that follows.

## Addressing Modes

The way in which the address of the operand is formed depends on the location of the operand as well as choices given in the instruction architecture. It is obvious that, in the case of stack or accumulator architecture, the address of the operand is implied and there is no need to specify the address of the operand. If the operand is in one of the GPRs the operand field in the instruction contains the number (address) of that particular register. This addressing mode is known as *register direct addressing* and is one of the simplest ways of pointing to the location of the operand. The addressing of an operand can be even simpler, in the case where the operand is contained within the instruction. This mode is called the *immediate addressing mode*. The location pointed to by the address formed from the information contained in the operand field of an instruction can contain the operand itself or an address of the operand. The latter case is referred to as *indirect addressing*. Examples of several ways of forming an address of the operand are given in [Fig. 132.3](#)

**Figure 132.3** Example of addressing modes. (Adapted from Stallings, W. 1993. *Computer Organization and Architecture*. Macmillan, New York.)

## Data Representation Formats

Another important issue in computer architecture is the determination of data formats. Data formats, along with instruction formats, were formerly of much influence in determining **word size**. Today it is commonly assumed that most of the machines use a 32-bit word size (which is gradually shifting toward 64-bit). This standard was not common in the past, and there was not a common word size used by the majority of the machines. A 36-bit word size was quite common (IBM's early machines: 701, 704), and word sizes of 12, 18, and 60 bits were represented as well (PDP-8, CDC 6600). In the early days of computer development, interaction with the operator was done mainly via the teletype machine (TTY), which used 6 bits to represent each character. Therefore the word sizes of the machines of that period were determined with the objective of being able to pack several characters in the machine word. The size of I/O interfaces was commonly 12 bits (two characters). Anticipation of the new standard for the representation of digits (USASCII-8) prompted IBM to introduce an 8-bit character (EBCDIC) in their introduction of System/360 architecture, which was also its reason for switching from 36-bit to a new 32-bit word size. Since then (and until today) 32-bit word size and the multiples of the 8-bit quantity (**byte**) have been the most common data formats among various computer architectures. The new standard for representation of digits, USASCII-8, however, did not materialize. Instead, a 7-bit standard for data representation, ASCII, has been commonly used almost everywhere, except by IBM, which could not diverge from the 8-bit character representation defined in its architecture.

Every architecture must specify its representation of

Characters

Integers

Floating-point numbers

Logical operands

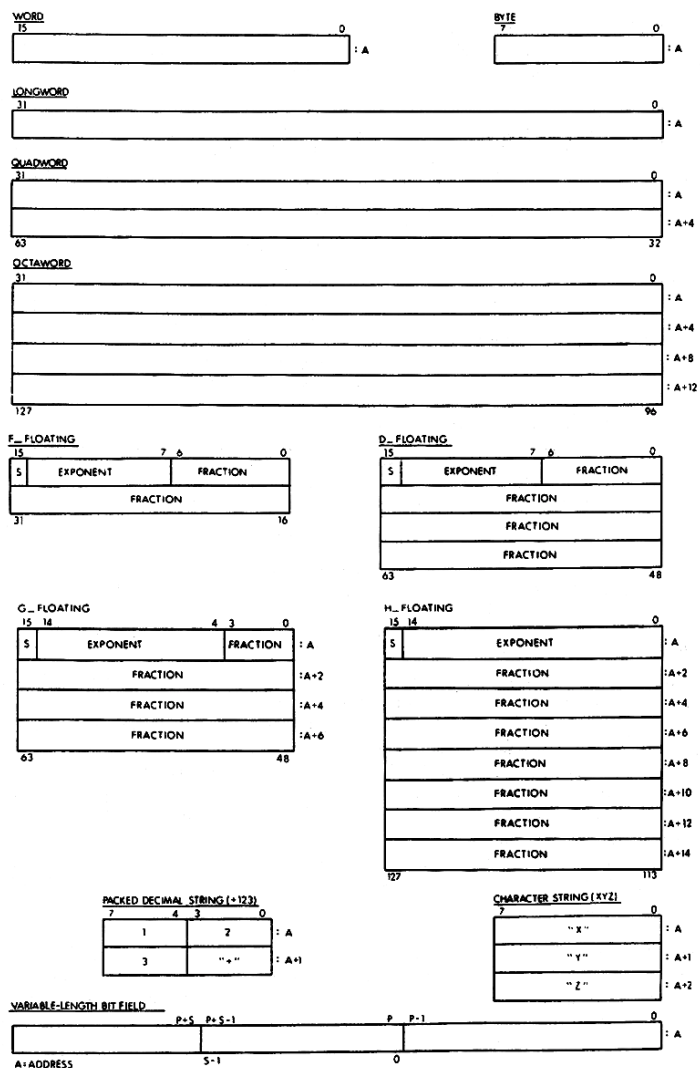

This representation must specify the number of bits used for every particular field, their order in the computer word, meaning of the special bits, interpretation, and the total length of data. Data types and data formats as defined in Digital Equipment Corporation VAX 11/780 architecture are shown in [Fig. 132.4](#).

**Figure 132.4** (a) Data types and (b) data formats as defined in Digital Equipment Corporation VAX 11/780 architecture. (*Source*: Digital Equipment Corporation. 1981. *VAX Architecture Handbook*. Digital Equipment Corporation, Maynard, MA. With permission.)

Figure 132.4

DATA TYPE	SIZE	RANGE (decimal)	
Integer		Signed	Unsigned
Byte	8 bits	-128 to + 127	0 to 255
Word	16 bits	-32768 to + 32767	0 to 65535
Longword	32 bits	$-2^{31}$ to $+ 2^{31} - 1$	0 to $2^{32} - 1$
Quadword	64 bits	$-2^{63}$ to $+ 2^{63} - 1$	0 to $2^{64} - 1$
Octaword	128 bits	$-2^{127}$ to $+ 2^{127} - 1$	0 to $+ 2^{128} - 1$
Floating Point			
F floating	32 bits	approximately seven decimal digits precision	
D floating	64 bits	approximately sixteen decimal digits precision	
G floating	64 bits	approximately fifteen decimal digits precision	
H floating	128 bits	approximately thirty-three decimal digits precision	
Packed Decimal String	0 to 16 bytes (31 digits)	numeric, two digits per byte sign in low half of last byte	
Character String	0 to 85535 bytes	one character per byte	
Variable-length Bit Field	0 to 32 bits	dependent on interpretation	
Numeric String	0 to 31 bytes (DIGITS)	$-10^{31}-1$ to $+ 10^{31}-1$	
Queue	> 2 longwords/queue entry	0 through 2 billion entries	

(a)

(b)

## Fixed-Point Data Formats

**Fixed-point** data forms are used to represent integers. Full-word (32 bit), half-word (16-bit), or double-word (64-bit) quantities are used for representation of integers. They can be signed or unsigned positive integers. In the case of signed integers one bit is used for representation of the sign, in order to represent a range of positive and negative integers. The most common representation of integers is 2s complement format. Another, not so common representation of integers is binary coded decimal representation (BCD), used to represent integers as decimal numbers. Each digit position is represented with 4 bits. The coding is straightforward for the numbers from 0 to 9, and the unused bit combinations are used to represent the sign.

For the *logical operand* a word is treated as a collection of individual bits, where each bit is assigned a Boolean value. A *variable bit field* can also be defined in cases where the field can be treated as a signed or unsigned field of bits.

## Floating-Point Data Formats

For scientific computation, the dynamic range achievable using integers is not sufficient, and **floating-point** data representation is therefore defined. Each number is represented with the *exponent* and *fraction* (or mantissa). For the representation of a single number, one or more words could be used if required by the desired precision. Floating-point data formats specified in IBM System/360 architecture are shown in Fig. 132.5(a).

**Figure 132.5** Floating-point data representation formats.

(a) IBM System/370 Formats

(b) IEEE 754 Formats

A floating-point standard known as IEEE 754 has recently been introduced. The standard specifies the way data are to be represented, as well as the way computation should be performed. The purpose of this standard is to ensure that floating-point computation always produces exactly the same results—regardless of the machine or machine architecture being used. This result can be achieved only if the architecture complies to the IEEE 754 standard for floating-point computation. Data formats prescribed by IEEE 754 are shown in [Fig. 132.5\(b\)](#).

## 132.2 RISC Architecture

---

A special place in computer architecture has been given to RISC. RISC architecture was developed as a result of the 801 project, which started in 1975 at the IBM T. J. Watson Research Center and was completed by the early 1980s [[Radin, 1982](#)]. This project was not widely known to the world—outside of IBM and two other projects with similar objectives started in the early 1980s at the University of California, Berkeley, and Stanford University [[Patterson and Sequin, 1982](#); [Hennessy, 1984](#)]. The term **RISC** (reduced instruction set architecture), used for the Berkeley research project, is the term under which this architecture became widely known and recognized today.

Development of RISC architecture started as a "fresh look at existing ideas" [[Hopkins, 1987](#)] after first revealing evidence that surfaced as a result of examination of how the instructions are actually used in the real programs. This evidence came from the analysis of the *trace tapes*, a collection of millions of the instructions that were executed in the machine running a collection of representative programs. This evidence showed that, for 90% of the time, only about 10 instructions from the instruction repertoire were actually used. Then the obvious question was asked: "Why not favor implementation of those selected instructions so that they execute in a short cycle, and emulate the rest of instructions." The following reasoning was used: "If the presence of a more complex set adds just one logic level to a 10 level basic machine cycle, the CPU has been slowed down by 10%. The frequency and performance improvement of the complex functions must first overcome this 10% degradation, and then justify the additional cost" [[Radin, 1982](#)]. Therefore, RISC architecture starts with a small set of the most frequently used instructions, which determines the pipeline structure of the machine, enabling fast execution of those instructions in one cycle. One cycle per instruction is achieved by exploitation of parallelism through the use of **pipelining**. It turns out that *parallelism through pipelining* is the single most important characteristic of RISC architecture—from which all the rest of the RISC features could be derived. We can characterize RISC basically as a performance-oriented architecture based on exploitation of parallelism through pipelining. A list of the remaining features of RISC architecture is given in [Table 132.1](#).

RISC architecture has proven itself; several *mainstream architectures* today are of the RISC type. These include SPARC (used by Sun Microsystems workstations, an outgrowth of Berkeley RISC), MIPS (an outgrowth of the Stanford MIPS project, used by Silicon Graphics), and a **super-scalar** implementation of RISC architecture, IBM RS/6000 (also known as PowerPC architecture).

**Table 132.1** Features of RISC Architecture

Feature	Characteristic
Load/store architecture	All of the operations are register to register. In this way, operation is decoupled from the access to memory.
Carefully selected subset of instructions	Control is implemented in hardware. There is no microcoding in RISC. Also, this set of instructions is not necessarily small.*
Simple addressing modes	Only the most frequently used addressing modes are used. It is also important that they can fit into the existing pipeline.
Fixed size and fixed fields instructions	This is necessary to be able to decode instruction and access operands in one cycle (though there are architectures using two sizes for the instruction format, IBM PC-RT).
Delayed branch instruction (known also as branch and execute)	The most important performance improvement through instruction architecture.
One instruction per cycle execution rate, CPI=1.0	Possible only through the use of pipelining.
Optimizing compiler	Close coupling between the architecture and the compiler. Compiler "knows" about the pipeline.
Harvard architecture	Separation of instruction and data cache, resulting in increased memory bandwidth.

\*IBM PC-RT instruction architecture contains 118 instructions, whereas IBM RS/6000 (PowerPC) contains 184 instructions. This should be contrasted to the IBM System/360, containing 143 instructions, and IBM System/370, containing 208. The first two are representatives of RISC architecture, whereas the latter two are not.

## Defining Terms

**Accumulator:** A special register always containing one operand and possibly also receiving the result.

**Architectural compatibility:** Ability to run programs on separate machines and expect them to produce the same results.

**Byte:** An 8-bit quantity being treated as a unit.

**Computer architecture:** The attributes of a computer, as seen by the machine language programmer that enable this programmer to write functionally correct, time-independent programs.

**Computer implementation:** System organization and hardware structure.

**Computer organization:** Hardware structure encompassing the major functional units, data paths, and control.

**Fixed point:** Positive or negative integer.

**Floating point:** A number format, containing a fraction and an exponent, used for representation of numbers covering a wide range of values. Used for scientific computation where the range is important.

**Pipelining:** The technique used to initiate one operation in every cycle without waiting for the final result to be produced, or completion of previously initiated operations.

**Principles of operation:** A definition of the machine. Term used for computer architecture in IBM.

**RISC:** Reduced instruction set computer.

**Super scalar:** Implementation of an architecture capable of executing more than one instruction in the same cycle.

**Upwardly compatible architectures:** Ability to efficiently run user programs written for the old architecture on the new models without modifications to the program, lacking however, the capacity to do the reverse.

**Word size:** A quantity defined as the number of bits being operated upon as a unit.

## Further Information

A good introductory text for computer architecture is a book by William Stallings, *Computer Organization and Architecture*, Macmillan Publishing Company, 1993.

For the advanced reader, more information on computer hardware, design, and performance analysis can be found in a book by David A. Patterson and John L. Hennessy, *Computer Organization and Design: The Hardware/Software Interface*, Morgan Kaufmann Publishers, 1994. For quantitative analysis of instruction usage and various factors affecting performance, as well as insight into RISC architecture, *Computer Architecture: A Quantitative Approach*, by the same authors and publisher, is highly recommended.

An important historical insight into the development of computer architecture is an interview with Richard Case and Andris Padegs, "Case Study: IBM's System/360-370 Architecture," conducted by editors David Gifford and Alfred Spector in *Communications of ACM*, volume 30, number 4, April 1987, as well as the paper "The Architecture of IBM's Early Computers," published in the *IBM Journal of Research and Development*, volume 25, number 5, September 1981. The first chapter of the book by David J. Kuck, *The Structure of Computers and Computation* (John Wiley & Sons, 1978), contains an excellent overview of the history of computer development.

Various useful articles on computer architecture, performance, and systems can be found in *Computer Magazine*, published by the Computer Society of IEEE. More advanced articles on the subject of computer architecture, performance, and design could be found in the *IEEE Transactions on Computers*, published by IEEE. The operating system of a computer is the software program responsible for controlling and administering all the hardware resources present in the system. The operating system is to be understood as the **control program** of a computer. It is through the basic set of services provided by the operating system that hardware devices can be brought into a computer system, used by the system, and exploited by other system services or by application software. Thus, the role of an operating system is to interface and communicate with all the hardware devices present in the system and to define, provide, and administer all the basic system facilities, or system services, that are present in a computer system. These system facilities are the building blocks for all other system services and for application software.

The system facilities offered by an operating system are normally exported to the rest of the system through a set of software functions named **system calls**. There are different manners in which system calls are implemented, yet their use is rather standard: Applications issue the calls as if they were part of the application program itself. To applications, system calls appear as functions provided by the environment.

Operating systems have evolved from being one-of-a-kind programs useful for only one type of hardware configuration to being portable programs that can be made to operate in a homogeneous family of hardware configurations and even in heterogeneous hardware platforms. The first operating system that operated on several different kinds of hardware configurations supporting many different kinds of devices was called OS/360. OS/360 was introduced by IBM in the early 1960s as a computing platform for commercial applications. OS/360 enabled, for the first time, the support of different generations of hardware devices in a continuous manner, without having to modify the software that ran in the systems and avoiding the creation of complete new operating systems to accommodate new devices.

The first operating system to operate in a wide variety of hardware platforms was Unix, introduced by AT&T Bell Laboratories in the mid-1970s as a computing platform for research and development of engineering applications. Unix had the characteristic that its size was small, and

thus it could operate in inexpensive computers used for small groups of people. The first operating system to be used massively was MS-DOS, introduced by Microsoft in the early 1980s as a computing platform for personal, or individual, use.

The services provided by operating systems vary depending on the intended use of the computer. In MS-DOS, for example, the computer can be doing only one **task** at the time, whereas in Unix the computer may be doing several tasks concurrently. Unix is called a multitasking operating system for this reason. The advantage of multitasking systems is that a user may have several different kinds of activities happening at once and thus users can make better use of time and resources while getting work done.

## 133.1 Typical Services

---

The services provided by an operating system can be organized in categories. Four possible categories are task control, file manipulation, device manipulation, and information maintenance. Task control has all the services needed to administer tasks, such as initiation and termination of a task, as well as services that may control the coordination of activities between tasks. File manipulation services are used to organize and access the data of users in files. File manipulation in advanced systems can be quite complex as there may be different kinds of files to optimize data availability or access time performance. The experimental system Swift/RAID is an example of a client/server file system in which files are stored in a manner that enhances the speed at which their data can be stored and retrieved and also enhances the availability of the data.

Device manipulation services provide the ability to communicate with and between devices in a system. The software in an operating system that directly accesses a hardware device is called a **device driver**. Information maintenance is an important category of services that tracks information on various aspects of a system and helps administer the resources present in the system.

Table 133.1 presents a base list of system services. The complexity of the operating system increases when the list of services is larger. For example, in computer systems composed of many processors and many devices where data are stored, the access to this data requires services that are substantially more complex than the one present in a personal computer. These advanced services are not represented in Table 133.1

**Table 133.1** Types of System Services

## 133.2 General Flow of Control

All devices—those that interact directly with the user, such as a keyboard, and those that are internal to the system, such as a hard disk—generate event **interrupts** when they complete a request made to them. (The interaction between a user and a computer through its input/output devices is explained in **Chapter 135**.) The operating system is programmed to first save the relevant information of an interrupt in locations called **registers** and then to service the interrupt.

With the information saved in registers the system determines what kind of event caused the interrupt. Then the operating system does the activities required by this interrupt and eventually returns control to the user application.

Figure 133.1 depicts a simplified general flow of an operating system. An important aspect missing in Figure 133.1 is the representation of all the synchronization activities that happen in the computer while concurrent tasks are active in one system.

**Figure 133.1** Simplified flow of an operating system.

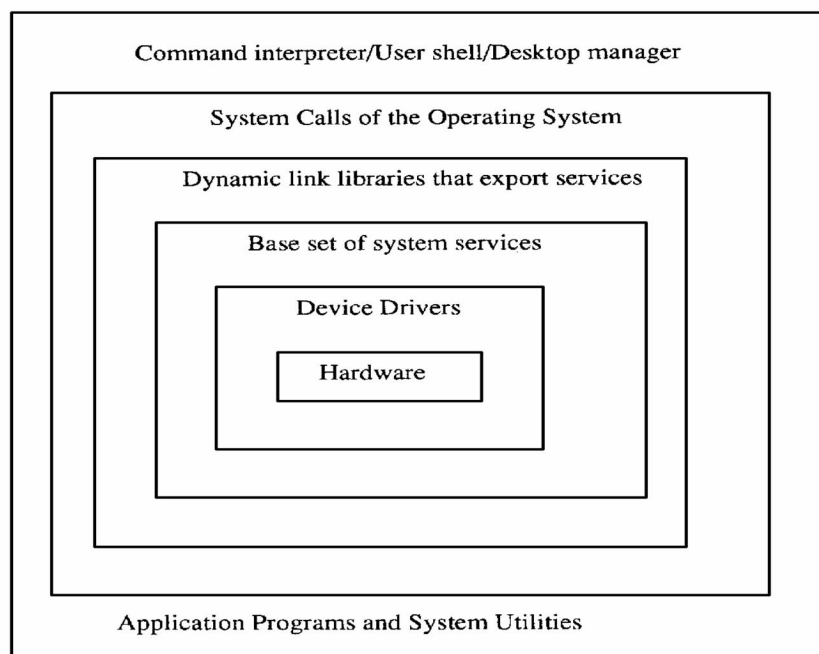

## 133.3 Structure

The organization of the structure of operating systems has also evolved over the years from being a monolithic set of system services whose boundaries were difficult to establish to being a structured set of system services with clear boundaries between them. Today, for example, some of these services, like the file system in charge of administering the file data stored by users, have boundaries, or software interfaces, that are standards regulated by organizations that are not related to any computer vendor. This modularization of operating systems into well-understood components provides the possibility to "mix and match" components from different vendors in one system. This trend toward pluggable system parts is accelerating with the formation of various consortia whose charters are to specify common, appropriate, and widely accepted interfaces for various system services.

Current operating systems are all based on the idea of building higher-level hardware abstraction from lower-level hardware-oriented function. In other words, current operating systems build higher-level abstractions from lower-level functions that are closer to the raw hardware. Thus, all kinds of hard disks, for example, are made to look and operate in the same manner by their low-level device drivers. Then, in turn, the operating system presents, with all other services in the system (such as the file system), a uniform, common view of a hard disk. This process of successive layers of abstraction is also followed within other services. In file systems, for example, a layer providing the abstraction of continuous storage that does not have device boundaries is built from the abstraction provided by the individual storage in several disks. [Figure 133.2](#) shows a layered depiction of an operating system.

**Figure 133.2** Layered depiction of an operating system.

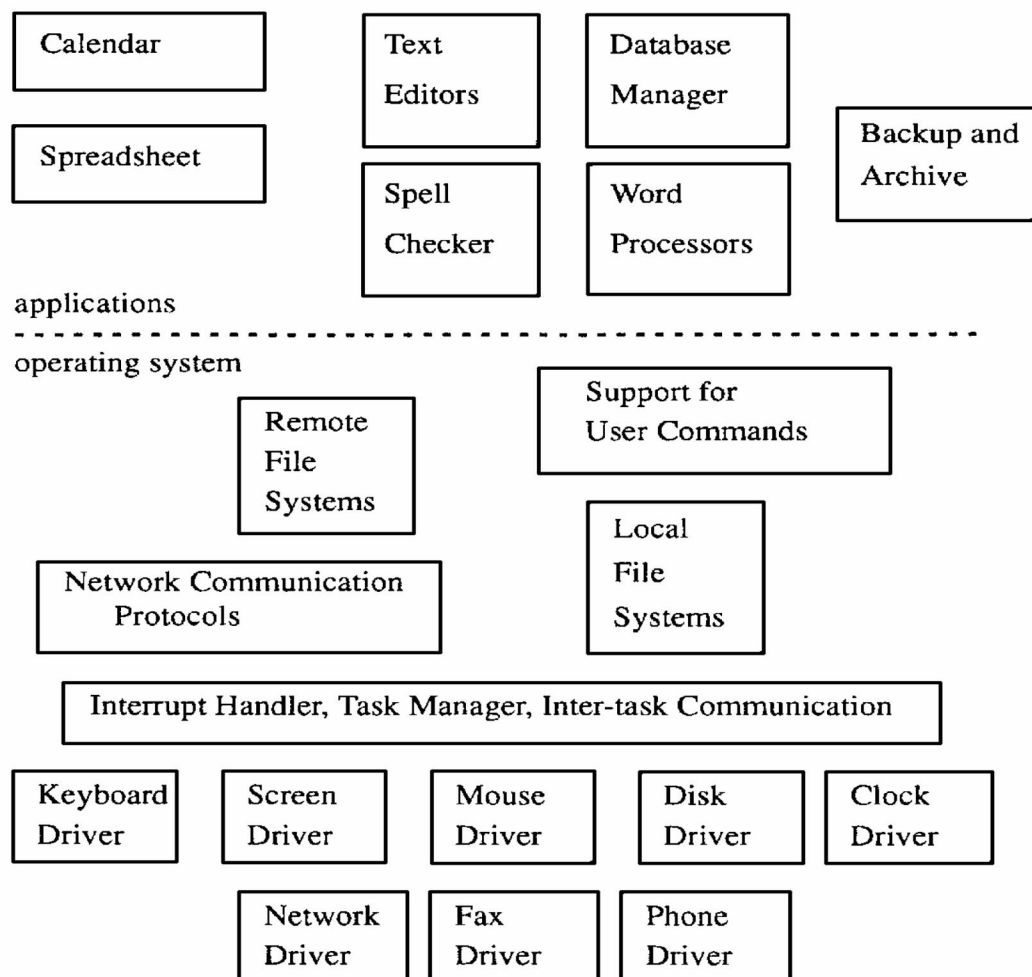

All computer systems have a base set of hardware components that need to be administered by the operating system. These components are the building set for all computing that can be done in the machine. Most current personal computers, for example, have a keyboard, a pointing device or mouse, a high-resolution screen, an internal clock, a phone modem, a diskette reader, and a hard disk.

The **kernel** of an operating system is the most basic set of service needed to build the complete system. The kernel always contains the interrupt handler, the task manager, and the interprocess communication manager. Sometimes it may also contain the **virtual memory** manager and the network subsystem manager. With these services the system can operate all the hardware present in the system and also coordinate the activities between tasks. Using these services, subsystems such as the file system and the network system can build their services. Applications can then provide their function by using these subsystems. A remote file service, for example, will use the network subsystem to provide the illusion of local files by connecting to a file system that can be accessed over the network. [Figure 133.3](#) shows a set of base operating system components and applications that may be found in a computer system.

**Figure 133.3** A set of base operating system components and applications that may be found in a computer system.

## 133.4 Communication

---

A fundamental characteristic that may vary from system to system is the manner of communication between tasks. The two manners in which this is done is via messages sent between tasks or via the sharing of memory where the communicating tasks can both access the data. Operating systems can support either. In fact, both manners can coexist in a system. In message-passing systems, the sender task builds a message in an area that it owns and then contacts the operating system to send the message to the recipient. There must be a location mechanism in the system so that the sender can identify the receiver. The operating system is then put in charge of delivering the message to the recipient. To minimize the overhead of the message delivery process, some systems try to avoid copying the message from the sender to the kernel and then to the receiver and provide means by which the receiver can read the message directly from where the sender wrote it. This mechanism requires that the operating system intervene if the sender wants to modify the contents of a message before the recipient has gone through its content.

In memory-sharing systems the sender and receiver use a common area of memory to place the data that is to be exchanged. To guarantee appropriate concurrent manipulation of these shared areas, the operating system has to provide synchronization services for mutual exclusion. A common synchronization primitive is the **semaphore**, which provides mutual exclusion for two tasks using a common area of memory. In a shared memory system the virtual memory subsystem must also collaborate to provide the shared areas of work.

There are several examples of commercial and experimental operating systems that share memory and send messages. The office-oriented computing systems commercialized by Xerox are examples of memory-sharing systems. In fact, in those systems that ran a version of the operating system called Pilot, all the tasks would share a substantial amount of memory, each having only a small area private to itself. A message-passing system that is increasing its commercial acceptance is Mach, which was first developed at Carnegie Mellon University.

There are systems in which the amount of data that can be shared or sent between tasks is minimal. In the original Unix, for example, different tasks would not have shared memory, and only a very limited form of message passing was provided. The messages were constrained to be event notification. In this environment, processes that desired to share data had to write in files and then share the files. To support file sharing, some systems provide a **locking** service that is used to synchronize the accesses to files by different tasks.

## 133.5 Advanced Data Management Services

---

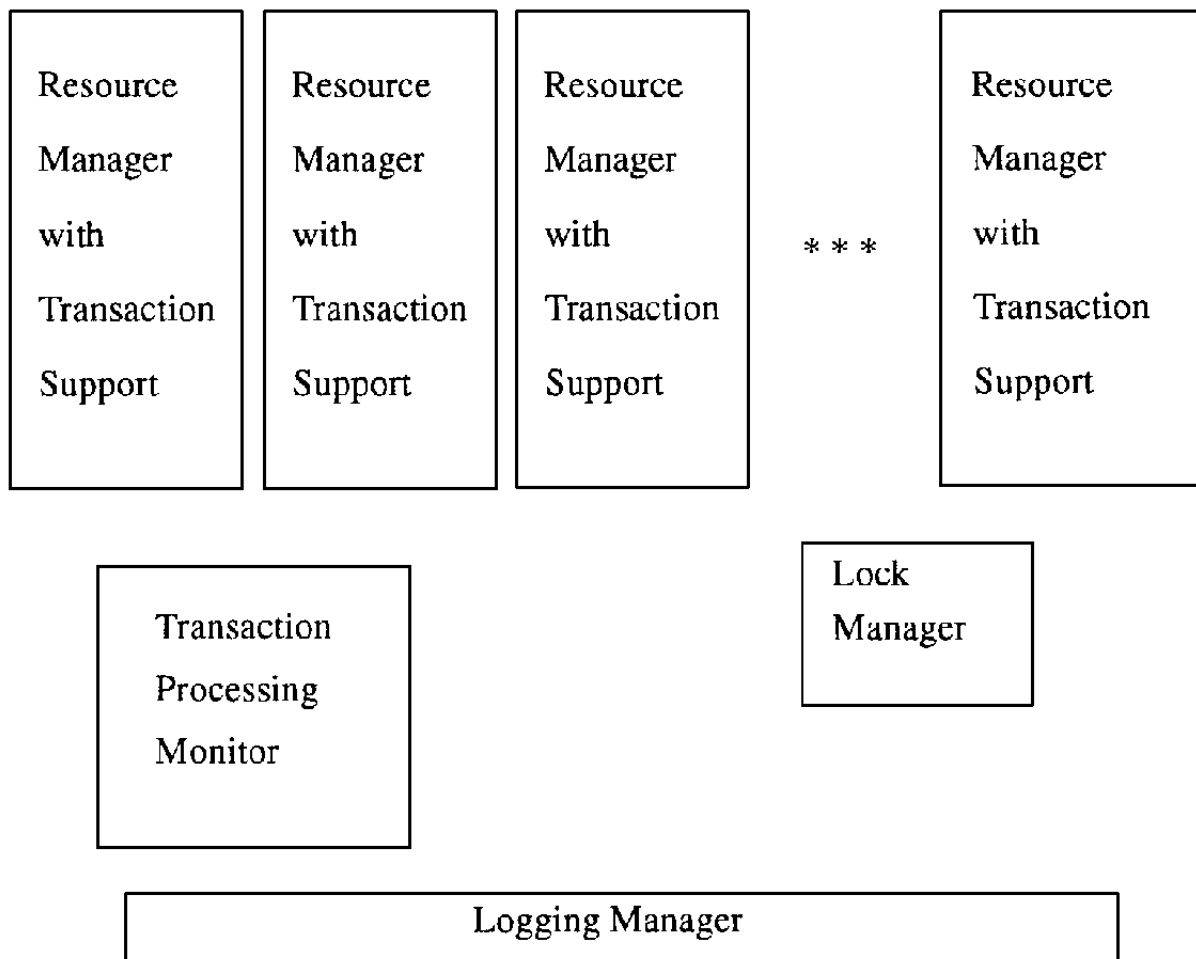

There are some operating systems in which data integrity is given a special attention so as to provide special function to support the transactional manipulation of data. Data are manipulated transactionally when sets of updates are treated as complete units of work, in that either all of them are made to happen at once or none of them happen. This atomicity property is useful to guard mission-critical data against partial updates caused by unexpected software or hardware failures. Commercial applications, such as banking, have used these techniques for decades.

Transactional manipulation of data acquires new benefits when the operations desired are to be done by a set of interconnected computers. To minimize the need for human intervention in the

administration of these installations, the transactional service is also useful as, upon restart from a failure, the system automatically rebuilds itself in a consistent state without the need of human intervention.

Figure 133.4 shows the typical services present in a system that provides transactional data administration. The transaction-processing monitor is in charge of the overall coordination of activities that allow to implement the atomicity and serialization properties. The resource managers with transaction support are the repositories of the data that are being manipulated transactionally. The lock and log managers are system services necessary to provide transactions.

**Figure 133.4** Typical components of a transaction-processing system.

## Defining Terms

**Control program:** A software program that administers the hardware resources present in a computer system. Through this software resources are accessed and the activities between different resources are coordinated and prioritized.

**Device driver:** Software that directly accesses a hardware device controlling its operation. Device drivers are specific, or one-of-a-kind, for each device in each operating system. As like devices have similar functions, there are similarities in their device drivers, particularly in the interfaces they provide the operating system.

**Interrupt:** An action initiated by the hardware of the computer that transfers control from any running activity to the operating system. The operating system relinquishes its control after having determined the type of interrupt and having performed the activities needed of its behalf.

**Kernel:** Essential set of services needed to build the complete operating system. Kernel services are the most basic services provided by a given system.

**Locking:** System service that enables callers of the service to explicitly synchronize their activities by placing locks on entities that require access synchronization and coordination.

**Register:** Locations in the processing unit of the computer used to store data for operations, the result of operations and the status of hardware devices.

**Semaphore:** Synchronization primitive used between tasks that share a common region of memory to achieve isolation of activity.

**System calls:** The set of software functions callable from different programming languages used by all applications to perform the functions provided by the operating system.

**Task:** A logical unit of work being done by a computer at a given time. This can be anything from a system activity, such as reading some data from a hardware disk or printing some region of a screen, to an activity done by an application, such as editing a file with an editor, using a spreadsheet program for some financial calculations, keeping track of a schedule of events with a calendar program, or displaying the time of day with a clock program.

**Virtual memory:** A system service that presents to applications the abstraction that there is more memory available for them in the system than the real amount of memory installed in the system.

Data Types • Syntax and Semantics • Encapsulation

## 134.2 Program Verification

## 134.3 Programming Language Paradigms

Concurrent and Distributed Programming • Real-Time Programming

**Dennis M. Volpano**

*Naval Postgraduate School*

The evolution of programming languages is an ongoing process. It is driven by new machine architectures, different models of computation, and the need for new techniques to express, at a more abstract level, algorithms for certain applications. Our understanding of programming languages and our ability to implement them has improved dramatically since the early days of Fortran. Programming paradigms, such as functional, logic, concurrent, and distributed programming, continue to be developed. Programming languages are typically distinguished according to these paradigms. However, for a given paradigm, a more fundamental distinction can be made based upon a set of principles. These principles are presented, as are other facets of modern programming paradigms.

## 134.1 Principles of Programming Languages

---

### Data Types

A programming language provides a collection of data types that determines the values that can be manipulated in the language. Languages often can be distinguished based on their data types. The primitive data types of a language are formed from two sets—the empty set (denoted **0**) and the singleton set {unit} (denoted **1**)—and from type-forming operations discriminated union (+), Cartesian product ( $\times$ ), function types ( $\rightarrow$ ), and recursive types (**fix**).

#### Discriminated Union

If  $S$  and  $T$  are types then their discriminated union is given by

$$S + T = \{\text{left } x \mid x \in S\} \cup \{\text{right } y \mid y \in T\}$$

Elements of  $S + T$  are tagged by applying constructors *left* and *right* to elements of  $S$  and  $T$ ,

respectively. For example, an enumeration type of truth values can be constructed by

$$\text{bool} = 1 + 1 = \{\text{left unit}, \text{right unit}\}$$

where *left unit* may denote true or false. Discriminated union is not the same as set union for  $1 \cup 1 = \{\text{unit}\}$ . Languages manifest the discriminated union type as the type of a variant record.

### Cartesian Product

If  $S$  and  $T$  are types then their Cartesian product is given by

$$S \times T = \{(x, y) \mid x \in S \wedge y \in T\}$$

For example, the following Cartesian product type is isomorphic to `bool`:

$$1 \times \text{bool} = \{(\text{unit}, \text{left unit}), (\text{unit}, \text{right unit})\}$$

Languages manifest the Cartesian product type as the type of a record or tuple.

### Function Types

If  $S$  and  $T$  are types then  $S \rightarrow T$  consists of all functions from  $S$  to  $T$ . For example, the function type `bool`  $\rightarrow$  `bool` consists of the constant true and false functions, the identity function, and the complement function. Languages manifest the function type as the type of a function declaration or function abstraction and, in the case of finite functions, also as the type of an array.

### Recursive Types

A poset  $(S, \leq)$  is a domain if there is a unique least element  $x \in S$ , meaning  $x \leq y$ , or  $x$  approximates  $y$ , for all  $y \in S$  and for every infinite increasing sequence  $x_0 \leq x_1 \leq x_2 \leq \dots$  there is a unique element  $z$ , called its *limit*, that is approximated by every  $x_k$ , and that approximates any other element that is approximated by every  $x_k$ . A function  $F$  between domains is *continuous* if it is monotonic and preserves limits—that is,  $F(x) \leq F(y)$  if  $x \leq y$ —and if the increasing sequence  $x_0 \leq x_1 \leq x_2 \leq \dots$  has limit  $z$  then increasing sequence  $F(x_0) \leq F(x_1) \leq F(x_2) \leq \dots$  has limit  $F(z)$ . Then if  $F$  is a continuous function between elements of a domain then **fix**  $F$  is the least fixed point of  $F$ .

For example, let  $F = \mathbf{fn} \ z \Rightarrow 1 + (H \times z)$ , where  $H$  stands for characters. Then **fix**  $F$  is a recursive type containing all finite strings. Successive approximations of **fix**  $F$  are given by  $Q_{k+1} = F(Q_k)$ , with  $Q_0 = 0$  and set inclusion as the partial order. Intuitively, the approximation

$$Q_1 = 1 + (H \times Q_0) = \{\text{left unit}\}$$

contains only the empty string, whereas

$$Q_2 = 1 + (H \times Q_1) = Q_1 \cup \{\text{right}(h, \text{left unit}) \mid h \in H\}$$

contains the empty string and all strings of length one. In general,  $Q_k$  contains all strings of length less than  $k$ . The limit of sequence

$$Q_0 \subseteq Q_1 = F(Q_0) \subseteq Q_2 = F(Q_1) \subseteq \dots$$

is given by  $Q = Q_0 \cup Q_1 \cup Q_2 \cup \dots$ . But  $Q$  is also the limit of sequence

$$F(Q_0) \subseteq F(Q_1) \subseteq F(Q_2) \subseteq \dots$$

which has as its limit  $F(Q)$ , since  $F$  is continuous. Therefore,  $Q = F(Q)$ , or  $Q$  is a fixed point of  $F$ . For any other fixed point  $Q'$  of  $F$ ,  $Q_0 \subseteq Q'$ , and if  $Q_k \subseteq Q'$  then  $Q_{k+1} = F(Q_k) \subseteq F(Q') = Q'$ . Since  $Q$  is the limit and  $Q'$  is approximated by every  $Q_k$ ,  $Q \subseteq Q'$ . This implies  $Q = \mathbf{fix} F$ , or  $Q$  is the least fixed point of  $F$ . Languages manifest the recursive type as the type of an element belonging to an *infinite* set. Some languages permit recursive types to be defined, and their run-time support typically includes **garbage collection**. Other languages allow only definition of self-referential structures using pointers. Here, memory allocation and deallocation are typically a programmer's responsibility.

## Syntax and Semantics

A programming language consists of three syntactic classes of phrases: definitions (**Def**), expressions (**Exp**), and commands (**Com**). These classes arise out of semantic differences between phrases. Expressions are evaluated for their values, commands are executed for their effect on a store, and definitions are evaluated for their effect on an environment. Let **L** denote locations, **B** basic values, and  $\mathbf{R} = \mathbf{L} + \mathbf{B}$  storable values. A *store* is an element of domain

$$\mathbf{S} = \mathbf{L} \rightarrow (\mathbf{R} + \{\text{error}\})$$

and maps a location to the value stored at that location. An *environment* is an element of domain

$$\mathbf{Env} = \mathbf{Id} \rightarrow (\mathbf{R} + \{\text{error}\})$$

and maps an identifier to a storable value. If an environment maps an identifier to a location, then the identifier stands for a *variable*; otherwise, it denotes a *constant*. A formal description of a phrase's semantics (meaning) may be given by semantic functions. There is one for each class:

$$\begin{aligned}
\mathcal{E}: \text{Exp} &\rightarrow \text{Env} \rightarrow \mathbf{S} \rightarrow (\mathbf{R} + \{\text{error}\}) \\
\mathcal{C}: \text{Com} &\rightarrow \text{Env} \rightarrow \mathbf{S} \rightarrow (\mathbf{S} + \{\text{error}\}) \\
\mathcal{D}: \text{Def} &\rightarrow \text{Env} \rightarrow \mathbf{S} \rightarrow (\text{Env} \times \mathbf{S})
\end{aligned}$$

where  $\mathcal{E}$ ,  $\mathcal{C}$ , and  $\mathcal{D}$  give meaning to expressions, commands, and statements, respectively. This kind of semantic description is called a *denotational semantics*. Each semantic function maps an element of a syntactic class to a function over semantic domains **Env**, **S**, and **R**.

## Expressions

An expression is evaluated for its value, although in some languages like C it may be evaluated for its effect as well. This kind of effect is called a *side effect*; it makes reasoning about programs more difficult since it compromises *referential transparency*, the ability to replace all occurrences of an expression in a program by a single value without changing the program's meaning. Examples of expressions are literals, identifiers, compound expressions (e.g., arithmetic expressions), block expressions, and procedure expressions.

Languages may differ in their interpretation of compound expressions in that subexpression evaluation order may vary. But if expressions are side effect-free, then evaluation order is irrelevant. Even without side effects, languages may still interpret expressions differently. For example, the conventional interpretation of an identifier  $I$  is given by

$$\mathcal{E}[I] \ e \ s = s(e \ I) \quad \text{if} \quad (e \ I) \in \mathbf{L} \quad \text{otherwise} \quad e \ I$$

which specifies that addresses of variables are implicitly dereferenced. Therefore, in languages like Pascal, C, and Ada, different occurrences of the same variable within a program may have different meanings! This is true in the assignment command  $x := x + I$ , where on the left side, the occurrence of variable  $x$  means  $(e \ I)$  and on the right it means  $s(e \ I)$ . Standard ML eliminates this inconsistency by adopting

$$\mathcal{E}[I] \ e \ s = e \ I$$

as its interpretation of identifiers. Now the store is applied explicitly via a dereference  $!x$  so that the assignment becomes  $x := !x + 1$ . Both occurrences of variable  $x$  have the same meaning  $(e \ I)$ .

Another kind of expression that may be interpreted differently by various languages is the procedure expression. Such an expression is used to create procedure abstractions, which in some languages may remain anonymous [Watt, 1990]. One common interpretation is given by

$$\mathcal{E}[\text{procedure } C] \ e \ s = \mathcal{C}[C] \ e$$

which conveys that procedure body  $C$  must be closed with respect to environment  $e$  but not with respect to store  $s$ , since  $e$  appears on the right side but  $s$  does not. Consequently, the procedure will be executed in the environment of its *definition* rather than the environment of its *invocation* and in the store of its invocation, not the store of its definition. This interpretation is called a **static**

**binding** semantics because any free identifiers in  $C$  will get their bindings from the environment at the point of definition. Programming languages Pascal, Modula, C, Ada, Scheme, and Common Lisp interpret procedure expressions in this way. In contrast, a **dynamic binding** semantics is given by

$$\mathcal{E}[\text{procedure } C] \text{ } e \text{ } s = \mathcal{C} [C]$$

where the environment is now supplied when the procedure is invoked. Free identifiers then get their bindings from the environment at the point of invocation. Early dialects of Lisp adopt this semantics.

The temporary rebinding of predefined identifiers for the purpose of debugging is one advantage of dynamic binding. There are many disadvantages, however. A free identifier may not have a unique binding, or, in other words, scope rules cannot be used to determine meaning. Local variables can be modified by procedures that fall outside the scopes of these local variables. Further, bound variables can no longer be consistently renamed without possibly changing a program's meaning. Achieving, in a language with dynamic binding, the static binding of free identifiers in functions passed as arguments has come to be known as the *funarg problem*.

## Commands

A command is executed for its effect on a store. Examples of commands are assignment, command composition, block commands (as in block-structured languages), conditionals, and procedure calls. A procedure call may transmit actual parameters that are referenced in the called procedure via its formal parameters. Parameter transmission is typically one of three kinds: *call-by-value*, *call-by-value-result*, or *call-by-reference*. Of the three, only call-by-value-result affects the epilogue of a procedure call, since it has a copy-out phase where values of the formal parameters are copied back to the corresponding actual parameters. In languages where identifiers may share a location, i.e., where they are *aliases* for each other, these transmission techniques can produce different results. A procedure whose correctness can be established independently of the type of one or more of its formal parameters is called a *polymorphic procedure*.

Call-by-value is also referred to as *eager evaluation*. Sometimes a called procedure may not need the values of all its formal parameters. In this case, evaluation of the corresponding actuals can be avoided. Evaluating an actual parameter if and only if its value is needed in the called procedure is called *call-by-name*. Under call-by-name, an actual parameter's evaluation is delayed until its corresponding formal is referenced, but each reference calls for another evaluation of it. If it is evaluated at most once, however, then parameter transmission is *call-by-need* [Friedman *et al.*, 1992]. Call-by-name is also referred to as *lazy evaluation*.

## Definitions

A definition is evaluated for its effect on an environment. Every definition has a *scope* as prescribed by a scope rule. The scope is a region of text. An applied occurrence of identifier  $I$  is *free* in  $R$  if it does not fall within the scope of a definition for  $I$ ; otherwise, it is bound in  $R$ . If a definition  $I = E$  has scope  $R$ , then every free occurrence of  $I$  in  $R$  denotes  $E$ .

There are two kinds of definitions in traditional imperative languages—*constant* and *variable*

definitions. Their meanings are given by

$$\mathcal{D}[\text{const } I = E] \ e \ s = (\text{fix fn } e' \Rightarrow e[I \mapsto \llbracket \mathcal{E} \rrbracket e' \ s], s)$$

$$\mathcal{D}[\text{var } I = E] \ e \ s = (e[I \mapsto l], s[l \mapsto \mathcal{E}[E] \ e \ s])$$

where  $l$  is a new location and  $e[I \mapsto l]$  is environment  $e$  updated so that  $I$  is mapped to  $l$ . A constant definition, **const**  $I = E$ , unlike a variable definition, never modifies a store. It also requires the scope of identifier  $I$  to include  $E$  in order to express *recursion*. One disadvantage of this requirement is that references to predefined identifiers can no longer be intercepted, say during debugging, unless some form of scope resolution is provided.

Suppose, for example, that *eof* is a predefined end-of-file predicate of one argument. Then

$$\text{const } eof = \text{fn } f \Rightarrow \dots eof \ f \dots;$$

is a recursive definition. However, our intention may be to create a user-defined version of *eof* from which some additional operations are performed before calling the predefined version of *eof*. Standard ML [Paulson, 1992] and Scheme [Friedman *et al.*, 1992] permit the desired definition to be expressed because they have forms of definition with different scope rules. For example, in Scheme,

$$(\text{let } ((eof \ (\text{lambda } (f)(\dots eof \ \dots)))) \dots)$$

gives the desired definition, as does

$$\text{val } eof = \text{fn } f \Rightarrow \dots eof \ f \dots;$$

in Standard ML. In each case the scope of *eof* does not include the definition. To include it, **letrec** is used in Scheme and **fun** or **val rec** in Standard ML:

$$\text{val rec } eof = \text{fn } f \Rightarrow \dots eof \ f \dots;$$

Though this definition appears circular, it is actually shorthand for the noncircular definition

$$\text{val } eof = \text{fix fn } eof \Rightarrow \text{fn } f \Rightarrow \dots eof \ f \dots;$$

which conveys that *eof* is defined as the least fixed point of functional  $\text{fn } eof \ \text{fn } f \Rightarrow \dots eof \ f \dots$ , assuming that the functional is continuous over some domain.

## Encapsulation

Large programs without a discipline for accessing global variables are hard to maintain and reuse because procedures that affect a global variable cannot be developed independently of other procedures that also access the variable. Modifications needed to accommodate a change in the global variable's declaration are not confined to a specific region of the program. To confine them, a global variable is declared within a *module* together with those procedures that affect it, so that its scope is limited to the module. Thus the variable is effectively hidden or inaccessible to all procedures declared outside the module. This is called *encapsulation* or *information hiding*.

### Modules and Objects

There are two basic kinds of modules: *objects* (modules with constant or variable definitions) and *structures* (modules with constant definitions only). An object also has an interface indicating the definitions whose scopes extend beyond the object, that is, are exported. An object declaration affects the environment and store. A package body in Ada with a variable declaration that is not specified in the package specification is an example of an object with a hidden variable [Barnes, 1992]. An *object class* declaration, unlike an object, affects only the environment, not the store; but its instantiation, which creates an object, affects both. A *class* in C++ is an example of an object class. An object class may be derived from multiple object classes in the sense that it *inherits* operations from these classes. Languages that permit derived object class declarations of this kind, such as C++ and Eiffel [Meyer 1989], are called **object-oriented languages**.

A structure is a tuple of constant definitions. As such, its declaration affects only the environment. A structure is used to group logically related definitions or to implement an abstract data type. An *abstract data type* is a heterogeneous algebra that may have multiple representations. Each representation has a *coupling invariant* that relates abstract and concrete values [Gries and Volpano, 1990]. A language supports abstract data types if it prohibits *impersonation*, applying abstract operations to representation values, and *unauthorized access*, applying representation operations to abstract values. A language that does not prevent unauthorized access cannot guarantee that programs will always be independent of abstract data type representations. Some languages, such as Standard ML, permit type abstractions and their representations to be separately specified and allow mappings between structures, called *functors*, to be defined, which serve as useful system-building operations.

## 134.2 Program Verification

---

Program verification is concerned with mathematically proving the correctness of a program. It requires a set of axioms and inference rules for programming language constructs, called a *programming logic*. A formal proof of a statement about a program is a sequence of facts ending with the statement, such that every fact is an instance of an axiom or follows from preceding facts by an inference rule.

An example of a programming logic is Floyd-Hoare logic. In this logic,  $\{P\}C\{Q\}$  is a *partial correctness* specification, where  $P$  is a precondition,  $Q$  is a postcondition, and  $C$  a command. It is true if whenever  $C$  is executed in a state that satisfies  $P$  and execution of  $C$  terminates, then it does

so in a state that satisfies  $Q$ . The specification may be true even though  $C$  does not always terminate. A stronger kind of specification is a **total correctness** specification, which also requires that  $C$  terminate whenever it is executed in a state satisfying  $P$  [Gries, 1981]. Let  $P[E/V]$  denote  $P$  with all free occurrences of  $V$  replaced by  $E$ . Then, an example of a Floyd-Hoare axiom is the assignment axiom,

$$\vdash \{P[E/V]\} \quad V := E \quad \{P\}$$

where  $V$  is any variable,  $E$  any side effect-free expression, and  $P$  a postcondition. An instance is

$$\vdash \{a[j] = 0\} \quad a[i] := 0 \quad \{a[i] = a[j]\}$$

Notice that the precondition is not implied by  $i = j$ , even though  $\{i = j\} \quad a[i] := 0 \quad \{a[i] = a[j]\}$  is true. A more suitable precondition is the *weakest precondition*, as is given in the instance

$$\vdash \{a[j] = 0 \vee i = j\} \quad a[i] := 0 \quad \{a[i] = a[j]\}$$

A programming logic is *sound* with respect to a semantics if deductions in the logic are consistent with the semantics. For example, the above assignment axiom is unsound in the language C since

$$\vdash \{j = 0\} \quad i = j++; \quad \{j = 0\}$$

can be deduced but is false. A logic is *complete* with respect to a semantics if every specification that is true for the semantics can be proved in the logic [Gordon, 1988].

## 134.3 Programming Language Paradigms

---

The kinds of phrases that a programming language allows is primarily what distinguishes it from other languages. A language with commands is called an **imperative language**. Programs written in such a language are formally characterized as store (state) transitions. Examples include block-structured languages, such as Algol-60 and its descendants—Pascal, Modula, and Ada. A programming language without commands is a declarative language and includes **functional languages** [Hudak, 1989] and **logic languages** [Shapiro, 1989]. Distributed programming languages support computation by independent processes that communicate by message passing. Processes may be distributed across distant nodes of a network. Parallel or concurrent languages, on the other hand, are aimed at supporting concurrent execution of sequential processes that communicate by shared variables.

# Concurrent and Distributed Programming

## Concurrent Programming

A *concurrent program* is a set of sequential programs that execute simultaneously on a computer in which processes communicate via shared variables and are able to call a centralized operating system to receive a service. This is typically called *large-grained concurrency*, compared to the small-grained variety, such as data and control parallelism provided by parallel vector processors and parallel function units.

Reasoning about the behavior of a concurrent program is facilitated by regarding its execution as an interleaved execution sequence of atomic instructions of sequential processes. There may be more than one sequence, so a property of a concurrent program is a property that holds for all interleavings. Sequential processes may share a resource for which mutually exclusive access is necessary. That portion of a process in which the resource is needed is called its *critical section*. A concurrent program has the *mutual exclusion property* if instructions from the critical sections of two or more processes are never interleaved. Dekker's algorithm ensures this property for two processes, whereas Peterson's algorithm [Peterson, 1983] ensures it for any number of processes.

Other important properties of a concurrent program include freedom from deadlock and starvation. *Deadlock* arises when all sequential processes are prevented from making further progress due to mutually unsatisfiable demands for additional resources. A concurrent program may detect, prevent, or avoid deadlock. *Starvation* exists if one process is prevented indefinitely from entering its critical section.

Higher-level support for mutual exclusion is provided by semaphores and monitors. A *semaphore* is an integer-valued variable  $S$  ranging over natural numbers with two atomic operations—**wait**( $S$ ), which may cause a process to suspend on semaphore  $S$ , and **signal**( $S$ ), which may resume execution of a suspended process. There are various kinds of semaphores, including blocked-set, blocked-queue, busy-wait, and binary semaphores. A semaphore is considered unstructured because its correct use depends on independent calls to primitives **wait** and **signal**. Structured support for mutual exclusion is provided by a *monitor*, which is an object with the property that at most one process can execute its procedures at a time. Monitors are used extensively in concurrent programming, and dialects of Pascal have been developed with monitor-based programming primitives [Bustard et al., 1988].

## Distributed Programming

A *distributed program* is like a concurrent program, except that sequential programs may execute on different computers and communicate by sending messages to each other. In a physically distributed system, processes communicate through the exchange of messages using a *protocol*, which prescribes a format for messages and detects and corrects errors in their transmission. With *synchronous communication*, message exchange requires both the sender and receiver to participate. Each must reach a designated point in its execution, called a *rendezvous*, before a message can be exchanged between them. If one reaches this point before the other, then it must wait. This form of communication is found in Ada. If a sender is allowed to send a message and continue without blocking, then communication is *asynchronous*. In this case the sender may send multiple messages before the receiver responds, so message buffering is needed. Linda is a concurrent language with asynchronous communication [Gelernter, 1985].

## Real-Time Programming

A *real-time program* is a program whose execution is subject to real-time constraints on response time. Such programs are found in embedded computer systems, such as flight-control systems. A real-time program may be implemented by a synchronous clock-driven scheduler. Processor time is divided into frames and tasks into segments so that every segment can complete in one frame. A *scheduling table* assigns segments to frames so that all segments in a frame complete their execution by the end of the frame. When the clock signals the start of a frame, the scheduler calls the segments for that frame as prescribed by the table. An alternative to partitioning tasks is to assign them priorities instead, as in Ada [Barnes, 1992]. Tasks execute asynchronously but are scheduled by a preemptive scheduler, which interrupts a running process if a higher-priority task becomes ready to execute.

## Defining Terms

**Dynamic binding:** A free variable's binding in the environment at the point of invocation.

**Functional language:** A language whose programs are mappings between values expressed using only expressions and function declarations.

**Garbage collection:** The systematic recycling of inaccessible memory cells during program execution.

**Imperative language:** A language whose programs are mappings between stores expressed using variables, commands, and side effects.

**Logic language:** A language whose programs are relations expressed using only expressions and clauses.

**Object-oriented language:** A language whose programs may be written with derived object classes.

**Static binding:** A free variable's binding in the environment at the point of definition.

**Total correctness:** A correctness criterion requiring partial correctness and termination.

## Further Information

A good introduction to the theory and practice of concurrent and distributed programming can be found in Ben-Ari's textbook *Principles of Concurrent and Distributed Programming*, Prentice Hall, 1990. It puts a wide range of solutions to well-known problems in perspective. Another good book on the same topic is by Greg Andrews, *Concurrent Programming: Principles and Practice*, Benjamin/Cummings, 1991. David Watt's book *Programming Language Processors*, Prentice Hall, 1993, provides a nice overview of the implementation of programming languages. New implementation techniques can be found in the proceedings of the annual ACM Conference on Programming Language Design and Implementation. Theoretical and practical aspects of programming in a wide variety of paradigms can be found in the quarterly journal *ACM Transactions on Programming Languages and Systems* and the proceedings of the biennial IEEE International Conference on Computer Languages. Foundations of programming languages are the subject of the annual ACM Symposium on Principles of Programming Languages. For information on practical issues in distributed and parallel programming, see the quarterly journal *IEEE Parallel and Distributed Technology*.

### 135.1 Input/Output Subsystem

#### 135.2 I/O Devices

Human-Oriented I/O • Communications-Oriented I/O • Storage-Oriented I/O

#### Rich Freitas

*IBM Almaden Research Center*

The computer senses and affects the environment around it through input/output (I/O). In some sense its CPU characteristics are secondary; the computer is really "defined" by the quantity, variety, and attachment strategy of its I/O devices. Therefore, a full and complete understanding of computers and how to use them must be founded on a good understanding of the characteristics and capabilities of the computer's I/O subsystem and the I/O devices attached to it. This chapter presents brief descriptions of typical components of I/O subsystems and several I/O devices.

## 135.1 Input/Output Subsystem

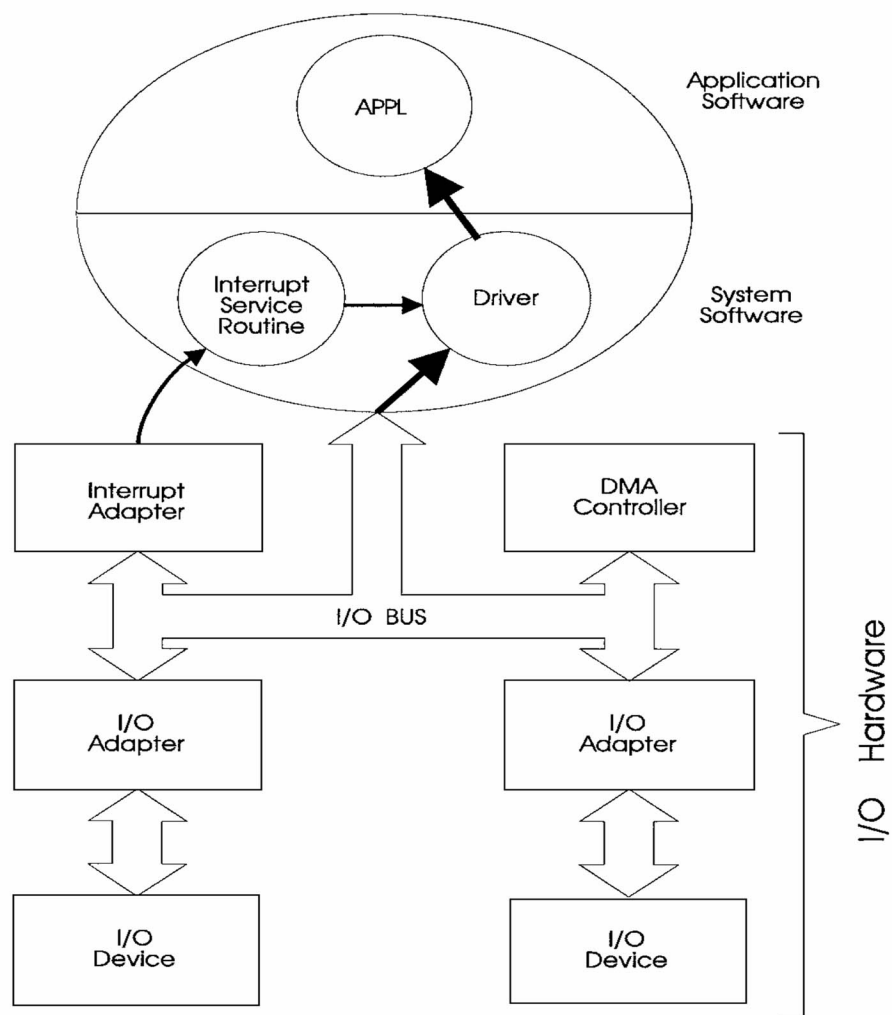

---

[Figure 135.1](#) depicts an I/O subsystem. The circle represents software and the rest is the I/O hardware. The upper half of the circle is application software, which generates or consumes the I/O data. The application software selects or names some I/O data or an I/O device. It may also specify the type of transfer and a target location in memory.

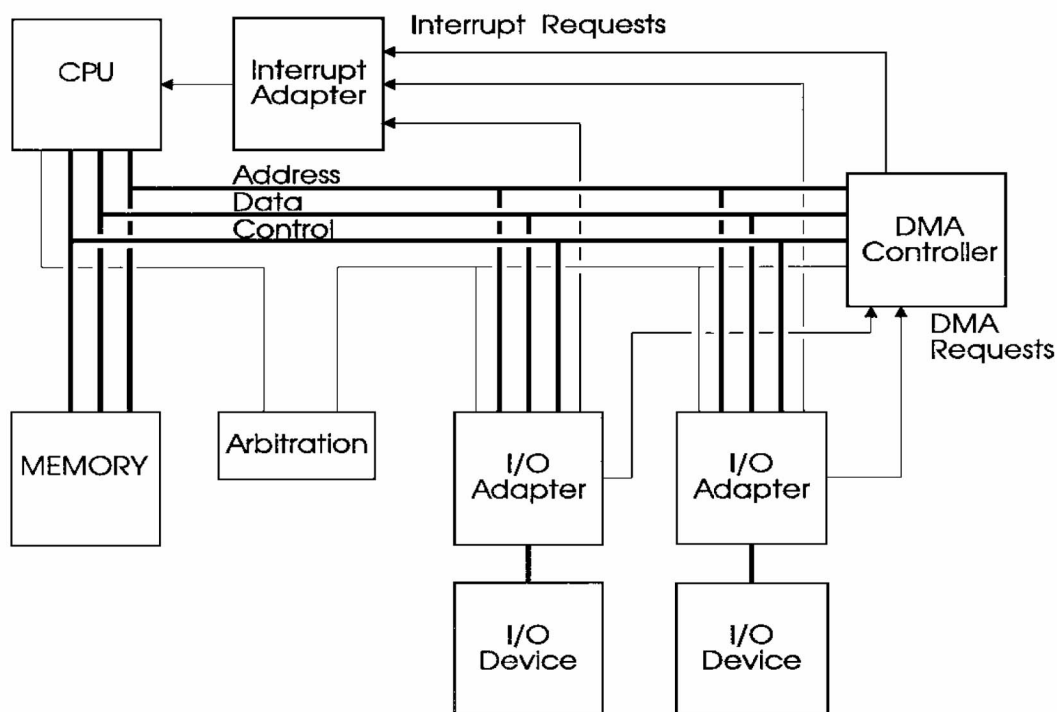

**Device drivers** are part of the system software, which includes the file system and operating system. The role of the device driver is to map the high-level names used by the application software into the addresses recognized by adapters on the I/O bus, to manage the sequence of events, and to perform error recovery. Device drivers deal with the device-specific aspects of the I/O software, and thus may have to queue the operation, select a device, address it, assess its status, check the legality of the operation, arm and enable **interrupts**, initialize the **direct memory access (DMA)** controller, start the **I/O adapter**, and deal with the resulting interrupts, status conditions, and errors. In personal computers this function is performed by a combination of the operating system (DOS, OS/2, or Windows) and the ROM resident BIOS.

The I/O hardware consists of the I/O bus, the interrupt controller, the DMA controller, the I/O adapters, and the I/O devices. The I/O bus connects the I/O hardware with the memory and the CPU on which the software runs. [Figure 135.2](#) depicts a typical I/O bus. It consists of lines for data, address, control, arbitration, and interrupts. The functions of the address, data, and control lines is straightforward; these lines provide the means and control signals to move data to and from the CPU, memory, and the adapters. The arbitration lines govern who has control of the bus. Many such buses exist in the industry, and a few are described in [Table 135.1](#).

**Figure 135.1** Input/output subsystem.

**Figure 135.2** Input/output busing.

**Table 135.1** Characteristics of Typical I/O Buses

Bus	Data Width	Single Transfer Wait State	Burst Transfer Wait State
ISA	8, 16	8.33 MB/s	8.33 MB/s
EISA	32	8.33	33
MCA	32, 64	20	80
PCI	32, 64	33/44 (R/W)	132
VMEbus	16, 32	25	27.9
FutureBus	32,...,256	37	95

ISA—industry standard architecture

MCA—micro channel architecture

PCI—peripheral component interconnect

EISA—extended ISA

VMEbus—VERSAbus-E

Interrupts are signals from the I/O adapters to the interrupt controller indicating that a hardware event has occurred, to which the software is expected to respond. The interrupt controller notifies the CPU, which suspends execution, saves its state, and executes an interrupt service routine. When the routine is finished, the CPU restores the saved state and resumes executing the interrupted program. For complicated situations, such as two or more interrupts occurring "simultaneously" or preventing interrupts in critical sections of the software, the interrupt controllers prioritize, disable, or mask interrupts. A signalled interrupt with high priority blocks all interrupts at its priority and any of lower priority. A masked interrupt is blocked because its associated mask or arm bit is off. The whole interrupt system can be masked; this is called *disabling* the interrupt system. There are interrupts that cannot be disabled or disarmed. Serious error indications (e.g., uncorrected memory error) are often reported as nonmaskable interrupts, and many kinds of programming errors (e.g., divide by zero) are reported by a lower priority nonmaskable interrupt called a *trap*.

The I/O adapter is the hardware entity directly addressed by the device driver. Its role is to "adapt" I/O devices to the shared I/O environment. It responds to commands from the device driver and then manages the sequencing and timing of operations between the I/O bus and the I/O device; does error detection and error correction; collects, maintains, and reports status information; buffers data and/or acts as a data cache; and converts or translates data from one physical or logical environment to another.

There are three I/O modes: programmed I/O, interrupt-driven I/O, and direct memory access. In programmed I/O the software has direct access and control of all I/O data, control, and status information. It writes and reads hardware registers either by using special I/O commands or, in memory-mapped I/O systems, by accessing the address in memory address spaces assigned to the hardware register. If the software needs to test for the occurrence of a hardware event, it loops reading the status register and checking for the indication of the event; this process is called *polling*. Polling I/O events is time consuming and inefficient. If the hardware event is signaled as an interrupt, then the software need not poll. This is called *interrupt driven I/O*. Programmed I/O and interrupt-driven I/O are effective for transferring control and status information and small amounts of data. However, if large block transfers of data—especially at high speed—are required, the software overhead is very high and can dramatically decrease the overall system performance.

Direct memory access, the third I/O mode, was devised to free the software from dealing with long contiguous data transfers. The DMA controller performs all the necessary tasks once the

software has selected a DMA channel (i.e., selected an adapter); stored the memory address, byte count, and transfer direction into DMA control registers; and started the selected I/O adapter. At the transfer of each byte (word, etc.) the count is decremented and the address is incremented. When the count goes to zero, the hardware prepares to stop. In some DMA controllers, additional sets of address and byte count are stored in DMA registers so that the DMA controller can continue to transfer data. Such hardware automatically continues the data transfer using this new information; this process is called chaining. If chaining is not performed, the hardware interrupts the software to indicate that the count equals zero. The software then completes the termination of the transfer. If the DMA controller manages the address and count registers for the adapter, a third-party DMA transfer has occurred. If the adapter manages the registers, a first-party DMA transfer has occurred.

## 135.2 I/O Devices

---

There are three classes of I/O devices: those devices that interface with humans, those that interface with machines, and those that interface with storage media. We will briefly discuss representative devices in each of these categories.

### Human-Oriented I/O

The video display; printer; keyboard; and pointing devices such as the mouse, TrackPoint II™, and tablet are typical human-oriented I/O devices—that is, a transducer and associated electronics that interface a computer with a human sense. By far the most common output device is the video display. The block diagram of a typical video display system is shown in [Fig. 135.3](#). It consists of a **frame buffer**, a **display controller**, and a display. The frame buffer contains information about the intensity and color of each picture element (pixel) on the screen. The display controller uses the information in the frame buffer to paint a picture on the display screen. If the software wishes to change that picture, it must change the contents of the frame buffer. Such changes are made through and managed by the display controller.

For desktop computers the most commonly used video display system is based on the use of the color cathode ray tube (CRT). A CRT consists of an evacuated glass vessel, electron gun(s), a beam-focusing yoke, and a screen coated with a fast phosphor. To draw a picture on the CRT's screen, the beam must irradiate every pixel on the screen that information stored in the frame buffer says should be on. The information must be fetched in order and in synchrony with the movement of the beam. In present day CRTs the beam is scanned across the screen and then down the screen. One complete scan of the screen is called a *frame*. Since the phosphor decays rapidly, the frame must be scanned many times per second to provide a stable, flicker-free image, typically 30 to 80 times per second.

CRTs fail to meet the requirements of one of the fastest-growing segments of the personal computer market: mobile or portable computing. CRTs are heavy, power-hungry, and large in volume. The requirements of mobile computing are presently being met by another display, the flat panel display. The most common flat panel display today is the **liquid crystal display (LCD)**, which consists of two sheets of glass encasing a liquid crystal. On the surface of the glass

**Figure 135.3** Display adapter.

are parallel conductors. On one sheet all the conductors are horizontal and on the other they are all vertical. At each intersection of the two perpendicular lines is a pixel. When the lines are energized the electric field formed between them causes the optical properties of the liquid crystal at the intersection to change. See [Table 135.2](#) for typical characteristics of CRT and LCD displays.

**Table 135.2** Characteristics of Typical Displays

Characteristic	CRT	LCD Flat Panel
Diagonal	12"–19"	6"–10"
Weight	Heavy	Light
Volume	Large	Small
Bandwidth	High	Medium
Refresh rate	30–80 Hz	.01–50 Hz
Brightness	20–60 fL	3–10 fL
Contrast ratio	~30 : 1	3.5–15 : 1

Another output device is the printer. It is the counterpart to the video display in that it produces a hard copy. Printers may be classified according to their technology: impact versus nonimpact (i.e., does the print head strike the paper to print the character?). They may also be classified according to their print mode (character, line, and page) or according to their mechanism (drum printers, band printers, dot matrix printers, ink-jet printers, and electrographic or laser printers). Regardless of the classification scheme chosen, printers almost always interface with the computer using one of two interface standards. One is serial; it is the RS232 protocol, which is used to asynchronously ship data at moderate speed to the printer over potentially long lines. The other is the byte-parallel, 25-pin centronics interface; it is used to send data to the printer at higher speed but much shorter distances.

Typical input devices include the keyboard and pointing devices. The keyboard is an electrical device for translating pressure on one or more of the keys into a 7- or 8-bit number. That transformation is effected by a matrix of switches monitored by a small microcomputer housed in the keyboard. Once the microcomputer has determined a key code, it formats the code into a serial bit stream and sends it over the keyboard cable to an adapter in the computer. The computer may also send messages to the keyboard to drive the buzzer and turn on indicator lights.

Pointing devices such as the mouse, TrackPoint II™, and tablet are used to select a point on the computer display. This point is indicated by an icon called the *cursor*. The software picks a (0,0) point and then derives the cursor's position by keeping track of the  $\delta x$  and  $\delta y$  registers maintained by the pointing device hardware. Associated with both the mouse and the TrackPoint II™ are two or three buttons whose state is returned by the hardware.

The mouse consists of a ball and two shaft encoders mounted at right angles to each other. Attached to each shaft encoder is a wheel. As the mouse is moved over the surface, the ball moves and the wheels, which touch the ball, turn proportionally with the  $x$  and  $y$  displacement; the shaft encoders generate pulses accordingly. These pulses increment and/or decrement the  $\delta x$  and  $\delta y$  registers. These registers are typically sampled at 5 ms intervals, and the changes are reported to the computer. The mouse is separate from the computer and keyboard and tethered to the computer

by a cable over which power and the sampled data are sent.

The TrackPoint II™, on the other hand, is built into the keyboard. It is a small shaft that sticks up between the G, H, and B keys of the keyboard. At its base are a set of strain gages. When the user pushes on the shaft, the pressure is measured and used to determine the position of the cursor. Basically, the vector sum of the strain gages indicates the direction in which the cursor should move, and its speed is a nonlinear function of the magnitude of the force applied. For "small" forces the speed is zero. For "medium" forces the speed is linearly proportional to the force applied, and for "high" forces the speed is a constant.

The pen and tablet constitute a different sort of pointing device. The display screen, usually a flat panel screen such as an LCD, is overlaid with a transparent mesh of wires. Each line in the  $x$  and  $y$  dimension is individually pulsed in sequence. When the pen touches the screen, it either capacitively senses or electromagnetically modifies pulses on the  $x$  and  $y$  lines that cross under it. From knowledge of the timing of the pulses, the associated hardware determines the specific  $x$  and  $y$  lines. The hardware reports this position information to the computer as an absolute ( $x, y$ ), instead of relative ( $\delta x, \delta y$ ), value as used by the mouse and the TrackPoint II™. Sampling rates are about the same—200 points per second.

See [Table 135.3](#) for typical human-machine data communications rates.

**Table 135.3** Human-to-Machine Data Rates

Human	Data Rate	Limited by	Machine
Read text at 1000 wpm	.083 kB/s	H	Alphanumeric display
Visual pattern recognition	30–70 MB/s	M	Graphic display
Type at 100 wpm	.008 kB/s	H	Keyboard
Pointing/selecting	1 kB/s	H	Mouse; TrackPoint II™; tablet
Hard copy	1–100 kB/s	M	Printer

The Hewlett-Packard DeskJet printers are the best-selling monochrome and color-optional printers in the world. (Photo courtesy of Hewlett-Packard.)

#### AFFORDABLE DESKJET PRINTERS FOR THE HOME MARKET

Hewlett-Packard Company has introduced the HP DeskJet 540 printer for PCs and the HP DeskWriter 540 printer for Macintosh. These two printers replace best-selling monochrome and color-optional printers previously offered by HP. They are targeted for the rapidly growing home market and offer the best black print quality at an affordable price. HP DeskJet printers offer color as a standard or as an option. Affordable color upgrade kits for these printers give HP the distinction of having the lowest price available for color printing.

HP's ColorSmart technology, which is used in the printers, renders vivid, vibrant color automatically. ColorSmart uses object identification to recognize text, graphics, and photographic elements separately, selecting the optimal color or grayscale tone for each element. By reducing the process to a single step, ColorSmart has revolutionized color printing in much the same way that autofocus cameras have reduced the expertise required for 35 mm photography.

## Communications-Oriented I/O

Communications-oriented I/O devices make up the computer's vehicle for accessing computer networks to share resources and send messages (e.g., the Internet). See Tanenbaum [1988] for more information about computer networks. The "communications device" is an I/O adapter interfacing with a communications channel(s). A channel is a single path or line over which data is transferred. Channels are either simplex (a single, strictly one-way path), half duplex (a shared path used part-time in each direction) or full duplex (two simplex paths connected in opposite directions). The media for the channels can be twisted-pair wires, coaxial cables, fiber optic cables, radio waves, and so forth. See Table 135.4 for a few examples of communications devices. The I/O behavior of the I/O device reflects the characteristics of the channel. For example, low-speed communications over a single telephone modem can easily be handled by a background interrupt-driven device driver, whereas FCS communications at 100 MB/s requires a complex, high-speed adapter performing DMA transfers over a high-speed bus to a high-performance memory system.

**Table 135.4** Machine-to-Machine I/O

Medium	Bandwidth	Mode*
Telephone modem	1.2–19.2 kb/s	C
Wireless wide-area net	4–19.2 kb/s	P
Wireless LAN	200 kb/s	P
Ethernet	10 Mb/s	P
Token ring	16 Mb/s	P
FDDI	100 Mb/s	P
FCS	100 Mb/s	C or P
ATM	51.84 Mb/s–2.488 Gb/s	C or P

\*C—connection; P—packet

## Storage-Oriented I/O

Storage-oriented I/O devices exploit physical phenomena to provide high-capacity, inexpensive, nonvolatile data storage. Table 135.5 lists several such storage devices. With the exception of flash memory, all provide reliable permanent data storage with access times much slower than DRAM. Since flash memories are based on semiconductor memory technology, they provide a storage subsystem with speeds comparable to main memory. Unfortunately, this technology suffers from write wear-out. In general, storage devices interface with computers as a DMA device with a long access time and a moderate transfer rate. Once they start to transfer, they need to continue transferring. Therefore, most of the adapter cards that support such devices have an onboard buffer to help match the speed differences and in some cases act as a cache.

**Table 135.5** Machine-to-Storage I/O

Device	Data Rate	Access Time	Latency	Formatted Capacity
Floppy disk	.125–1 MB/s	50–150 ms	100–200 ms <sup>1</sup>	.36–2.88 MB
Flash memory	10 MB/s	.0001 ms	—	—
Disk drive	1–10 MB/s	8–20 ms	7–16 ms	.02–2 GB
CD ROM	.2–5 MB/s	200–500 ms	50–150 ms <sup>2</sup>	.6–2 GB
Tape	.2–2 MB/s	—	30–90 s	2 GB

<sup>1</sup>500 ms spin up time

<sup>2</sup>6 s spin up time

## Defining Terms

**Device driver:** Modern operating systems and applications are written to be portable; that is, they are written to run on many computers and with many different I/O configurations and with I/O devices that did not exist when the software was written. Therefore, all I/O device-specific code needed to use a device is written as a separate program, either by a device vendor or the user, thus permitting new devices and upgrades to old devices without requiring changes to the operating system or the application. This separate program is called a **device driver**.

**Direct memory access (DMA):** The method of using hardware, either the I/O adapter or a specialized controller, to transfer I/O data directly between the memory and the I/O device without the direct involvement of the software.

**Display controller:** Digital electronics that controls access to a display's frame buffer.

**Frame buffer:** Each dot on a display screen is described by a small block of data. The information stored there ranges from whether the dot should be present to intensity information for all three colors. This information is stored in a memory called a **frame buffer**.

**Interrupt:** An interrupt is a signal from an I/O adapter to the software indicating that a hardware event has occurred. The event is usually expected by the hardware, and the interrupt causes the software to start executing a higher-priority task.

**I/O adapter:** Hardware interface between I/O bus and I/O device.

**Liquid crystal display (LCD):** A light, low-power, flat panel display used primarily in laptop and smaller computers.

# Memory and Mass Storage Systems

---

## 136.1 Aspects of Storage Devices

## 136.2 Types of Storage Devices

Solid-State Storage Devices • Magnetic Storage Devices • Optical Storage Devices

## 136.3 Storage Organization

### **Peter M. Chen**

*University of Michigan*

Memory and mass storage systems compose one of the core components of a computer system. The basic task of a computer is to process data, and memory and mass storage systems provide a fundamental aspect of this data processing—that of remembering information.

To appreciate how fundamental the storing and retrieving of information is to computers, let us examine a typical transaction at a bank's automated teller machine (ATM). The customer first feeds his ATM card into the bank machine. The magnetic strip on the ATM card stores the account number of the customer. The ATM contains a storage device that can read this magnetic strip and feed it into the bank's computer. The bank's computer runs a program to interact with the customer; this program typically resides in the computer's memory. The screen that displays the menus and information for the customer uses memory to remember what to display. The customer then interacts with the bank's computer, providing a password and one or more account transactions. The password that the customer enters is verified by comparison to the password stored in the computer. Account transactions manipulate the account balances; these too are stored in the computer. In addition, the computer stores a log of all transactions. Video cameras are often present at the ATM to capture the faces of ATM users. These video cameras and tapes are also a type of memory and mass storage.

As is evident from the above example, computers need memory and storage to function. Memory and storage devices store the instructions that computers follow, the databases that computers manipulate, and the screens that computers display.

*Memory* typically refers to devices that are closer to the processor and can be accessed quickly, whereas *storage* typically refers to devices that are farther away. In the rest of this chapter the term *storage* will refer to all of these devices.

## 136.1 Aspects of Storage Devices

---

Storage devices are used throughout the computer system. No single type of storage device is appropriate for all of these uses; rather, there is a wide variety of storage devices. Choosing an

appropriate device for a particular purpose requires understanding the ways that devices differ and weighing the trade-offs involved in using various devices [Chen and Patterson, 1993] .

*Performance* refers to the speed of a storage device and can be broken down into two parts, **throughput** and **latency**. Throughput is the rate at which a device can accomplish work; this work typically is storing and retrieving data. Throughput is often expressed as bytes per second or requests per second. Latency is the time it takes to do a portion of work. The ideal storage device has high throughput and low latency.

*Reliability* refers to the rate at which the storage device fails; this can also be inverted to express the expected time between failures. For example, devices may quote failure rates of 1 error every 100 trillion accesses or 1 failure every 10 years.

*Capacity* refers to the amount of data that a device can store. Closely related to this concept is cost, since a customer can usually buy more devices to increase capacity. Cost is related to all metrics, since it is usually possible to get more by spending more.

*Volatility* refers to whether or not a device can retain information after power is turned off. Volatile devices need power to store information; nonvolatile devices do not. Of course, both volatile and nonvolatile devices require power to store new information or retrieve old information. Volatility can be viewed as a component of reliability, since a power failure is one way to cause a volatile device to fail. Devices discussed here can be assumed to be nonvolatile unless otherwise noted.

*Writable* refers to whether a device can store new information. Almost all applications require the ability to read a storage device, but many do not require the ability to write new information to the device. Devices discussed here can be assumed to be writable unless otherwise noted.

**Random access** refers to the ability of a device to quickly store and retrieve any information in any order. Some devices only access information **sequentially**, that is, in an order that depends on the location of the stored information. Other devices can access information randomly, that is, fairly independently of where the data are stored.

Table 136.1 provides a summary of the ways that storage devices differ.

**Table 136.1** Aspects of Storage Devices

Type	Summary Question	Units	Examples
Throughput	How much work can be done in a given time?	Bytes/second, requests/second	This device can sustain a throughput of 5 million bytes per second.
Latency	How long does it take to do work?	Seconds	This device responds with an average latency of 10 milliseconds.
Reliability	What is the frequency at which this device fails?	1/second, 1/access	This device returns the wrong information once every 100 trillion accesses. You can expect this device to work for 10 years before failing.
Capacity	How much information can this	Bytes	This device can store 1 billion

	device store?		bytes of information.
Cost	How much does this device cost?	Dollars	This device costs \$1000.
Volatility	Does this device lose information if power is turned off?	Yes or no	This device will retain information for 100 years without power.
Writable	Can this device store new information?	Yes or no	This device can store new information, but it cannot erase information once it is stored.
Random-access	Can this device access information independently of how that information was stored?	Yes or no	This device will read information 1000 times faster if the data are read in consecutive order.

---

## 136.2 Types of Storage Devices

---

Numerous types of storage devices exist, and new ones are constantly being invented. Current storage devices can be roughly categorized into three groups—solid-state, magnetic, and optical—but the volatile nature of this field makes it difficult to predict what methods will be used to store and retrieve data in ten years.

### Solid-State Storage Devices

Solid-state storage devices use integrated circuit technology to store information. For most types of solid-state memories, the information is stored by manipulating charges, that is, electrons. These electrons may be stored in explicit capacitors or implicit capacitors (such as those that cause propagation delay), or they may be trapped in transistor gates. Devices that store charge in capacitors are volatile because capacitors allow charge to slowly leak away; devices that trap charge in gates are typically nonvolatile. For a few types of solid-state memories—specifically, ROM (read-only memory) and PROMS (programmable read-only memory)—devices have a set of connections, and the pattern of these electrical connections (fuses) stores information. Solid-state storage devices are currently by far the fastest type of storage.

DRAM (dynamic random access memory) is currently the densest type of solid-state storage device. DRAMs use only one transistor and one capacitor to store one **bit** (binary digit) of information [Wakerly, 1994]. Though they are very dense, DRAM chips are relatively slow for solid-state memory. The charge stored in the capacitor slowly leaks away. To store information for more than a few milliseconds, the charge on these capacitors must be periodically restored; this process is called *refresh*. Because of the high density of DRAMs, they are typically used to store the main memory of a computer system.

SRAM (static random access memory) is optimized for speed rather than density and uses four to six transistors to store a bit of information. Unlike DRAMs, SRAMs do not require periodic refresh. Because of their high speed, SRAMs typically store the data that the processor uses most

frequently.

There are several types of solid-state storage devices that are designed primarily for retrieving data. These include ROM (read-only memory), PROM (programmable read-only memory), EPROM (erasable, programmable read-only memory), and EEPROM (electrically erasable, programmable read-only memory). ROMs and PROMs store information with a set of electrical connections; they can be set only once. EPROMs and EEPROMs store data in the floating gates of transistors; this allows them to be erased and then written with fresh information. However, erasing and writing data is very slow in EPROMs and EEPROMs (many seconds to several minutes) and may only be done a limited number of times (such as 10 000).

## Magnetic Storage Devices

Magnetic storage devices store most of the information for nearly all computer systems, from personal computers to large commercial computers. These storage devices store information on a thin layer of magnetic coating. A bit of information is stored by changing the polarity of tiny magnetic regions in this coating. A **read/write head** creates the magnetic field that induces this change in polarity. Because the state is stored in the polarity of magnets, magnetic storage devices are nonvolatile. In some magnetic storage devices the **storage media** may even be removed from the actual device, allowing the user to multiply greatly the amount of data that can be accessed by a single device.

Magnetic storage devices deposit the magnetic coating on distinct substrates. A hard disk drive deposits the coating on rigid platters. These platters spin underneath an electromagnetic read/write disk head. Because a hard disk is rigid and hermetically sealed, it can use very tight tolerances to pack a high number of bits per square inch and to spin the platters at high speeds. As a result, the hard disk currently has the best performance of any magnetic storage device. Hard disks are the main storage device used in nearly all computer systems.

Floppy disks deposit magnetic coating on a flexible platter. The flexible substrate and unsealed nature of floppy disk drives create looser tolerances than hard disks, which lowers density and performance. Because the floppy disk is inexpensive and can be removed from its drive, it serves as an ideal medium for exchanging data.

Magnetic tapes deposit the magnetic coating on a spool of flexible tape. Examples of machines that use magnetic tape include VCR machines and audio cassette players. The flexible tape is rolled up, which has two significant effects. First, accessing data requires winding through the tape until the head reaches the location on the tape where the data are stored. This winding makes the speed of accessing data in nonsequential locations prohibitively slow, so tapes are read and written sequentially. Second, rolling the tape enables extraordinarily high volumetric densities compared to devices that use platters. Magnetic tapes are also removable, which further decreases their effective cost. Because of their low cost and slow performance, magnetic tapes are used primarily to archive unused data, though this may be changing as the amount of data needed by applications increases.

# Optical Storage Devices

Optical storage devices use lasers to write and/or read data, either alone or in conjunction with magnetic disk technology. Lasers can be focused to read or write a very small spot on the disk, which enables the optical device to store information very densely on the medium. Current optical storage devices allow the removal of the medium that contains the data, which makes them particularly useful for archiving large amounts of infrequently used data. The main disadvantage of optical devices is their speed—magnetic disks are currently several times faster than the fastest optical device.

There are several methods for writing and reading optical storage devices. WORM (write-once, read-many) disk drives were an early type of optical disk. As the name implies, each spot on this device can only be written once. The device writes data by using a laser to burn a pit in the medium at various locations. Future-read accesses sense how the laser is reflected off those pits. CD-ROMs (compact disk read-only memory) are similar to WORMs but are written en masse by stamping a pattern of pits on the disk. These disks cannot be modified; they are used throughout the music and computer industry to inexpensively distribute large quantities of information.

Magneto-optical disk drives use both magnets and optics to write data. As in magnetic disks, the drive uses a magnetic write-head to change the polarity of regions on the magnetic medium. To achieve higher densities than magnetic disk drives, magneto-optical disk drives use a laser to heat up a small part of the medium; only the heated portion of the medium is actually changed by the magnet. To read the stored information, magneto-optical disks sense how the magnetic polarities change the reflection of the laser. Current magneto-optical disks require additional time to prepare the medium before writing new information; this slows down performance considerably.

Phase-change optical disks use relatively new technology and were designed to improve performance over magneto-optical disks. Phase-change optical disks use lasers to heat small regions on the medium; this heat changes the region into one of two states. The state of a region can then be read by measuring how the region reflects laser beams.

Table 136.2 shows characteristics for a range of storage devices.

**Table 136.2** Characteristics for a Range of Storage Devices

	SRAM (1 chip)	DRAM (1 chip)	Magnetic Floppy Disk	Magnetic Hard Disk	Magnetic Tape	Magneto-Optical Disk
Technology	Solid-state	Solid-state	Magnetic	Magnetic	Magnetic	Magnetic and optical
Sustainable throughput (bytes per second)	10 <sup>7</sup> –10 <sup>8</sup>	10 <sup>7</sup>	10 <sup>5</sup> –10 <sup>6</sup>	10 <sup>6</sup> –10 <sup>7</sup>	10 <sup>6</sup> –10 <sup>7</sup>	10 <sup>5</sup> –10 <sup>6</sup>
Latency for random access (seconds)	10 <sup>–9</sup> –10 <sup>–7</sup>	10 <sup>–8</sup> –10 <sup>–7</sup>	10 <sup>–2</sup> –10 <sup>–1</sup>	10 <sup>–3</sup> –10 <sup>–1</sup>	10 <sup>1</sup> –10 <sup>3</sup>	10 <sup>–2</sup> –10 <sup>–1</sup>
Capacity (bytes)—for removable media, assume 1 medium	10 <sup>3</sup> –10 <sup>6</sup>	10 <sup>5</sup> –10 <sup>7</sup>	10 <sup>6</sup> –10 <sup>7</sup>	10 <sup>8</sup> –10 <sup>10</sup>	10 <sup>8</sup> –10 <sup>10</sup>	10 <sup>8</sup> –10 <sup>10</sup>

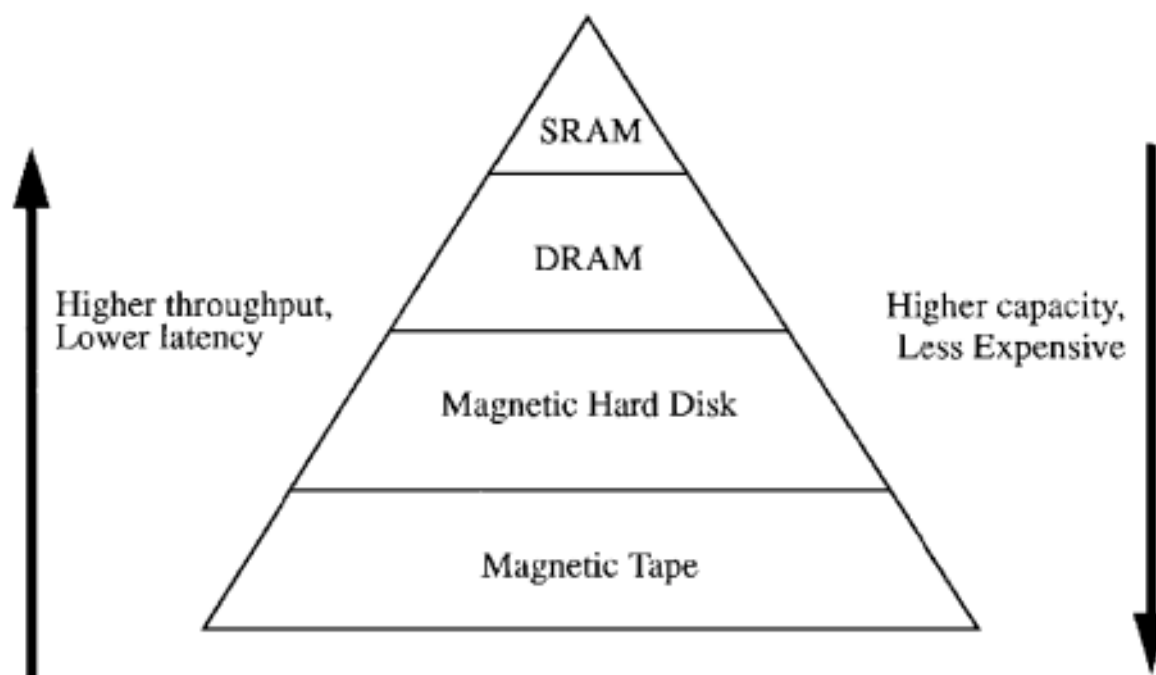

Cost per byte (dollars)—for removable media, assume 100 media per drive	$10^{-4}$ – $10^{-3}$	$10^{-5}$ – $10^{-4}$	$10^{-7}$ – $10^{-6}$	$10^{-7}$ – $10^{-6}$	$10^{-9}$ – $10^{-7}$	$10^{-7}$ – $10^{-6}$
Volatile	Yes	Yes	No	No	No	No
Removable	No	No	Yes	No	Yes	Yes

These approximate numbers for 1994 give a rough indication of aspects of various storage technologies. The rapid pace of innovation in the storage area can lead to changes of up to 50% per year, yet these figures help us to appreciate the diversity of available storage technologies.

## 136.3 Storage Organization

A typical computer system contains many types of storage devices, ranging from very fast and expensive devices such as SRAM, to slow, inexpensive devices such as magnetic tape. They are almost always organized into a **hierarchy** of levels, as in Fig. 136.1[Katz, 1992]. The goal of such an organization is to achieve the speed of the fastest, most expensive device, but to do so at the cost of the slowest, least expensive device. To achieve low average cost per **byte**, the hierarchy allocates more bytes of storage to the cheaper devices. To accomplish high average performance, computer systems store the most frequently used data in the fastest devices. Since average access time is weighted by the frequency of access, the access time of the fastest, most frequently used devices dominates the overall performance.

**Figure 136.1** Storage hierarchy.

This logical organization corresponds well to how devices are connected to the computer system. Devices that are close to the computer's processing unit can be accessed more quickly than devices that are far away. It is thus natural to place fast, frequently accessed devices such as SRAM and

DRAM close to the processing unit. Devices that are far away take longer to access, but the greater distance gives more room for expansion. It is thus natural to place devices that store more information, such as magnetic disk and tape, farther away from the processing unit.

## Defining Terms

**Bit:** One binary digit of information; a bit can store a 0 or 1.

**Byte:** Eight bits of information. This is enough to hold one alphabetic character.

**Latency:** The length of time a system takes to do work, also called *response time*.

**Random access:** Describes a storage device that can access any of its locations in approximately the same amounts of time.

**Read/write head:** The portion of a storage device that changes and/or senses the state of the storage media.

**Sequential access:** Describes a storage device that takes significantly longer to access nonconsecutive information.

**Storage hierarchy:** An organization of multiple storage devices that combines a large amount of a slow, cheap device with a small amount of a fast, expensive device. A storage hierarchy may consist of many types of devices.

**Storage medium (or medium):** The part of the storage device that physically stores data. Some devices allow this medium to be removed from the storage device.

**Throughput:** The rate at which a system can accomplish work, also called *bandwidth*.

The HP E5050A Colloid Dielectric Probe is a Hewlett Packard instrumentation system used to measure permittivity on colloidal liquids. It comprises a colloidal dielectric probe that can be immersed into the liquid material; a general purpose precision LCR-meter for sampling data, eliminating nonlinearities, and calculating LCR component values; and a personal computer and monitor for data processing, data display, and data storage. Most modern precision instrumentation systems consist of similar components: a sensor/transducer unit, a signal processing unit, and a computer. (Photo courtesy of Hewlett-Packard Company.)

Basic Bioinstrumentation Systems • Applications and Examples • Summary

HUMAN BEINGS, CONFINED TO THE WORLD inside of their skin, experience the world outside through the five senses. These senses are extremely sophisticated and exceptionally sensitive to physical events important to our survival and are surprisingly insensitive to almost all other events. To extend the sensitivity of our five senses and to experience physical phenomena outside the reach of our senses, we have invented and developed ever more complicated instruments and devices. For instance, we now probe the world of atoms and molecules with the atomic force microscope and explore outer space with the Hubble Space Telescope. Numerous other instruments measure the domains between these microscopic and macroscopic worlds. In addition to extending our knowledge of the physical world, we want to harness nature's forces for our own purposes. Modern methods of controlling these forces, such as controlling the combustion cycle of an automobile engine, depend on measuring many process variables and determining appropriate responses. Special sensor-transducer units, sensitive to one variable and insensitive to others, measure such process variables and convert them to an electrical voltage or current. Once available as electrical signals, they can be amplified, filtered, combined with other signals, or otherwise processed to yield a control signal for an actuator, to drive an output device, or to be stored on magnetic tape or optical disk.

Fundamental to the scientific understanding and control of the physical world are measurements. A measurement determines the value or magnitude of a physical quantity or variable and expresses the result in terms of a number and a unit. The number reflects the value of the measurement, while

the unit communicates the scale of the measurement. The scientific and engineering communities use the SI system of units, although the English system of units continues to be used in some disciplines.

Almost all measurements require instruments to determine the value of a physical quantity. Such instruments may be as simple as a measuring tape, pendulum, or cup or as complicated as the Hubble Space Telescope. Complicated instruments may use elaborate schemes to transform the physical quantity to be measured into a numerical value. Scientific research instruments require high accuracy, precision, and reliability, while their cost and ease of operation is usually not important. Medical and diagnostic instruments also need to be highly accurate and precise, but their cost is a major factor for health care providers and their ease of operation is important to clinicians. In contrast, instruments in commercial products often require neither high accuracy nor precision.

A sensor interacts with the physical quantity to be measured, either directly or indirectly. Sensors are designed with three main goals in mind: to provide an output signal proportional to the measured physical quantity, to be insensitive to other physical quantities, and to minimize the unavoidable disturbance of the measured physical quantity and its environment. A transducer changes one form of energy into another one. In modern instrumentation systems the output of a transducer is typically an electrical voltage or current. Sensors and transducers often form one physical unit. Signal conditioning, in general, refers to any linear or nonlinear process that changes an analog or digital signal. Analog signal conditioning units may include amplifiers, filters, rectifiers, triggers, comparators, or wave shapers, and digital signal processing consists mostly of process algorithms implemented on microprocessors. Analog or digital signals can be stored on magnetic tape, displayed on a liquid crystal display, recorded on a strip chart recorder, or transmitted wirelessly to another device (telemetry). The topic of bioinstrumentation deals with measuring and monitoring electrophysiological variables on living human beings. The engineer designing biomedical instruments needs to know the physical and engineering principles behind these measurements and also understand how living biological systems work.

Unfortunately, this introduction to measurement and instrumentation is brief and incomplete; more complete information is available to the reader in the reference materials listed at the end of each chapter.

### Rosemary L. Smith

*University of California, Davis*

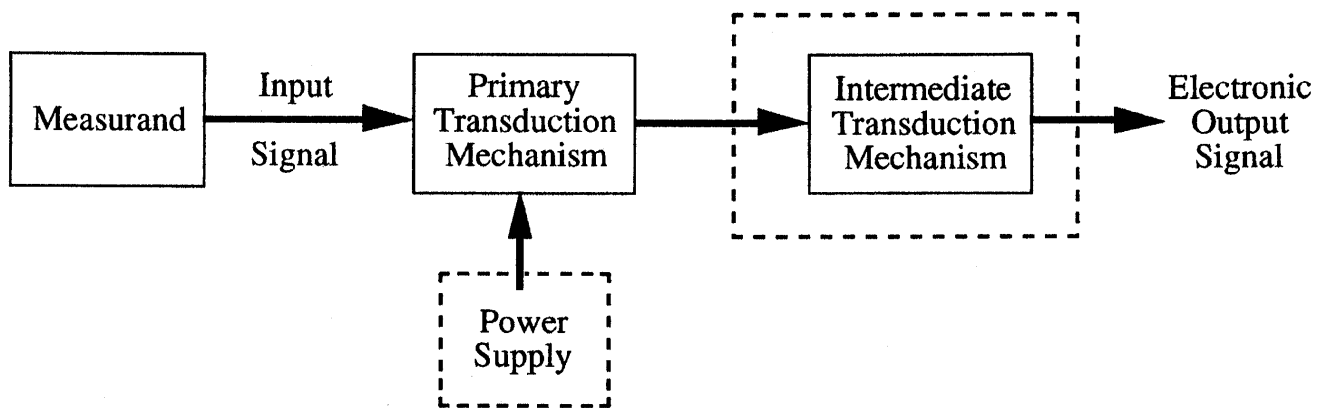

**Sensors** are critical components in all measurement and control systems. Along with the always-present need for sensors in science and medicine, the demand for sensors in automated manufacturing and processing is rapidly growing. In addition, small, inexpensive sensors are finding their way into all sorts of consumer products, from children's toys to dishwashers to automobiles. Because of the vast variety of useful things to be sensed and sensor applications, sensor engineering is a multidisciplinary and interdisciplinary field of endeavor. This chapter introduces some basic definitions, concepts, and features of sensors and illustrates them with several examples. The reader is directed to the references and further information for more details and examples.

The terms *sensor*, **transducer**, *meter*, *detector*, and *gage* are often used synonymously. Generally, a transducer is defined as a device that converts energy from one form to another. However, the most widely used definition for sensor is that which has been applied to electrical transducers by the Instrument Society of America [[ANSI, 1975](#)]: "Transducer—A device which provides a usable output in response to a specified measurand." The measurand can be any physical, chemical, or biological property or condition to be measured. A usable output refers to an optical, electronic, or mechanical signal. Following the advent of the microprocessor, a usable output has come to mean an electronic output signal. For example, a mercury thermometer produces a change in volume of mercury in response to a temperature change via thermal expansion. The output is the change in height of the mercury column and not an electrical signal. A thermometer is still a useful sensor since humans sense the change in mercury height using their eyes as a secondary transducing element. However, in order to produce an electrical signal for use in a control loop, the height of the mercury has to be converted to an electrical signal, for example, using optical or capacitive effects. However, there are more direct temperature-sensing methods, that is, methods in which an electrical output is produced in response to a change in temperature.

An example is given in the next section, on physical sensors.

Most, but not all, sensors are transducers, employing one or more transduction mechanisms to produce a usable output signal. Sometimes sensors are classified as direct or indirect sensors according to how many transduction mechanisms are required to produce the desired output signal. Most commercial gas flow rate sensors are indirect sensors. Flow rate is usually inferred from other measurements, such as the displacement of an object placed in the flow stream (e.g., rotometers), the temperature of the gas measured downstream from a hot element (anemometer), or the difference in pressure measured at two points along the flow path. Figure 137.1 depicts a typical sensor block diagram identifying the measurand and associated input signal, the primary and intermediate transduction mechanisms, and the electronic output signal. Active sensors require an external power source in order to produce a usable output signal. A piezoresistor, for example, is a resistor that changes value when strained. But in order to sense the change in resistance, a current is passed through the resistor and the measured output voltage is related to resistance by Ohm's law:  $V = I \cdot R$ . Table 137.1 is a  $6 \times 6$  matrix of the more commonly employed physical and chemical transduction mechanisms. Detailed descriptions of most of these mechanisms can be found in college-level physics textbooks.

**Figure 137.1** Sensor block diagram. Active sensors require input power to accomplish transduction. Many sensors employ multiple transduction mechanisms in order to produce an electronic output in response to the measurand.

**Table 137.1** Physical and Chemical Transduction Properties

Primary Signal	Secondary Signal					
	Mechanical	Thermal	Electrical	Magnetic	Radiant	Chemical
Mechanical	(Fluid) mechanical and acoustic effects (e.g., diaphragm, gravity balance, echo sounder)	Friction effects (e.g., friction calorimeter), cooling effects (e.g., thermal flow meters)	Piezoelectricity; piezoresistivity; resistive, capacitive, and inductive effects	Magnetomechanical effects (e.g., piezomagnetic effect)	Photoelastic systems (stress-induced birefringence), interferometers, Sagnac effect, Doppler effect	
Thermal	Thermal expansion (bimetal strip, liquid-in-glass, and gas thermometers; resonant frequency), radiometer effect (light mill)		Seebeck effect, thermoresistance, pyroelectricity, thermal (Johnson) noise		Thermo-optical effects (e.g., in liquid crystals), radiant emission	Reaction activation (e.g., thermal dissociation)
Electrical	Electrokinetic and electromechanical effects (e.g., piezoelectricity, electrometer, Ampere's law)	Joule (resistive) heating, Peltier effect	Charge collectors, Langmuir probe	Biot-Savart's law	Electro-optical effects (e.g., Kerr effect, Pockels effect, electroluminescence)	Electrolysis, electromigration
Magnetic	Magnetomechanical effect (e.g., magnetorestriction, magnetometer)	Thermomagnetic effects (e.g., Righi-Leduc effect), galvanomagnetic effects (e.g., Ettingshausen effect)	Thermomagnetic effects (e.g., Ettingshausen-Nernst effect), alvano-magnetic effects (e.g., Hall effect, magnetoresistance)		Magneto-optical effects (e.g., Faraday effect, Cotton-Mouton effect)	
Radiant	Radiation pressure	Bolometer, thermopile	Photoelectric effects (e.g., photovoltaic effect, photoconductive effect)		Photorefractive effects, optical bistability	Photosynthesis, dissociation
Chemical	Hygrometer, electrodeposition cell, photoacoustic effect	Calorimeter, thermal conductivity cell	Potentiometry, conductimetry, amperometry, flame ionization, Volta effect, gas sensitive field effect	Nuclear magnetic resonance	(Emission and absorption) spectroscopy, chemiluminescence

In choosing a particular sensor for a given application, many factors must be considered. These deciding factors or specifications can be divided into three major categories: environmental factors, economic factors, and sensor performance. The most commonly encountered factors are listed in [Table 137.2](#), although not all of these may be pertinent to a particular application. Most of the environmental factors determine the *packaging* of the sensor—which refers to the encapsulation or insulation that provides protection or isolation—and the input/output leads, connections, and cabling. The economic factors determine the type of manufacturing and materials used in the sensor and to some extent the quality of the materials. For example, a very expensive sensor may be cost-effective if it is used repeatedly, operates reliably for very long periods of time, or has exceptionally high performance. On the other hand, a disposable sensor, such as is desired in many medical applications, should be inexpensive. The performance requirements of the sensor are usually the specifications of primary concern. The most important parameters are **sensitivity**, **stability**, and **repeatability**. Normally, a sensor is only useful if all three of these parameters are tightly specified for a given range of measurand and time of operation. For example, a highly sensitive device is not useful if its output signal drifts greatly during the measurement time, and the data obtained are not reliable if the measurement is not repeatable. Other output signal characteristics, such as selectivity and linearity, can often be compensated for by using additional, independent sensors or with signal-conditioning circuits. In fact, most sensors have a response to temperature, since most transduction mechanisms are temperature-dependent.

**Table 137.2** Factors in Sensor Selection

Environmental Factors	Economic Factors	Sensor Performance
Temperature range	Cost	Sensitivity
Humidity effects	Availability	Range
Corrosion	Lifetime	Stability
Size	Performance	Repeatability
Overrange protection		Linearity
Susceptibility to EM interferences		Error
Ruggedness		Response time
Power consumption		Frequency response
Self-test capability		

Sensors are most often classified by the type of measurand—that is, physical, chemical, or biological. This approach provides a much simpler means of classification than by transduction mechanism or output signal (e.g., digital or analog), since many sensors use multiple transduction mechanisms and the output signal can always be processed, conditioned, or converted by a circuit so as to cloud the definition of output. A description of each class and examples are given in the following sections. In section 137.4, **microsensors** are introduced with some examples.

## 137.1 Physical Sensors

Physical measurands include temperature, strain, force, pressure, displacement, position, velocity, acceleration, optical radiation, sound, flow rate, viscosity, and electromagnetic fields. Referring to [Table 137.1](#), note that all but those transduction mechanisms listed in the chemical row are used in the design of physical sensors. Clearly, physical sensors compose a very large proportion of all sensors. It is impossible to illustrate all of them, but three measurands stand out in terms of their widespread application: temperature, displacement (or associated force), and optical radiation sensors.

### Temperature Sensors

Temperature is an important parameter in many control systems, most familiarly in environmental control systems. Several distinct transduction mechanisms have been employed. The mercury thermometer was mentioned earlier as a non-electronic sensor. The most commonly used electronic temperature sensors are thermocouples, thermistors, and resistance thermometers. Thermocouples operate according to the Seebeck effect, which occurs at the junction of two dissimilar metal wires, for example, copper and constantan. A voltage difference is generated at the hot junction due to the difference in the energy distribution of thermally energized electrons in each metal. A temperature gradient produces the requisite, albeit minute, current that enables the measurement of the junction voltage across the cool ends of the two wires. The voltage changes linearly with temperature over a given range, depending on the choice of metals. To minimize measurement error, the cool end of the couple must be kept at a constant temperature and the voltmeter must have a high input impedance. Connecting thermocouples in series creates a

thermopile that produces an output voltage approximately equal to a single thermocouple voltage multiplied by the number of couples.

The resistance thermometer relies on the increase in resistance of a metal wire with increasing temperature. As the electrons in the metal gain thermal energy, they move about more rapidly and undergo more frequent collisions with each other and the atomic nuclei. These scattering events reduce the mobility of the electrons, and since resistance is inversely proportional to mobility, the resistance increases. Resistance thermometers consist of a coil of fine metal wire. Platinum wire gives the largest linear range of operation. To determine the resistance indirectly, a constant current is supplied and the voltage is measured. A direct measurement can be made by placing the resistor in the sensing arm of a Wheatstone bridge and adjusting the opposing resistor to "balance" the bridge, which produces a null output. A measure of the sensitivity of a resistance thermometer is its temperature coefficient of resistance:  $TCR = (\Delta R/R)(1/\Delta T)$ , in units of percent resistance per degree of temperature.

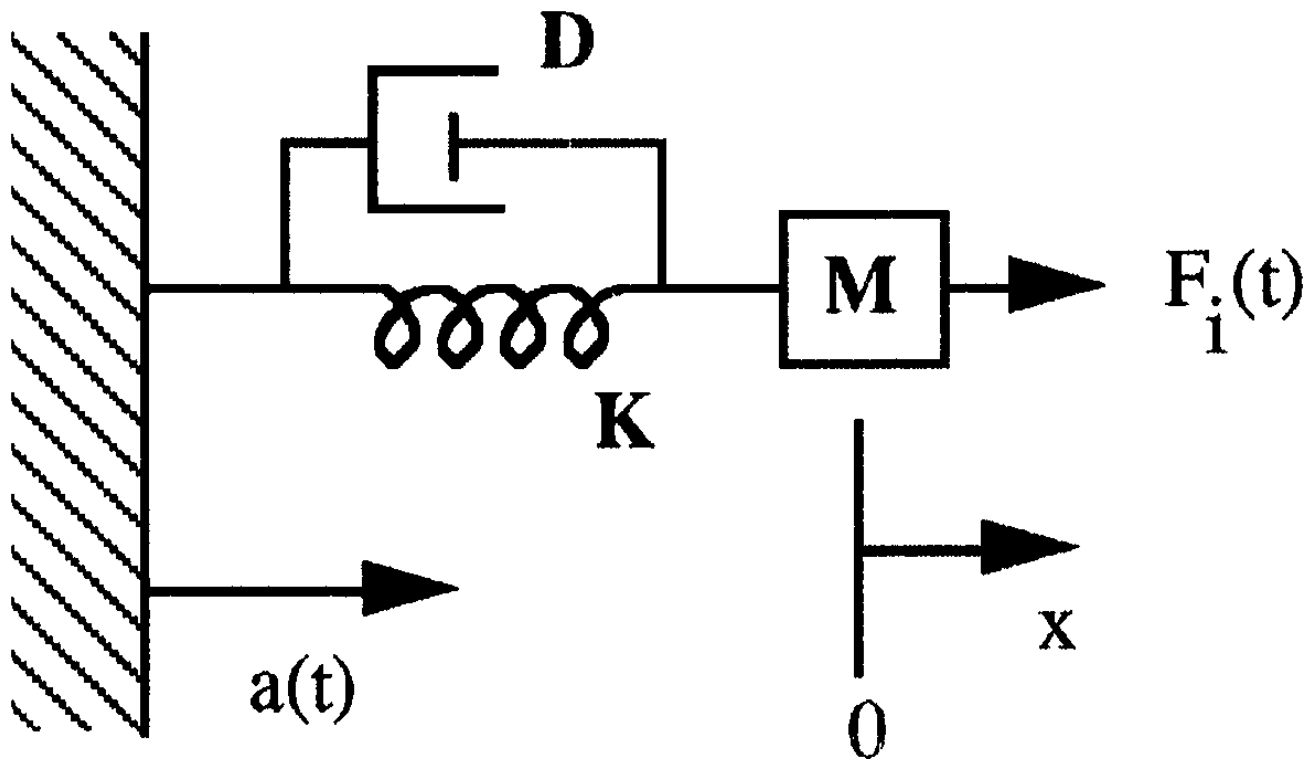

Thermistors are resistive elements made of semiconductive materials and have a negative coefficient of resistance. The mechanism governing the resistance change of a thermistor is the increase in the number of conducting electrons with an increase in temperature due to thermal generation; that is, the electrons that are tightly bound to the nucleus by coulombic attraction gain sufficient thermal energy to break away from the nucleus and become influenced by external fields. Thermistors can be measured in the same manner as resistance thermometers, but thermistors have up to 100 times higher TCR values.

## Displacement and Force Sensors

Many types of forces are sensed by the displacements they create. For example, the force due to acceleration of a mass at the end of a spring will cause the spring to stretch and the mass to move. This phenomenon is illustrated in [Fig. 137.2](#). The displacement,  $x$ , of the mass,  $M$ , from its zero acceleration position, is governed by the force generated by acceleration ( $F = M \cdot a$ ) and the restoring force of the spring ( $F = K \cdot x$ ). For a constant negative acceleration,  $-g$ , the steady state displacement,  $x$ , is equal to  $M \cdot g/K$ . Therefore, measurement of the displacement of a known mass can determine its acceleration.

**Figure 137.2** Schematic diagram of a mechanical oscillator made up of a mass at the end of a spring. The displacement of the mass,  $x(t)$ , in response to an acceleration,  $a(t)$ , is given by  $F_i = -M \cdot a(t) = M\ddot{x} + D\dot{x} + Kx$ , where  $K$  is the spring constant,  $D$  is viscous drag,  $M$  is the mass, and  $F_i$  is the force exerted on the mass. For a constant negative acceleration,  $-g$ , the steady state solution to this differential equation yields  $x = Mg/K$ . The displacement of a known mass, therefore, can be used to determine its acceleration.

**Figure 137.2**

Another example of force sensed by displacement is the displacement of the center of a deformable membrane due to a difference in pressure across it. Both the pressure sensor and the accelerometer examples use multiple transduction mechanisms to produce an electronic output. The primary mechanism converts force to displacement (mechanical to mechanical). An intermediate mechanism is used to convert displacement to an electrical signal (mechanical to electrical). Displacement can be determined by measuring the capacitance between two plates that move with respect to each other. The gap between the two plates is the displacement, and the associated capacitance is given by  $C = \text{area} \times \text{dielectric constant} / \text{gap length}$ . The ratio of plate area to gap length must be greater than 100, since most dielectric constants are on the order of  $1 \cdot 10^{-13}$  farads/cm and capacitance is readily resolvable to only about  $10^{-11}$  farads. This is because measurement leads and contacts create parasitic capacitances of about  $10^{-12}$  farads. If the capacitance is measured at the generated site by an integrated circuit (see the discussion of microsensors), capacitances as small as  $10^{-15}$  farads can be measured. Displacement is also commonly measured by the movement of a ferromagnetic core inside an inductor coil. The displacement produces a change in inductance that can be measured by placing the inductor in an oscillator circuit and measuring the change in frequency of oscillation.

The most commonly used force sensor is the strain gage. It consists of metal wires that are fixed to an immobile structure at one end and to a deformable element at the other. The resistance of the wire changes as it undergoes strain; that is, resistance changes in length, since the resistance of a wire is  $R = \text{resistivity} \times \text{length} / \text{cross-sectional area}$ . The wire's resistivity is a bulk property of the metal, which is a constant for constant temperature. For example, a strain gage can be used to measure acceleration by attaching both ends of the wire to a cantilever beam, with one end of the

wire at the attached beam end and the other at the free end. The cantilever-beam free end moves in response to an applied force, such as the force due to acceleration, which produces strain in the wire and a subsequent change in resistance. The sensitivity of a strain gage is described by the unitless gage factor,  $G = (\Delta R/R)/(\Delta L/L)$ . For metal wires, gage factors typically range from 2 to 3. Semiconductors are known to exhibit *piezoresistivity*, a change in resistance in response to strain that involves a large change in resistivity in addition to the change in linear dimension. Piezoresistors have gage factors as high as 130. Piezoresistive strain gages are frequently used in microsensors.

## Optical Radiation Sensors

The intensity and frequency of optical radiation are parameters of growing interest and utility in consumer products, such as the video camera and home security systems, and in optical communications systems. The conversion of optical energy to electronic signals can be accomplished by several mechanisms; however, the most commonly used is the photogeneration of electrons in semiconductors. The most often used device is the PN junction photodiode. The construction of this device is very similar to that of the diodes used in electronic circuits as rectifiers. The diode is operated in reverse bias, where very little current normally flows. When light is incident on the structure and is absorbed in the semiconductor, energetic electrons are produced. These electrons flow in response to the electric field sustained internally across the junction, producing an externally measurable current. The current magnitude is proportional to the light intensity and also depends on the frequency of the light.

Sensing infrared radiation (IR) by means of photogeneration requires very small band-gap semiconductors, such as HgCdTe. Since electrons in semiconductors are also generated by thermal energy (e.g., thermistors), these IR sensors require cryogenic cooling in order to achieve reasonable sensitivity. Another means of sensing IR is to first convert the optical energy to heat and then measure the temperature change. Accurate and highly sensitive measurements require passive sensors, such as a thermopile or a pyroelectric sensor, since active devices will generate heat themselves.

## 137.2 Chemical Sensors

---

Chemical measurands include ion concentration, chemical composition, rate of reactions, reduction-oxidation potentials, and gas concentration. The last row of [Table 137.1](#) lists some of the transduction mechanisms that have been, or could be, employed in chemical sensing. Two examples of chemical sensors are described here: the ion-selective electrode (ISE) and the gas chromatograph. These sensors were chosen because of their general use and availability and because they illustrate the use of a primary (ISE) versus a primary plus intermediate (gas chromatograph) transduction mechanism.

### Ion-Selective Electrode

As the name implies, ISEs are used to measure the concentration of a specific ion concentration in

a solution of many ions. To accomplish this, a membrane that selectively generates a potential dependent on the concentration of the ion of interest is used. The generated potential is usually an equilibrium potential, called the *Nernst potential*, and develops across the interface of the membrane with the solution. This potential is generated by the initial net flow of ions (charge) across the membrane in response to a concentration gradient. From that moment on, the diffusional force is balanced by the generated electric force, and equilibrium is established. This potential is very similar to the built-in potential of a PN junction diode. The ion-selective membrane acts in such a way as to ensure that the generated potential is dependent mostly on the ion of interest and negligibly on any other ions in solution. This condition is brought about by enhancing the exchange rate of the ion of interest across the membrane, so it is the fastest moving and therefore the species that generates and maintains the potential.

The most familiar ISE is the pH electrode. In this device the membrane is a sodium glass that possesses a high exchange rate for  $H^+$ . The generated Nernst potential,  $E$ , is given by the expression:  $E = E_0 + (RT/F) \ln[H^+]$ , where  $E_0$  is a constant for constant temperature,  $R$  is the gas constant, and  $F$  is the Faraday constant. The pH is defined as the negative of the  $\log[H^+]$ ; therefore  $pH = (E_0 - E)(2.3)F/RT$ . One pH unit change corresponds to a tenfold change in the molar concentration of  $H^+$  and a 59 mV change in the Nernst potential at room temperature. Other ISEs have the same type of response, but specific to a different ion, depending on the choice of membrane. Some ISEs employ ionophores trapped inside a polymeric membrane. An ionophore is a molecule that selectively and reversibly binds with an ion and thereby creates a high exchange rate for that particular ion.

The typical ISE consists of a glass or plastic tube with the ion-selective membrane closing the end of the tube that is immersed into the test solution (see [Fig. 137.3](#)). The Nernst potential is measured by making electrical contact to either side of the membrane. This contact is made by placing a fixed-concentration, conductive filling solution inside the tube and placing a wire into the solution. The other side of the membrane is contacted by a reference electrode placed inside the same solution under test. The reference electrode is constructed in the same manner as the ISE, but it has a porous membrane or leaky plug that creates a liquid junction between its inner filling solution and the test solution. That junction is designed to have a potential that is invariant with changes in concentration of any ion in the test solution. The reference electrode, the solution under test, and the ISE form an electrochemical cell. The reference electrode potential acts like the ground reference in electric circuits, and the ISE potential is measured between the two wires emerging from the respective two electrodes. The details of the mechanisms of transduction in ISEs are beyond the scope of this article. The reader is referred to the book by Bard and Faulkner [1980] or the book by Koryta [1975].

**Figure 137.3** An electrochemical cell comprising an ion-selective electrode (ISE) and reference electrode in an ionic solution. The ion exchange membrane of the ISE generates a potential,  $E$ , that is proportional to the log of the concentration of the ion of interest.

## Gas Chromatograph

Molecules in gases have thermal conductivities that are dependent on their masses; therefore, a pure gas can be identified by its thermal conductivity. One way to determine the composition of a gas is to first separate it into its components and then measure the thermal conductivity of each. A gas chromatograph does exactly that. The gas flows through a long narrow column, which is packed with an adsorbent solid (for gas-solid chromatography), wherein the gases are separated according to the retentive properties of the packing material for each gas. As the individual gases exit the end of the tube one at a time, they flow over a heated wire. The amount of heat transferred to the gas depends on its thermal conductivity. The gas temperature is measured a short distance downstream and compared to a known gas flowing in a separate sensing tube. The temperature is related to the amount of heat transferred and can be used to derive the thermal conductivity according to thermodynamic theory and empirical data. This sensor required two transductions: a chemical-to-thermal energy transduction, followed by a thermal-to-electrical transduction.

## 137.3 Biosensors

---

**Biosensors** respond to biological measurands, which are biologically produced substances, such as antibodies, glucose, hormones, and enzymes. Biosensors are not the same as biomedical sensors, which are any sensors used in biomedical applications, such as blood pressure sensors or electrocardiogram electrodes. Many biosensors are biomedical sensors; however, the former are also used in industrial applications, for example, the monitoring and control of fermentation reactions. [Table 137.1](#) does not include biological signals as primary signals because they can be classified as either chemical or physical in nature. Biosensors are of special interest because of the very high selectivity of biological reactions and binding. However, detection of that reaction or binding is often elusive. A very familiar commercial biosensor is the in-home pregnancy test sensor, which detects the presence of human growth factor in urine. That device is a nonelectronic sensor since the output is a color change that your eye senses. In fact, most biosensors require multiple transduction mechanisms to arrive at an electrical output signal. Two examples are given below: an immunosensor and an enzyme sensor.

### Immunosensor

Most commercial techniques for detecting antibody-antigen binding utilize optical or x-radiation detection. An optically fluorescent molecule or radioisotope is attached or tagged to the species of interest in solution. The complementary binding species is chemically attached to a glass substrate or glass beads, which are packed into a column. The solution containing the tagged species of interest, say the antibody, is passed over the antigen-coated surface, where the two selectively bind. The nonbound fluorescent molecules or radioisotopes are washed away, and the antibody concentration is determined by fluorescence spectroscopy or with a scintillation counter, respectively. These sensing techniques are quite costly and bulky, and therefore other biosensing mechanisms are rapidly being developed and commercialized. One technique uses the change in the permittivity or index of refraction of the bound antibody-antigen complex in comparison to an unbound surface layer of antigen. The technique utilizes surface plasmon resonance as the mechanism for detecting the change in permittivity. Surface plasmons are charge density oscillations that propagate along the interface between a dielectric and a thin metal film. They can be generated by the transfer of energy from an incident, transverse magnetic (TM) polarized light beam. Plasmon resonance, or maximum energy transfer, occurs when the light beam is incident at a specific angle that depends on, and is extremely sensitive to, the dielectric permittivity at the interface on either side of a given metal film. At resonance, the optical beam intensity reflected from the metal film drops to a minimum; therefore, the resonance angle can be determined by recording reflected intensity (e.g., with a photodiode), versus incident light beam angle. The binding of antibody to an antigen layer attached to the metal film will produce a change in the resonance angle.

### Enzyme Sensor

Enzymes selectively react with a chemical substance to modify it, usually as the first step in a chain of reactions to release energy (metabolism). A well-known example is the selective reaction of glucose oxidase (enzyme) with glucose to produce gluconic acid and peroxide, according to the

following formula:

An enzymatic reaction can be sensed by measuring the rise in temperature associated with the heat of reaction or by the detection and measurement of by-products. In the glucose example, the reaction can be sensed by measuring the local dissolved peroxide concentration. This is done via an electrochemical analysis technique called *amperometry* [Bard and Faulkner, 1980]. In this method a potential is placed across two inert metal wire electrodes immersed in the test solution, and the current that is generated by the reduction/oxidation reaction of the species of interest is measured. The current is proportional to the concentration of the reducing/oxidizing species. A selective response is obtained if no other available species has a lower redox potential. Because the selectivity of peroxide over oxygen is poor, some glucose-sensing schemes employ a second enzyme called *catalase*, which converts peroxide to oxygen and hydroxyl ions. The latter produces a change in the local pH. As described earlier, an ISE can then be used to convert the pH to a measurable voltage. In this latter example, glucose sensing involves two chemical-to-chemical transductions followed by a chemical-to-electrical transduction mechanism.

## 137.4 Microsensors

---

Microsensors are sensors that are manufactured using integrated circuit fabrication technologies and/or micromachining. Integrated circuits are fabricated using a series of process steps that are done in batch fashion, meaning that thousands of circuits are processed together at the same time in the same way. The patterns that define the components of the circuit are photolithographically transferred from a template to a semiconducting substrate using a photosensitive organic coating. The coating pattern is then transferred into the substrate or into a solid-state thin film coating through an etching or deposition process. Each template, called a *mask*, can contain thousands of identical sets of patterns, with each set representing a circuit. This "batch" method of manufacturing is what makes integrated circuits so reproducible and inexpensive. In addition, photoreduction enables one to make extremely small features, on the order of microns, which is why this collection of process steps is referred to as *microfabrication*. The resulting integrated circuit is contained in only the top few microns of the semiconductor substrate and the submicron thin films on its surface. Hence, integrated circuit technology is said to consist of a set of planar microfabrication processes. **Micromachining** refers to the set of processes that produces three-dimensional microstructures using the same photolithographic techniques and batch processing as for integrated circuits. Here, the third dimension refers to the height above the substrate of the deposited layer or the depth into the substrate of an etched structure. Micromachining produces third dimensions in the range of 1–500 microns (typically). The use of microfabrication to manufacture sensors produces the same benefits as it does for circuits: low cost per sensor, small size, and highly reproducible behavior. It also enables the integration of signal conditioning, compensation circuits, and actuators—that is, entire sensing and control systems—which can dramatically improve sensor performance for very little increase in cost. For these reasons there is a great deal of research and development activity in microsensors. The first

microsensors were integrated circuit components, such as semiconductor resistors and PN junction diodes. The piezoresistivity of semiconductors and optical sensing by the photodiode were discussed earlier. Diodes are also used as temperature-sensing devices. When forward biased with a constant diode current, the resulting diode voltage increases approximately linearly with increasing temperature. The first micromachined microsensor to be commercially produced was the silicon pressure sensor. It was invented in the mid-to-late 1950s at Bell Labs and commercialized in the 1960s by General Electric, Endevco, and Fairchild Control Division (now Foxboro/ICT, Inc.). This device contains a thin silicon diaphragm ( $\approx 10$  microns) that deforms in response to a pressure difference across it (Fig. 137.4). The deformation produces two effects: a position-dependent displacement, which is maximum at the diaphragm center, and position-dependent strain, which is maximum near the diaphragm edge. Both of these effects have been used in microsensors to produce an electrical output that is proportional to differential pressure. The membrane displacement is sensed capacitively, as previously described, in one type of pressure sensor. In another, the strain is sensed by placing a piezoresistor, fabricated in the same silicon substrate, along one edge of the diaphragm. The two leads of the piezoresistor are connected to a Wheatstone bridge. The latter type of sensor is called a *piezoresistive pressure sensor* and is the more common type of commercial pressure microsensor. Pressure microsensors constituted about 5% of the total U.S. consumption of pressure sensors in 1991. Most of them are used in the medical and automotive industry because of their low cost and small, rugged construction. Many other types of microsensors are available commercially, including accelerometers, flow rate sensors, gas sensors, and biosensors.

**Figure 137.4** Schematic cross section of a silicon piezoresistive pressure sensor. A differential pressure deforms the silicon diaphragm, producing strain in the integrated piezoresistor. The change in resistance is measured via a Wheatstone bridge.

# APPARATUS FOR TESTING ACIDITY

Arnold O. Beckman and Henry E. Fracker

Patented October 27, 1936

#2,058,761

An excerpt:

In accordance with the present invention, we substitute for the delicate and fragile galvanometer, previously considered necessary, a simple and mechanically rugged milliammeter in combination with a specially designed vacuum tube amplifier employing standard radio tubes and energized from dry cells. The entire apparatus can be housed in a compact portable case, it is extremely accurate and is substantially foolproof in operation so that it can be manipulated by unskilled operators without danger of it being ruined or being thrown out of adjustment.

This was the modern pH meter. Using vacuum-tube DC amplifiers (a relatively new field) they were able to measure potentials in a circuit of very high resistance, making determination of hydrogen ion concentration (or pH) much easier and reliable. Beckman Instruments, Inc., started because of this invention, today still produces pH meters, probes and other modern instrumentation products. (© 1995, DewRay Products, Inc. Used with permission.)

## Defining Terms

**Biosensor:** A sensor that responds to biologically produced substances, such as enzymes, antibodies, and hormones.

**Micromachining:** The set of processes that produce three-dimensional microstructures using sequential photolithographic pattern transfer and etching or deposition in a batch-processing method.

**Microsensor:** A sensor that is fabricated using integrated circuit and micromachining technologies.

**Repeatability:** The ability of a sensor to reproduce output readings for the same value of measurand, when applied consecutively and under the same conditions.

**Sensitivity:** The ratio of the change in sensor output to a change in the value of the measurand.

**Sensor:** A device that produces a usable output in response to a specified measurand.

**Stability:** The ability of a sensor to retain its characteristics over a relatively long period of time.

**Transducer:** A device that converts one form of energy to another.

Engineers are increasingly being asked to monitor or evaluate the efficiency of a process or the performance of a device. Results are often derived from the combination of values determined from a number of individual measurements. In the planning of an experiment, an attempt is usually made to minimize the error associated with the experimental measurements. Unfortunately, every measurement is subject to error, and the degree to which this error is minimized is a compromise between the (overall) accuracy desired and the expense required to reduce the error in the component measurements to an acceptable value.

Good engineering practice dictates that an indication of the error or uncertainty should be reported along with the derived results. In the worst case, the error in a derived result could be treated as the sum of the errors of the component measurements. Implicit in this assumption is that the worst-case errors will occur simultaneously and in the most detrimental fashion. This condition is unlikely, and therefore such an analysis usually results in an overprediction of the error in a derived result.

A more realistic estimate of error was presented by Kline and McClintock [1953] based on single-sample uncertainty analysis. This analysis will be described later in this chapter, but first let us undertake to describe measurement errors. The following discussion is meant to provide an insight into measurement uncertainty rather than a rigorous treatment of the theoretical basis. Readers are encouraged to consult the many references [e.g., ANSI/ASME, 1985] dealing with these issues if they consider it necessary.

### 138.1 Measurement Errors, Accuracy, and Precision

---

**Measurement error** may be defined as the difference between the true value and the measured value of the quantity:

$$e \equiv x - x_{\text{true}}$$

where

$e$  is the error in  $x$

$x$  is a measured or observed value of some physical quantity

$x_{\text{true}}$  is the actual value

The errors that occur in an experiment are usually categorized as mistakes or recording errors, systematic or fixed errors, and accidental or random errors.

- Mistakes or recording errors are usually the result of measurement errors (e.g., the observer reads 10.1 instead of 11.1 units on the scale of a meter). It is assumed that careful experimental practices will minimize the occurrence of this type of error.
- **Systematic errors** or **bias errors** are errors that persist and cannot be considered due entirely to chance. Systematic errors may result from incorrect instrument calibrations and relate to instrument accuracy (the ability of the instrument to indicate the true value).
- **Random errors** cause readings to take random values on either side of some mean value. They may be due to the observer or the instrument and are revealed by repeated observations. They are disordered in incidence and variable in magnitude.

In measurement systems, **accuracy** generally refers to the closeness of agreement of a measured value and the true value. All measurements are subject to both systematic (bias) and random errors to differing degrees, and consequently the true value can only be estimated. To illustrate the above concepts, consider the case shown in Fig. 138.1, where measurements of a fixed value are taken over a period of time.

**Figure 138.1** Repeated measurements of a fixed value.

As illustrated, the measured values are scattered around some mean value,  $x_m$ . In effect, if many measurements of the quantity were taken, we could calculate a mean value of the fixed quantity. If we further grouped the data into ranges of values, it would be possible to plot the frequency of occurrence in each range as a histogram (Fig. 138.2) If a large number,  $n$ , of measurements were recorded (i.e., as  $n$  goes to infinity), a plot of the **frequency distribution** of the measurements,

$f(x)$ , could be constructed (Fig. 138.3). Figure 138.3 is often referred to as a plot of the probability density function, and the area under the curve represents the probability that a particular value of  $x$  (the measured quantity) will occur. The total area under the curve has a value of 1, and the probability that a particular measurement will fall within a specified range (e.g., between  $x_1$  and  $x_2$ ) is determined by the area under the curve bounded by these values. Figure 138.3 indicates that there is a likelihood of individual measurements being close to  $x_m$ , and that the likelihood of obtaining a particular value decreases for values farther away from the mean value,  $x_m$ .

**Figure 138.2** Histogram of measured values.

**Figure 138.3** Frequency distribution of repeated measurements.

The frequency distribution shown in Fig. 138.3 corresponds to a **Gaussian or normal distribution curve** [Bolz and Tuve,1987], the form generally assumed to represent random measurement uncertainty. There is no guarantee that this symmetrical distribution, indicating an

equal probability of measurements falling above or below the mean value,  $x_m$ , will occur, but experience has shown that the normal distribution is generally suitable for most measurement applications. Other distributions could be determined based on taking large numbers of measurements and plotting the results [Bevington, 1969], but generally this information is unavailable.

In analyzing these results we may apply standard statistical tools to express our confidence in the determined value based on the probability of obtaining a particular result. If experimental errors follow a normal distribution, then a widely reported value is the **standard deviation**,  $\sigma$  [Bevington, 1969]. There is a 68% (68.27%) probability that an observed value  $x$  will fall within  $\pm\sigma$  of  $x_m$  (Fig. 138.3). Other values are often reported for  $\pm 2\sigma$  (probability 95.45%) or  $\pm 3\sigma$  (probability 99.73%). Values of probabilities are tabulated [Bolz and Tuve, 1987] for ranges from  $x_{k1}$  to  $x_{k2}$ , or  $x_m \pm k\sigma$ , as illustrated in Fig. 138.3.

In reporting measurements, an indication of the probable error in the result is often stated based on an absolute error prediction [e.g., a temperature of  $48.3 \pm 0.1^\circ \text{C}$  (based on a 95% probability)] or on a relative error basis [e.g., voltage of  $9.0 \text{ V} \pm 2\%$  (based on a 95% probability)]. The choice of probability value corresponding to the error limits is arbitrary, but a value of 95%, corresponding to  $\pm 2\sigma$ , appears to be widely used.

When considering the results in Fig. 138.3, lacking other information, our best estimate of the true value of the measured quantity is the mean (or average) of the measured values. Based on the previous discussions we may characterize measurements and instrumentation as being of high or low **precision**. This is illustrated in Fig. 138.4, where two probability distributions are plotted. As may be seen, the probability of obtaining values near the mean is greater for the high-precision measurement (i.e., the measurements are highly repeatable or precise). The low-precision measurements have a wider distribution and are characterized by a greater standard deviation,  $\pm\sigma_{lp}$ , compared with the high-precision measurements,  $\pm\sigma_{hp}$ .

**Figure 138.4** Frequency distributions for instruments of varying precision.

It is worth noting that while the low-precision measurement is not highly repeatable, if the mean value of a large number of measurements is calculated, then the value  $x_m$  should be the same as that determined from the precise measurement. Therefore, in the absence of bias or systematic error, the mean of a large sample of low-precision measurements theoretically indicates the true value.

The previous discussion, illustrating the concept of random measurement error, has not addressed the effects of systematic or fixed (bias) errors. In reality, even though a high probability exists that an individual measurement will be close to the mean value, there is no guarantee that the value of the mean of the large sample of measurements will be the true value (Fig. 138.5). In effect, a particular measurement and measurement instrument may be highly repeatable (or precise) but in error (i.e., not accurate). Systematic or bias errors may arise from either the observer or the instrument. They may be constant or vary in some regular way. An example of a source of systematic error is a pressure gauge needle that is bent (i.e., not zeroed).

**Figure 138.5** Measurements with bias errors in addition to random errors.

Bias errors may be significant but, by their nature, should be identifiable and their effects accounted for through careful calibration and comparison with other instruments. Recently, methods for combining bias and random error estimates into an overall error estimate have been presented [ANSI/ASME, 1985].

## 138.2 Estimating Measurement Uncertainty

In the previous discussion we considered multi-sample experiments of a single parameter.

**Multi-sample experiments** are those in which, for a given set of the independent experimental variables, the readings are taken many times. If we could repeat our tests many times, with many observers and a variety of instruments, we could apply statistics to determine the reliability of the results as in the previously discussed methods.

In engineering we are often forced to conduct "single-sample" experiments, and therefore we cannot estimate uncertainty by observing repeated tries. Single-sample experiments are those in which, for a given set of experimental conditions, the readings are taken only once. These are typical in engineering, where financial or time constraints limit the number of repetitions of a

particular test. In these cases the **uncertainty** in the measurements can usually only be estimated.

In estimating the uncertainty in a measurement, the experimenter must rely on judgment based on experience. Only an estimate of what would happen (if a large number of observations were made) can be made. In this case we refer to an "uncertainty distribution" rather than a "frequency distribution." The uncertainty distribution is the distribution of error which the experimenter believes would be found in a given variable if the variable were sampled a great many times. The experimenter also expresses the degree of confidence in the stated uncertainty based on "odds," in a manner analogous to the standard deviation. Therefore, odds of approximately 2 to 1 (e.g., the odds are 2 to 1 that the error on a particular reading will be within a specified interval) roughly corresponds to an interval of  $\pm\sigma$  (i.e., a probability of 68%). Therefore, based on the experience of the experimenter, an estimate of the uncertainty associated with a particular measurement can be made [i.e.,  $m \pm \omega$  ( $b$  to 1)], where  $m$  is the mean value,  $\omega$  is the uncertainty interval, and  $b$  is the odds]. The experimenter is wagering  $b$  to 1 that the error is less than  $\omega$  [e.g., voltage =  $12 \pm 1$  V (10 to 1 odds)].

### 138.3 Propagation of Measurement Uncertainty

---

As previously stated, results are often derived from the combination of values determined from a number of individual measurements. The propagation of uncertainty is defined as the way in which uncertainties in the variables affect the uncertainty in the results. Kline and McClintock [1953] have presented a technique for determining the propagation of errors in a derived result for single-sample experiments. In this technique a best estimate of the uncertainty in each variable is made by the researcher assuming odds (e.g., 20 to 1) that a measured value will fall within the uncertainty interval. Therefore, assuming that a desired result is derived from  $n$  independent variables or simultaneous measurements [e.g.,  $R = R(X_1, X_2, X_3, \dots, X_n)$ ] and letting  $\omega_1, \omega_2, \dots, \omega_n$  be the uncertainties in the independent variables, we can derive an expression for the uncertainty in the result,  $\omega_R$ .

If the same uncertainty estimate is used for all the component variables in the analysis (i.e., all the uncertainties must be given based on the same odds), the uncertainty in the result will be given by

$$\omega_R = \pm \left[ \left( \frac{\partial R}{\partial X_1} \omega_1 \right)^2 + \left( \frac{\partial R}{\partial X_2} \omega_2 \right)^2 + \left( \frac{\partial R}{\partial X_3} \omega_3 \right)^2 + \dots + \left( \frac{\partial R}{\partial X_n} \omega_n \right)^2 \right]^{1/2}$$

In certain instances (such as a product form of the equation, i.e.,  $R = X_1^a \cdot X_2^b \cdot X_3^c \dots X_n^m$ ), this equation can be reduced to

$$\frac{\omega_R}{R} = \pm \left[ \left( a \cdot \frac{\omega_1}{X_1} \right)^2 + \left( b \cdot \frac{\omega_2}{X_2} \right)^2 + \left( c \cdot \frac{\omega_3}{X_3} \right)^2 + \dots + \left( m \cdot \frac{\omega_n}{X_n} \right)^2 \right]^{1/2}$$

where  $\omega_R/R$  is the relative uncertainty in the result,  $R$  [Moffat, 1988].

## 138.4 Uncertainty Analysis in Experimental Design

The possible experimental errors should be examined before conducting an experiment to ensure the best results. The experimenter should estimate the uncertainties in each measurement. Uncertainty propagation in the result depends on the squares of the uncertainties in the independent variables; thus the squares of the large uncertainty values dominate the result. Thus, in designing an experiment, very little is gained by reducing the small errors (uncertainties). A series of measurements with relatively large uncertainties could produce a result with an uncertainty not much larger than that of the most uncertain measurement. Thus to improve the overall experimental result, the large uncertainties must be reduced [Moffat, 1985, 1988].

**Example.** Consider an experiment to measure the thermal efficiency,  $\eta$ , of a solar collector for heating water. During testing, the solar collector is connected in series with an electric reference heater, and cooling water is circulated through both. Values of  $\eta$  are obtained by individual measurements of: the temperature rise across the solar collector,  $\Delta T_c$ , and reference heater,  $\Delta T_h$ ; the power input to the reference heater,  $P_h$ ; and the total solar energy incident on the collector surface,  $G_i$ . The thermal efficiency,  $\eta$ , is determined according to

$$\eta = \frac{P_h}{G_i} \cdot \left( \frac{\Delta T_c}{\Delta T_h} \right)$$

To estimate the relative uncertainty in the measured value of  $\eta$ , the uncertainties in the component measurements must be estimated. The electrical power input to the reference heater was measured with a power transducer with an estimated uncertainty of  $\pm 2\%$  of reading. The measurement of solar radiation introduced the largest uncertainty and was estimated at  $\pm 10\%$  of reading. Errors in the measurement of temperature rise across the heater and collector were estimated at  $\pm 0.1^\circ \text{C}$ .

Therefore, the uncertainty values are

$$\omega P_h = \pm 0.02 \times P_h$$

$$\omega G_i = \pm 0.10 \times G_i$$

$$\omega \Delta T = \pm 0.1^\circ \text{C}$$

These values are based on best estimates and represent the odds of 20 to 1 that measured values will fall within these limits.

Applying the analysis described above, the relative uncertainty in determining  $\eta$  is

$$\frac{\omega_\eta}{\eta} = \pm \left[ \left( \frac{\omega P_H}{P_h} \right)^2 + \left( \frac{\omega G_i}{G_i} \right)^2 + \left( \frac{\omega \Delta T_h}{\Delta T_h} \right)^2 + \left( \frac{\omega \Delta T_c}{\Delta T_c} \right)^2 \right]^{1/2}$$

Substituting typical test conditions, e.g.,  $\Delta T_c \approx 3.5^\circ \text{C}$  and  $\Delta T_h \approx 6^\circ \text{C}$ , then

$$\frac{\omega_{\eta}}{\eta} = \pm[(0.02)^2 + (0.10)^2 + (0.1/6)^2 + (0.1/3.5)^2]^{0.5} = \pm 0.10$$

Thus, the relative uncertainty in the measured value of solar collector efficiency would be  $\pm 0.10$ , or  $\pm 10\%$  (based on 20-to-1 odds).

It is apparent from this analysis that the uncertainty in the solar radiation measurement,  $\omega G_i$ , dominates the uncertainty in the result; that is, decreasing the uncertainty in the other measurements has little effect on the result. However, if the value of  $\omega G_i$  is reduced to  $\pm 4\%$ , then  $\omega_{\eta}/\eta$  would be reduced to  $\pm 5\%$ . Further analysis shows that additional reductions in  $\omega G_i$  are less significant, as the uncertainties in the other measurements dominate. It is also worth noting that as  $\Delta T_c$  becomes smaller (corresponding to a reduction in  $\eta$ ), the overall uncertainty in the result increases. This effect could be minimized by reducing the uncertainty in the  $\Delta T_c$  measurement.

## Defining Terms

**Accuracy:** The closeness of agreement of a measured value and the true value.

**Bias error:** The tendency of an estimate to deviate in one direction from a true value.

**Frequency distribution:** A description of the frequency of occurrence of the values of a variable.

**Gaussian or normal distribution curve:** The theoretical distribution function for the conceptual infinite population of measured values. This distribution is characterized by a limiting mean and standard deviation. The interval of the limiting mean plus or minus two times the standard deviation will include approximately 95% of the total scatter of measurements.

**Measurement error:** The difference between true and observed values.

**Multi-sample experiments:** Experiments in which uncertainties are evaluated by many repetitions and many diverse instruments. Such experiments can be analyzed by classical statistical means.

**Precision:** The repeatability of measurements of the same quantity under the same conditions.

**Random errors:** Errors that cause readings to take random values on either side of some mean value. They may be due to the observer or the instrument and are revealed by repeated observations.

**Standard deviation:** A measure of dispersion of a population. It is calculated as the square root of the average of the squares of the deviations from the mean (root mean square) deviation.

**Systematic errors:** Errors which persist and cannot be considered as due to chance. Systematic errors may be due to instrument manufacture or incorrect calibration and relate to instrument accuracy (the ability of the instrument to indicate the true value).

**Uncertainty:** The estimated error limit of a measurement or result for given odds.

### 139.1 Linear Operations

Amplitude Scaling • Impedance Transformation • Linear Filtering

### 139.2 Nonlinear Operations

**Stephen A. Dyer**

*Kansas State University*

Kelvin's first rule of instrumentation states, in essence, that the measuring instrument must not alter the event being measured. For the present purposes, we can consider the instrument to consist of an input transducer followed by a signal-conditioning section, which in turn drives the data-processing and display section (the remainder of the instrument). We are using the term *instrument* in the broad sense, with the understanding that it may actually be a measurement subsystem within virtually any type of system.

Certain requirements are imposed upon the transducer if it is to reproduce an event faithfully: It must exhibit amplitude linearity, phase linearity, and adequate frequency response. But it is the task of the signal conditioner to accept the output signal from the transducer and from it produce a signal in the form appropriate for introduction to the remainder of the instrument.

Analog signal conditioning can involve strictly *linear* operations, strictly *nonlinear* operations, or some combination of the two. In addition, the signal conditioner may be called upon to provide auxiliary services, such as introducing electrical isolation, providing a reference of some sort for the transducer, or producing an excitation signal for the transducer.

Important examples of linear operations include *amplitude scaling*, *impedance transformation*, *linear filtering*, and *modulation*.

A few examples of nonlinear operations include obtaining the *root-mean-square (rms) value*, *square root*, *absolute value*, or *logarithm* of the input signal.

There is a wide variety of building blocks available in either modular or integrated-circuit (IC) form for accomplishing analog signal conditioning. Such building blocks include operational amplifiers, instrumentation amplifiers, isolation amplifiers, and a plethora of nonlinear processing circuits such as comparators, analog multiplier/dividers, log/antilog amplifiers, rms-to-DC converters, and trigonometric function generators.

Also available are complete signal-conditioning subsystems consisting of various plug-in input and output modules that can be interconnected via universal backplanes that can be either chassis- or rack-mounted.

## 139.1 Linear Operations

---

Three categories of linear operations important to signal conditioning are amplitude scaling, impedance transformation, and linear filtering.

### Amplitude Scaling

The amplitude of the signal output from a transducer must typically be scaled—either amplified or attenuated—before the signal can be processed.

#### Amplification

Amplification is generally accomplished by an *operational amplifier*, an *instrumentation amplifier*, or an *isolation amplifier*.

**Operational Amplifiers.** A conventional operational amplifier (op amp) has a differential input and a single-ended output. An *ideal* op amp, used often as a first approximation to model a real op amp, has infinite gain, infinite bandwidth, infinite differential input impedance, infinite slew rate, and infinite **common-mode rejection ratio (CMRR)**. It also has zero output impedance, zero noise, zero bias currents, and zero input offset voltage. Real op amps, of course, fall short of the ideal in all regards.

Important parameters to consider when selecting an op amp include:

1. DC voltage gain  $K_0$ .
2. Small-signal **gain-bandwidth product (GBWP)**  $f_T$ , which for most op amps is  $f_T \approx K_0 f_1$ , where  $f_1$  is the lower break frequency in the op amp's transfer function. The GBWP characterizes the closed-loop, high-frequency response of an op-amp circuit.
3. **Slew rate**, which governs the large-signal behavior of an op amp. Slew rates range from less than 1 V/ $\mu$ s to several thousand V/ $\mu$ s.

Other parameters, such as input and output impedances, DC offset voltage, DC bias current, drift voltages and currents, noise characteristics, and so forth, must be considered when selecting an op amp for a particular application.

There are several categories of operational amplifiers. In addition to "garden-variety" op amps there are many op amps whose characteristics are optimized for one or more classes of use. Some categories of op amps include:

1. *Low-noise* op amps, which are useful in the portions of signal conditioners required to amplify very-low-level signals.
2. *Chopper-stabilized* op amps, which are useful in applications requiring extreme DC stability.
3. *Fast* op amps, which are useful when large slew rates and large GBWPs are required.
4. *Power* op amps, which are useful when currents of greater than a few mA must be provided to the op amp's load.

5. *Electrometer* op amps, which are used when very high ( $>10^{13} \Omega$ ) input resistances and very low ( $<1$  pA) input bias currents are required.

An introduction to op amps and basic circuit configurations occurs in essentially any modern text on circuit theory or electronics, and the reader can find detailed theoretical developments and many useful configurations and applications in Roberge [1975], Graeme *et al.* [1971], Graeme [1973, 1977], Horowitz and Hill [1989], and Stout and Kaufman [1976].

**Instrumentation Amplifiers.** Instrumentation amplifiers (IAs) are gain blocks optimized to provide high input impedance, low output impedance, stable gain, relatively high **common-mode rejection (CMR)**, and relatively low offset and drift. They are well suited for amplification of outputs from various types of transducers such as strain gages, for amplification of low-level signals occurring in the presence of high-level common-mode voltages, and for situations in which some degree of isolation is needed between the transducer and the remainder of the instrument.

Although instrumentation amplifiers can be constructed from conventional op amps [a three-op-amp configuration is typically discussed; see, for example, Stout and Kaufman (1976)], they are readily available and relatively inexpensive in IC form. Some IAs have digitally programmable gains, whereas others are programmable by interconnecting resistors internal to the IA via external pins. More basic IAs have their gains set by connecting external resistors.

**Isolation Amplifiers.** Isolation amplifiers are useful in applications in which a voltage or current occurring in the presence of a high common-mode voltage must be measured safely, accurately, and with a high CMR. They are also useful when safety from DC and line-frequency leakage currents must be ensured, such as in biomedical instrumentation.

The isolation amplifier can be thought of as consisting of three sections: an input stage, an output stage, and a power circuit. All isolation amplifiers have their input stages galvanically isolated from their output stages. Communication between the input and output stages is accomplished by modulation/demodulation.

An isolation amplifier is said to provide two-port isolation if there is a DC connection between its power circuit and its output stage. If its power circuit is isolated from its output stage as well as its input stage, then the amplifier is said to provide three-port isolation. Isolation impedances on the order of  $10^{10} -$  are not atypical.

Isolation amplifiers are available in modular form with either two-port or three-port isolation. Both single-channel and multichannel modules are offered.

## Attenuation

Whereas the majority of transducers are low-level devices such as thermocouples, thermistors, resistance temperature detectors (RTDs), strain gages, and so forth, whose outputs require amplification, there are many measurement situations in which the input signal must be attenuated before introducing it to the remainder of the system.

**Voltage Scaling.** Most typically, the signals to be attenuated take the form of voltages. Broadly, the attenuation is accomplished by either a *voltage divider* or a *voltage transformer*.

*Voltage Dividers.* In many cases a simple chain divider proves adequate. The transfer function

of a two-element chain of impedances  $Z_1(s)$  and  $Z_2(s)$  is

$$\frac{V_o(s)}{V_{in}(s)} = \frac{Z_1(s)}{Z_1(s) + Z_2(s)}$$

where the output voltage  $V_o(s)$  is the voltage across  $Z_1(s)$  and the input voltage  $V_{in}$  is the voltage across the two-element combination.

Of course, the impedances of the source (transducer) and the load (the remainder of the system) must be taken into account when designing the divider network.

*Resistive dividers.* If the elements in the chain are resistors, then the divider is useful from DC up through the frequencies for which the impedances of the resistors have no significant reactive components. For  $Z_1(s) = R_1$  and  $Z_2(s) = R_2$ ,

$$\frac{V_o(s)}{V_{in}(s)} = \frac{R_1}{R_1 + R_2}$$

Other configurations are available for resistive dividers. One example is the Kelvin-Varley divider, which has several advantages that make it useful in situations requiring high accuracy. For a detailed description, see Gregory [1973].

*Capacitive dividers.* If the elements in the chain divider are capacitors, then the divider has as its transfer function

$$\frac{V_o(s)}{V_{in}(s)} = \frac{C_2}{C_1 + C_2}$$

This form of divider is useful from low frequencies up through frequencies of several megahertz. A common application is in the scaling of large voltages. *Inductive dividers.* If the elements in the chain divider are inductors, then an autotransformer results. Inductive dividers are useful over frequencies from a few hertz to several hundred kilohertz. Errors in the parts-per-billion range are achievable.

*Voltage Transformers.* Voltage transformers constitute one of the most common means of accomplishing voltage scaling at line frequencies. Standard double-wound configurations are useful unless voltages above about 200 kV are to be monitored. For very high voltages, alternative configurations such as the *capacitor voltage transformer* and the *cascade voltage transformer* are employed [Gregory, 1973].

**Current Scaling.** Current scaling is typically accomplished via either a current shunt or a current transformer.

A *current shunt* is essentially an accurately known resistance through which the current to be measured is passed. The voltage developed across the shunt as a result of the current is the quantity measured. Shunts are useful at DC and frequencies through the audio range. Two disadvantages are (1) that the shunt consumes power, and (2) that the measurement circuitry must be operated at

the same potential as the shunt.

The *current transformer* overcomes the mentioned disadvantages of the current shunt. Typically, the current transformer consists of a specially constructed toroidal core upon which the secondary (sense) winding is wrapped and through which the primary winding is passed. A single-turn primary is commonly used, although multiturn primaries are available.

**Other Attenuators.** In addition to the aforementioned means of voltage and current scaling are attenuator pads, which provide, in addition to voltage or power reduction, the ability to be matched in impedance to the source and load circuits between which it is connected. The common pads include the T, L, and  $\Pi$  types, either balanced or unbalanced. Resistive attenuator pads are discussed in most textbooks on circuit design [e.g., Cuthbert, 1983]. They are useful from DC through several hundred megahertz.

## Impedance Transformation

Oftentimes the impedance of the transducer must be transformed to a value more acceptable to the remainder of the measurement system. In many cases maximum power must be transferred from the transducer's output signal to the remaining circuitry. In other cases it is sufficient to provide buffering that presents a very high impedance to the transducer, a very low impedance to the rest of the system, and a voltage gain of unity.

Matching transformers, passive matching networks such as attenuator pads, and unity-gain buffers are standard means of accomplishing impedance transformation. Unity-gain buffers are available in IC form.

## Linear Filtering

Although, in general, digital signal processing offers many advantages over analog techniques for filtering signals, there are many relatively simple applications for which *frequency-selective analog filtering* is well suited.

Filters are used within signal conditioners (1) to reduce the effects of noise that corrupts the input signal, (2) as part of a demodulator, (3) to limit signal bandwidth, or (4) if the signal is to be sampled, to limit its bandwidth in order to prevent aliasing. These filters can be built either entirely of passive components or based on active devices such as op amps.

There are many good references that discuss methods of characterizing, specifying, and implementing frequency-selective analog filters. See Van Valkenburg [1960] for design of passive filters; for the design of active-RC filters, see Sedra and Brackett [1978] and Stephenson [1985].

## 139.2 Nonlinear Operations

---

There is a wide variety of nonlinear operations useful to signal-conditioning tasks. Listed below are some typical nonlinear blocks along with brief descriptions. Most of the blocks are available as ICs.

1. *Comparator.* A comparator is a two-input device whose output voltage,  $V_o$ , takes on one of

two stable values,  $V_{o0}$  and  $V_{o1}$ , as follows:

$$V_o = \begin{cases} V_{o0} & \text{if } V_2 < V_1 \\ V_{o1} & \text{otherwise} \end{cases}$$

where  $V_1$  and  $V_2$  are the voltages at the two inputs.

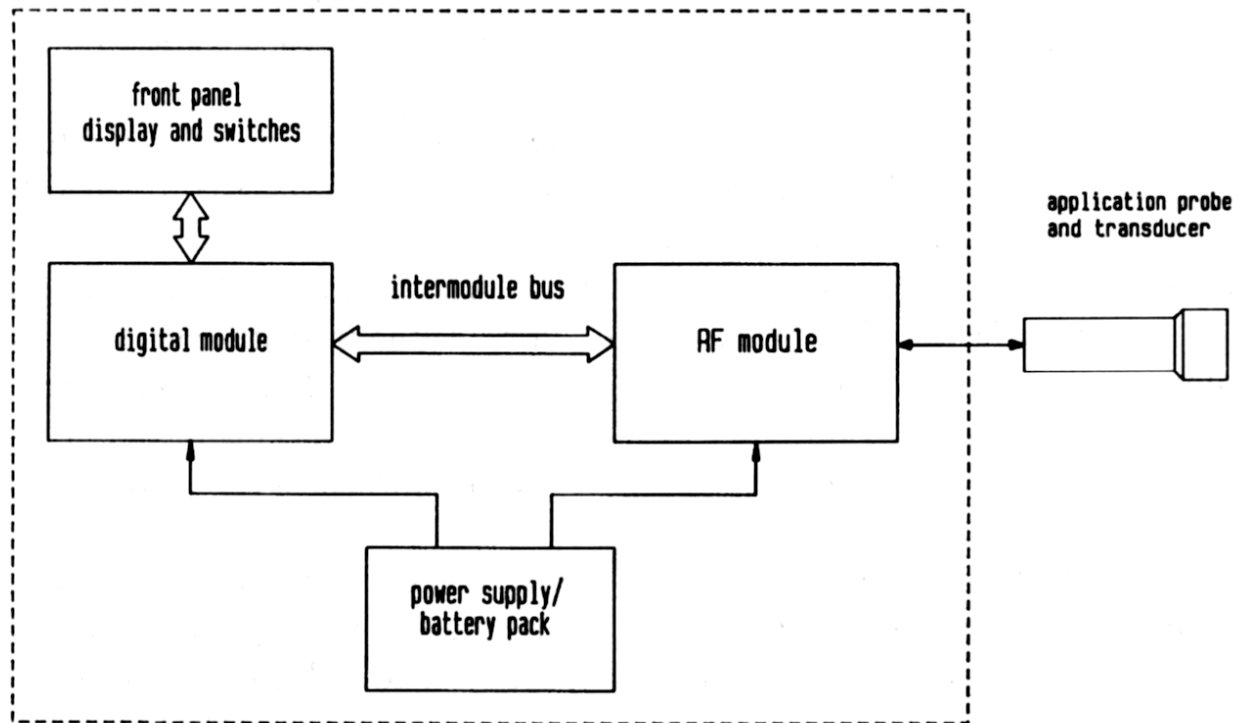

2. *Schmitt trigger*. A Schmitt trigger is a comparator with hysteresis. It can be constructed from a comparator by applying positive feedback.
3. *Multiplier*. A two-input multiplier supplies an output voltage that is proportional to the product of its input voltages.
4. *Divider*. A two-input divider has as its output a voltage proportional to the ratio of its input voltages. The functions of multiplication and division are usually combined within a single device.
5. *Squarer*. A squarer has as its output a voltage proportional to the square of its input. Squarers can be constructed by a number of means: from multipliers, based on diode-resistor networks, based on FETs, and so forth.
6. *Square-rooter*. A square-rooter has as its output a voltage proportional to the square root of its input. A square-rooter can be built most easily from either a divider or a log/antilog amplifier.
7. *Logarithmic/antilogarithmic amplifier*. A log/antilog amplifier produces an output voltage proportional to the logarithm or the antilogarithm of its input voltage.
8. *True RMS-to-DC converter*. A true RMS-to-DC converter computes the square root of the average, over some interval of time, of the instantaneous square of the input signal. The averaging operation is generally accomplished via a simple low-pass filter whose capacitor is selected to give the desired interval.
9. *Trigonometric function generator*. Generators are available in IC form that produce as their outputs any of the standard trigonometric functions or their inverses, taken as functions of the differential voltage at the generator's inputs.
10. *Sample-and-hold and track-and-hold amplifiers*. A sample-and-hold amplifier (SHA) is a device that samples the signal at its input and holds the instantaneous value whenever commanded by a logic control signal. A track-and-hold amplifier is identical to an SHA but is used in applications where it spends most of its time tracking the input signal (i.e., in "sample" or "track" mode), in contrast to the SHA, which spends most of its time in "hold" mode.
11. *Precision diode-based circuits*. Circuits such as precision half-wave rectifiers, absolute-value circuits, precision peak detectors, and precision limiters are relatively easy to design and implement based on diodes and op amps. See Horowitz and Hill [1989], Stout and Kaufman [1976], and Graeme [1977].

A detailed description of these and other nonlinear circuit blocks can be found in Sheingold [1976].

**Example.** We provide briefly an example of a device that has embedded within it several

signal-conditioning circuits. [Figure 139.1](#) shows the basic block diagram of a therapeutic ultrasound unit, which finds widespread use in physical medicine.

**Figure 139.1** Basic block diagram of the therapeutic ultrasound unit discussed as an example.

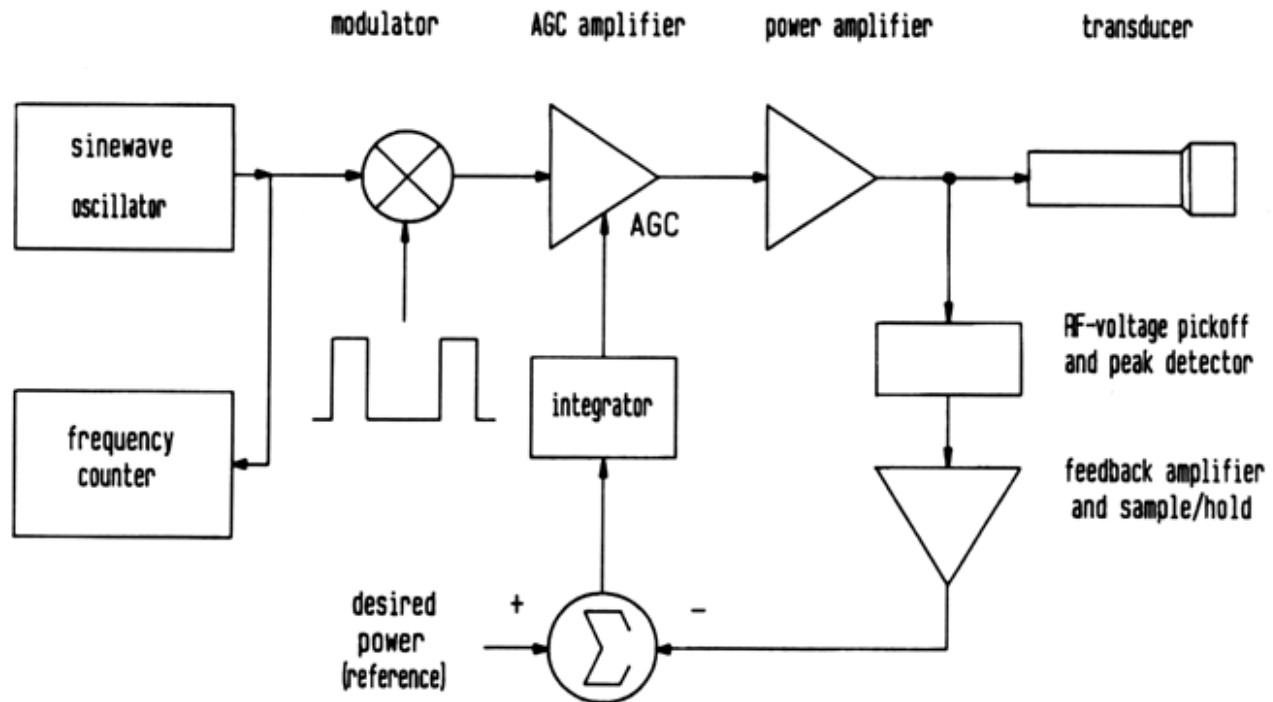

The particular unit being discussed consists of five principal subsystems:

1. An application probe and ultrasound transducer, which imparts ultrasonic energy to the tissue being treated. *Note that this transducer is NOT an input transducer such as has been discussed in relation to signal conditioners.*
2. A radio-frequency (RF) module, which provides electrical excitation to the ultrasound transducer.
3. Front-panel display and switches, which allow communication between the unit and its operator.
4. A microprocessor-based digital module, which orchestrates the overall control of the ultrasound unit.
5. A power supply/battery pack, which provides operating power to the unit.

We focus now on the RF module, whose basic block diagram is shown in [Fig. 139.2](#). The module consists of a sine-wave oscillator that produces a signal at the resonant frequency of the transducer, a modulator that allows that signal to be pulse-modulated, and an amplifier with RF-voltage feedback. Incorporated in the amplifier are a power amplifier capable of driving the transducer and automatic-gain-control (AGC) circuitry required to adjust the output power to coincide with that selected by the operator. The AGC uses a standard feedback-control loop to

maintain a constant-voltage envelope on the RF signal output from the power amplifier.

**Figure 139.2** Simplified block diagram of the RF module used in the ultrasound unit of Fig. 139.1.

Some of the signal conditioners employed within the RF module include the following:

1. The RF-voltage pickoff at the output of the power amplifier. The pickoff employs a half-wave rectifier, followed by a simple capacitive chain divider for voltage scaling.
2. A precision peak detector, which obtains the peak value of the output from the voltage divider during a modulation cycle and presents that value to the feedback loop.
3. An amplifier, having digitally selectable gain, which amplifies the output of the peak detector.
4. A sample-and-hold amplifier, used to hold the amplified output from the peak detector during the "off-time" of the modulator. The SHA is needed since the time constant of the peak detector is not sufficient to prevent significant "droop" during the off-time of the modulator.
5. An integrator (an example of frequency-selective filtering), which develops the control voltage for the AGC loop from the output of the differencer.
6. A current shunt, not shown in Fig. 139.2, that is used to monitor the DC current supplied to the power amplifier.

As can be seen from this simple example, several signal-conditioning functions may be

employed within a single system, and the system itself might not even be an instrument!

## Defining Terms

**Common-mode rejection (CMR):** CMRR given in dB.  $CMR = 20 \log |CMRR|$ . CMR is a nonlinear function of common-mode voltage and depends on other factors such as temperature.

**Common-mode rejection ratio (CMRR):** The ratio of the differential gain to the common-mode gain of an amplifier.

**Gain-bandwidth product (GBWP):** The product of an amplifier's highest gain and its corresponding bandwidth. Used as a rough figure of merit for bandwidth.

**Slew rate:** The maximum attainable time rate of change of an amplifier's output voltage in response to a large step change in input voltage.

## Telemetry

---

[140.1 Telemetry Systems](#)

[140.2 Frame Telemetry](#)

[140.3 Packet Telemetry](#)

**Stephen Horan**

*New Mexico State University*

Telemetry systems are found in a variety of applications—from automobiles, to hospitals, to interplanetary spacecraft. Although these examples represent a broad range of applications, they all have many characteristics in common: a natural parameter is measured by a sensor system, the measurement is converted to numbers or data, the data are transported to an analysis point, and an end user makes use of the data gathered—after all, the implication of telemetry is to "measure at a distance."

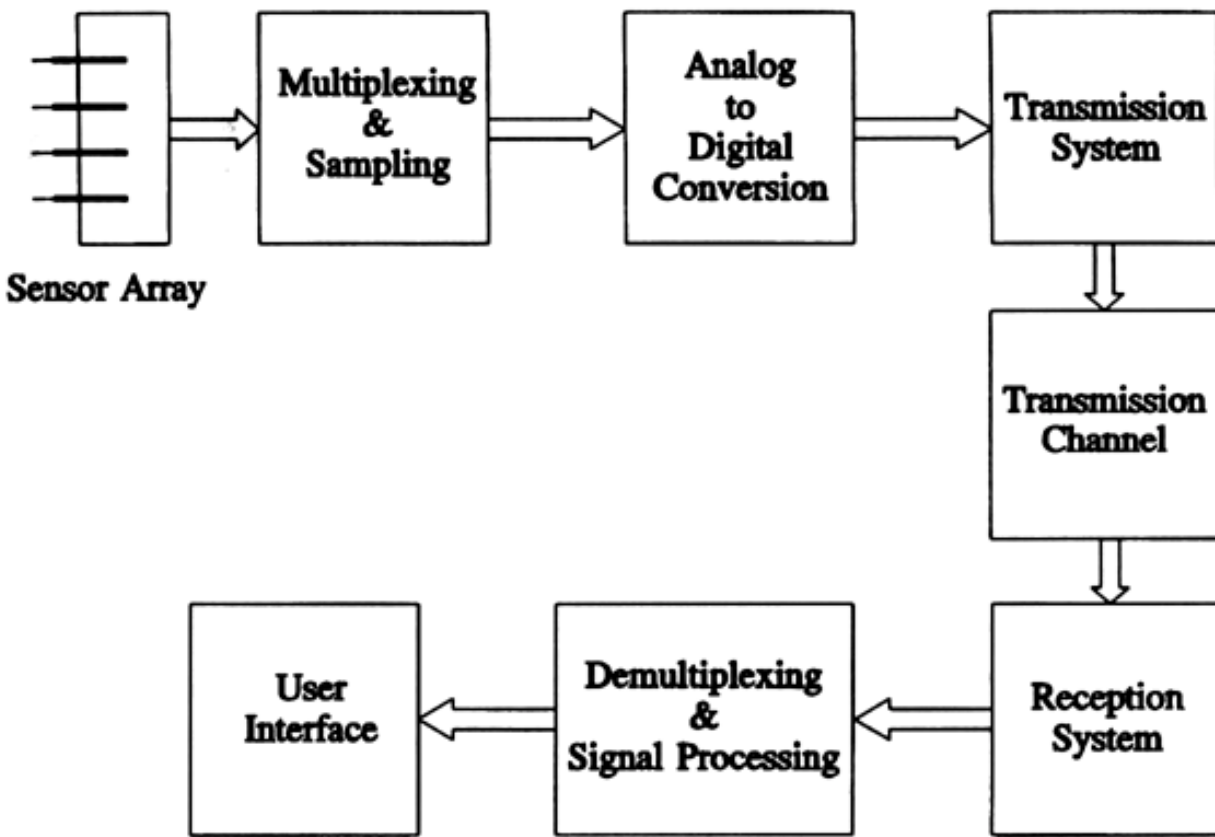

### 140.1 Telemetry Systems

---

The basic telemetry system components are illustrated in [Fig. 140.1](#). The system starts with the sensor array for measuring the natural world. These sensors are specific to the measurement task being performed, for example, atmospheric parameters, flow rates, position measures, accelerations, and so forth. The output of the sensor array is usually an analog voltage level proportional to the signal the sensor is measuring. Some sensors make their output in terms of a current or a time difference instead of a voltage. The sensor output is then sampled at a rate appropriate for the bandwidth of the signal. The sampled signals are then frequently digitized by using an analog-to-digital converter. This produces a **pulse-coded modulation (PCM)** data stream. The channel bandwidth is a limiting factor to the system because it restricts the volume of data that can be reliably sent. Consequently, the digitized signals are then time-multiplexed in a repeating pattern for transmission. When the signals for the sensors are received, the processing stage will demultiplex the data streams into sensor channels. The PCM signal will either be converted back to an analog waveform or left as a series of discrete measurements for use and analysis. The user interface may be a display screen, a set of gages, or a chart recorder. The user interface often contains data-logging capabilities to provide a permanent record of the measurements.

**Figure 140.1** Overall telemetry system components.

The sampling rate for each sensor is determined by the signal's **Nyquist rate**. If  $W$  is the signal bandwidth in hertz, the Nyquist sampling rate,  $f_N$ , in samples per second, is given by

$$f_N = 2W \quad (140.1)$$

In practice, a minimal sampling rate of five times the signal bandwidth is necessary to accurately reconstruct the signal. When the telemetry system is designed, a master clock is established to determine the base rate of signal sampling or the system commutation rate. For most signals this forms the highest sampling rate necessary. Signals having a lower Nyquist rate will be sampled at a rate that is an integer multiple of the sampling period for the higher rate signals. The data are transmitted from the sensors to the users over some type of channel. This channel may be a radio link, a fiber cable, an electrical cable, or a computer network. The choice of which medium is used depends upon the application, the signal bandwidth, the distance to be covered, and the transmission energy available. While the data are being transmitted, the samples may be packaged into frames or packets to give structure to the data and to allow the receiving end to efficiently synchronize to the data stream for processing.

Many systems contain a return command link from the user to the sensor system to allow the sensor system to be controlled. This type of return link is referred to as a *telecommand link*.

## 140.2 Frame Telemetry

Frame telemetry is the traditional method for time-multiplexing data from the source to the

$$P_{FL} = \frac{\sum_{i=0}^k \binom{N}{i}}{2^N} \quad (140.2)$$

where  $N$  is the length of the synchronization code in bits and  $k$  is the number of differences allowed between the received code and the exact code value.

The synchronization code can also be missed if the data become corrupted in the channel. The probability of a missed synchronization code,  $P_M$ , due to channel errors is given by

$$P_M = \sum_{i=k+1}^N \binom{N}{i} p^i (1-p)^{N-i} \quad (140.3)$$

where  $p$  is the channel bit-error rate and  $N$  and  $k$  are as before.

The synchronization process for a telemetry frame follows these steps:

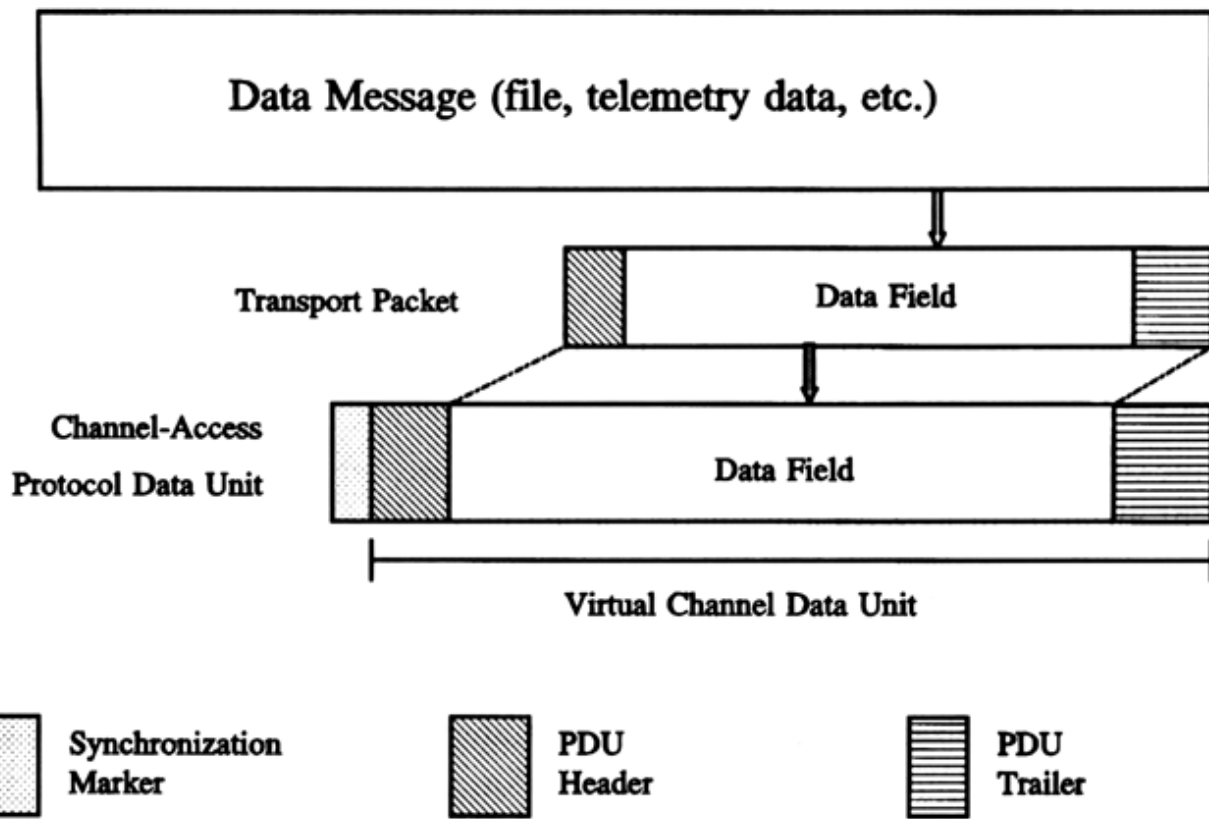

1. Find the individual bits in the data stream using a bit synchronizer circuit.
2. Find the occurrences of the frame synchronization word by using a correlator comparing the data with the desired stored pattern.
3. Once the synchronization marker is reliably found, ensure that it repeats at the minor frame rate and that any management information in the frame is intact by using a frame synchronizer.
4. Once the frame structure is fully identified, begin processing the data.

## 140.3 Packet Telemetry

---

Packet telemetry systems are becoming more common, especially in systems where the data acquisition and data reception subsystems have high degrees of computational capability and the link between them can be viewed as a reliable link. Packet systems have several advantages over frame systems, with the main advantage being flexibility. With a packet system, instead of having a master commutation rate, the sampling rate for each sensor or sensor system can be individualized to the natural signal bandwidth. For example, battery voltages being measured may not change significantly over five minutes. With frame telemetry they may be sampled more frequently than once per minute. With packets they may be sampled only as needed. Packets also have the advantage of allowing the data to be more easily routed over a computer network for analysis and distribution to end users. An example of a packet system is the one developed by the members of the Consultative Committee for Space Data Standards [CCSDS, 1993]. Figure 140.3 shows how the packet system is organized for transmission into individual protocol data units (PDU). The telemetry data are normally organized as a large block of data or a data file. This file is normally too large to be sent in a single packet; therefore, the overall data set is broken into manageable transport packets. These provide end-to-end accounting and reconstruction of the data set. For actual sending across the transmission channel, a channel packet is used. This packet may multiplex the transport packets from several subsystems together for efficient transport. It is common for the channel packets to be sent at regular intervals to maintain transmission synchronization. When this is done, fill packets are used to keep the channel active if there are no actual data to be sent. The packet header will then have a special code to indicate that the packet is a fill packet and should not be processed.

**Figure 140.3** Packet telemetry transmission.

The general packet format is composed of a header, containing accounting and addressing information, followed by the actual data. The packet may end with a trailer composed of error-checking codes or other administrative information. The addressing information in the packet identifies the sensor system originating the packet and the destination process for analysis. Other information included in the header might be counters to identify the sequence number or a time stamp to show when the packet was created. The header will often contain a size parameter to specify the length of the data field.

The packet usually begins with a synchronization marker, just as frame telemetry does. The same synchronization codes can be used in packet systems as in frame systems. After synchronization the header is analyzed to identify the type of processing to be performed based on the source of the data.

## Defining Terms

**Commuted data:** Data that are sampled once per main sampling interval. This main sampling interval is called the *commutation rate*. Minor frames, major frames, and subframes are tied to this commutation rate.

**Major frame:** The set of an integer number of minor frames where each sensor value is sampled at least once.

**Minor frame:** The set of sensor values, synchronization markers, and other management data between successive synchronization words.

**Nyquist rate:** The minimum sampling rate for signal recovery. If a signal of limited bandwidth is sampled at twice this rate, then the signal can be reconstructed in principle. Most signals are sampled at a higher rate than the Nyquist rate to give better reconstruction.

**Pulse-coded-modulation (PCM):** Modulation in which each analog sensor value is converted to a digital number once per sampling interval. The number of bits used in the representation is typically 8 to 16 bits.

**Subcommutated data:** Data whose sampling interval is less frequent than the commutation rate.

**Subframe:** A group of sensors that are subcommutated together. Usually, the data are tied to a single physical subsystem.

**Supercommutated data:** Data whose sampling interval is more frequent than the commutation rate.

*Johnson Yokogawa Corporation*

A dozen years ago, industrial **recorders** were often considered large, inflexible analog instruments that occupied huge volumes of panel space and offered relatively few modern advantages in return. Slow to scan and easy to wear because of many mechanical parts, chart recorders required frequent maintenance and visual chart interpretation.

Although recorders were a fixture in many process applications, automation professionals declared that they had become outdated. They had no built-in capability for communicating or computing, so plant personnel were required to read and analyze data off-line. In the early 1980s, leading recorder manufacturers began redesigning the instruments to meet the more advanced needs of modern, digital plants.

Today's chart recorders offer speed and high performance in a smaller, more reliable, and more versatile package. Cost of ownership has actually decreased due to the longer life cycle, reduced maintenance, and on-board computing/communication capability of modern recording instruments.

### 141.1 Types of Recording Instruments

---

The engineer is faced with a myriad of selections and options when choosing a recording instrument. Recording and data acquisition instruments are typically classified as strip chart, circular chart, or paperless.

Modern-day recording instruments have added power and expanded capabilities to meet changing market demands. High-resolution data displays, personal computer links, surface-mount technology, application-specific integrated circuits, and microprocessors have changed the instrument from a simple trending on paper to a sophisticated and diverse computing device.

## Analog vs. Hybrid Recorders

The term *hybrid* defines a fundamental separation from conventional, older analog recorders which operate electromechanically and do not incorporate microprocessors.

## Strip Chart Recorders

Strip chart recorders print data on a chart in either a continuous trace or a multipoint arrangement. These continuous-paper-feed instruments are used to record data for virtually all market segments, covering a multitude of applications. In order to select the correct instrument for the application, users must consider sample rate, recording time, number of measuring points, and planned use of recorded data. There are basically two types of strip chart recorders: process and test devices. For the purpose of this chapter, the distinction between process and test classifications for recorders will be based on the method of installation. Process will denote those recorders mounted in a panel or some other fixed piece of equipment, as opposed to test recorders, which require portability and flexibility.

## Writing Technology

Continuous ink pen, print head dot matrix or raster scan with a color ribbon, and thermal print on paper represent the different writing technologies available for recording data on the chart. Colors assist the user in distinguishing the multiple-trace data on the paper. With the increased color selection offered by some manufacturers, ten or more colors in multipoint units, shorter ribbon life may result in units that double-strike the ribbon to increase color selection.

## 141.2 Methods of Data Recording

---

### Chart

Chart recording of data is the most commonly used form. Typical paper sizes range from 100 mm (4 in.), as in the instrument shown in [Fig. 141.1](#), to 250 mm (10 in.). Chart width considerations include number of points and resolution—the wider the chart, the greater the resolution. The addition of microprocessors to recorders, digital notation of data and digital logging minimize the resolution consideration. Added information to the chart record, such as tags, units, headers, and messages, are available in many units.

**Figure 141.1** MicroR1000 4-in. recorder.

Chart records are required for several industries to comply with regulations such as EPA (environmental monitoring), FDA (food and pharmaceutical), and NERC (power grid interchange). Storage of the chart requires little special handling. Review of the chart is simple for the user. Many recorders offer fanfold paper, which allows the user to view several days or weeks of data with little effort.

## Circular Chart

Similar to the strip chart recorder, the distinctive advantage of the circular chart is the ability to look at 24 hours, 7 days, or 30 days of trace information without operator intervention. Paper sizes range up to 12 inches. Many circular chart models offer math, totalization, and PID control loops.

## Paperless

Paperless is a term referring to the growing variety of recorders that don't use paper. Basically, the

paperless recorder replaces the chart with a CRT, LCD, or TFT display. Some recorders incorporate chart data recording and electronic medium storage simultaneously. A paperless recorder is also a form of data acquisition. Like the traditional chart recorder, the paperless unit has advanced to do more than just record data. Serving as a front end, the recorder performs signal conditioning for I/O to a computer, programmable controller (PLC), or distributed control system (DCS) host. A paperless recorder stores data to an electronic medium such as hard disk, IC memory card, floppy disk, optical disk, or magnetic tape.

The amount of time needed to store data, the sample rate, and the capacity of disk, card, or tape are issues that must be resolved to ensure sufficient storage capacity. The question of what is required to enable the user to view or produce graphs of the data after collection should also be explored. Some store in ASCII comma-delimited files, which require importation to a spreadsheet or database program. Others provide programs that allow the user to select the type of file for data conversion, such as parsed data files with .WKS extensions, which can be read directly in most spreadsheet or database programs.

The initial cost of the paperless unit is higher than that of its counterpart with paper for comparable point capacity. A careful cost analysis must be performed to determine cost of ownership for both options, which includes pens and charts for the paper model and disk and effort to store data for the paperless models. The expected life of paperless displays for continuous operation also should be factored into the evaluation. Most displays have a limited life in continuous operation.

What must one do to keep the data for several years? Many units require additional steps to maintain or archive stored data for long periods after the recorder has collected the electronic information. One example is the IC memory card, although the battery fails in time. Disk and tapes also have limited storage times compared with paper, but longer than those of battery-powered devices.

## Pen Recorders

Pen recorders have one dedicated analog-to-digital converter per input. These are typically used in faster applications such as flow or other rapidly changing inputs. The pen recorder is better able to graph a true representation of the input signal. In some applications, like those found in the NERC regulation for power interchange monitoring, a continuous-writing pen-to-paper chart recorder is specified.

Modern advances of servo pen continuous recorders have dramatically reduced the maintenance associated with old designs incorporating slide wires with contacts, DC brush motors, and wire cables to position the pen. New or improved technologies available in pen recorders are DC brushless servo motors, as shown in [Fig. 141.2](#), and noncontact ultrasonic positioning for the servo pen, which have greatly reduced maintenance by eliminating wiper contacts for pen position and the brushes in the DC motor.

**Figure 141.2 Noncontact servo with brushless DC motor.**

## Multipoint Recorders

Multipoint recorders have several inputs sharing an analog-to-digital converter. The advantage is the recorder's ability to accept more inputs in a given space. Due to the slower scan speed in most models, the multipoint recorder is best suited for more slowly changing signals, such as most temperature measurements. It should be noted that some manufacturers have made significant improvements in scan speed. Modern-day instruments meet or exceed a rate of 1 second for all points.

Recording times also have improved and must be evaluated to determine the suitability of the chart for the data application. Some manufacturers use the latest technology to increase reliability and quality of measurement data. Surface-mount circuit board design and other advanced technologies increase the mean time between failure (MTBF) for electronic components.

Inputs are switched using high-breakdown-voltage, solid state switches to give higher quality and consistency of measurements. In units that use solid state relays, no contact resistance change as a result of make-and-break contact wear or corrosion is possible, nor are mechanical input switch failures.

Following are typical switch technologies used in industrial recorders:

*Electro-mechanical relay:* This traditional technology is subject to wear and regular replacement. Changes in contact surfaces alter resistance, which affects measurement consistency. Improved contact material extends life only marginally. This type of relay can withstand high electrical noise spikes and offers low contact resistance.

*Reed relay:* This type of mechanical relay technology can withstand normal industrial noise

voltages. Low switch resistance allows measurements of low-level voltage signals (such as RTDs). The reed relay is a mechanical switch, however, and must be replaced. The reed relay requires "settling time" and is therefore slower than solid state relay technology.

*Solid state relay:* Initial designs had 30–50 V voltage limits and were subject to failure with high-frequency noise. New designs have overcome these limitations to provide the best of both worlds: noise characteristics similar to hard-contact, electro-mechanical relays and the long life of an integrated circuit.

From a maintenance point of view, units that eliminate potentiometers for adjustments in favor of ADC calibration, with all adjustments accomplished electronically, are preferred.

Some recorder manufacturers state speed in hertz instead of or in addition to scan rate. The simplest method of translating a speed specification from hertz to second is to apply the conversion 1 hertz equals 1 scan per second. Therefore, if a recorder time is stated as 30 hertz, the effective scan rate is 30 times a second. Some test and measurement recorders offer speeds as fast as 100 kHz. The scan rate or speed of data measurement and recording is an important consideration in choosing the correct instrument for the application.

## Process Recorders

Process recorders consist of signals that monitor either continuous or batch process parameters such as temperature, pressure, flow, pH, conductivity, and/or the 4–20 mA inputs found in power generation, refineries, chemical plants, cement plants, pharmaceutical and biotech applications, and others. Most of the signals are slower-changing, requiring a slower scan or sample time.

## Test Recorders

Test recorders are found primarily in laboratory applications and applications that require faster sample collection of data. Test recorders are also found in a diverse market encompassing inspection, R&D, and quality control. Commonly measured inputs are strain gage, accelerometers, pressure, AC transients, power line monitoring, and transducers.

## 141.3 Future Directions: Distributed Data Acquisition and Recording

---

Recorders have added features that greatly expand their role in conditioning data as front-end devices in addition to performing basic recording. Offering universal inputs, recorders are involved in signal conditioning, providing alarm annunciators, relay outputs, digital display capability, providing chart records with digital notation of alarms and messages, and front-end data to PC, PLC, and DCS systems.

With increased power, speed, and communication capability, the recording instrument is

becoming a distributed data acquisition and recording key component. The differences in performance will narrow between process and test recorders.

The present trend of enhanced functionality will continue into the foreseeable future. Although paperless recorders are beginning to appear, the need for hard-copy chart records for regulatory agencies will keep traditional paper recorders on the market for a long time to come.

Recorders will grow in scope as increased microprocessor power yields benefits in speed, function, and application versatility. Recording instruments will continue to move into more sophisticated applications and will assume nontraditional roles as smart network devices and data nodes. With the move toward fieldbus interoperable communications, recording instruments may incorporate elements of control and offer entirely new presentations of data formats.

## **Defining Term**

**Recorder:** A device that provides historical data records to a specific medium and with a given accuracy from sensor inputs.

[142.1 Basic Bioinstrumentation Systems](#)[142.2 Applications and Examples](#)[142.3 Summary](#)**Wolf W. von Maltzahn***University of Karlsruhe***Karsten Meyer-Waarden***University of Karlsruhe*

Biomedical instruments measure, amplify, process, record, and store physiological quantities to help physicians diagnose illnesses, set up treatment plans, or restore lost functions. The scope of such instruments is enormous, both in complexity and in the range of applications. Only a few can be covered in this chapter. Since a choice among topics must be made, this chapter focuses primarily on instruments that measure physiological signals; it does not cover devices that treat diseases or restore compromised physiological functions. For further information, the reader should consult the references.

In contrast to technical systems, physiological systems comprise living cells and organs. This requires that measurements do not adversely affect the living system by introducing toxic substances; by destroying delicate tissues; or by otherwise interfering with the chemical, electrical, or mechanical balance of the living cell or organ. Furthermore, many physiological measurement sites are either inaccessible for direct measurements or only accessible invasively—that is, by puncturing the skin. Noninvasive biomedical instruments often use indirect measurement methods, even though these methods are usually less accurate, slower, and less informative than their direct counterparts.

Physiological measurements seldom depend on one variable alone. The electrical impedance of tissue, for instance, depends not only on resistivity, cross-sectional area, and length, but also on electrolytes, enzymes, temperature, and other factors related to life processes. To extract meaningful information from impedance measurements, the system needs to focus on one of these factors and suppress the others. Physiological events in living systems are unstationary, stochastic, time-dependent, and noisy. It takes a lot of skill and ingenuity to measure them.

Biological cells pump primarily sodium and potassium ions across the cell membrane to maintain specific concentration differences. The resulting membrane potential of about  $-90$  mV

can be calculated from a modified Nernst equation. Nerve and muscle cells are excitable cells and generate action potentials by first changing the membrane permeability of sodium and then that of potassium. Action potentials influence the electric fields in the tissues surrounding the excitable cells all the way to the skin, from where they can be detected and recorded as surface biopotentials. These biopotentials are characterized by high source impedances, small signal voltages, significant interference voltages, and a modest frequency range. Special biopotential amplifiers convert these biopotentials into high-quality signals by amplifying them, suppressing interferences, and preparing them for further signal processing, display, or recording.

Biomedical instruments operate in hospital rooms, where they interact with other devices, work in the vicinity of other devices, or connect to patients. Such interconnections not only cause unpredictable interferences, but also provide current pathways that may endanger the lives of patients and/or operators. To ensure high-quality measurements and electrical safety, requirements must be imposed on biomedical instruments, uncommon in typical industrial measurement systems. Biomedical measurements must do the following:

- Amplify the biosignal and suppress interferences
- Protect input stages against high voltages generated by other devices
- Be electrically safe for operator and subject
- Avoid adversely affecting the living system

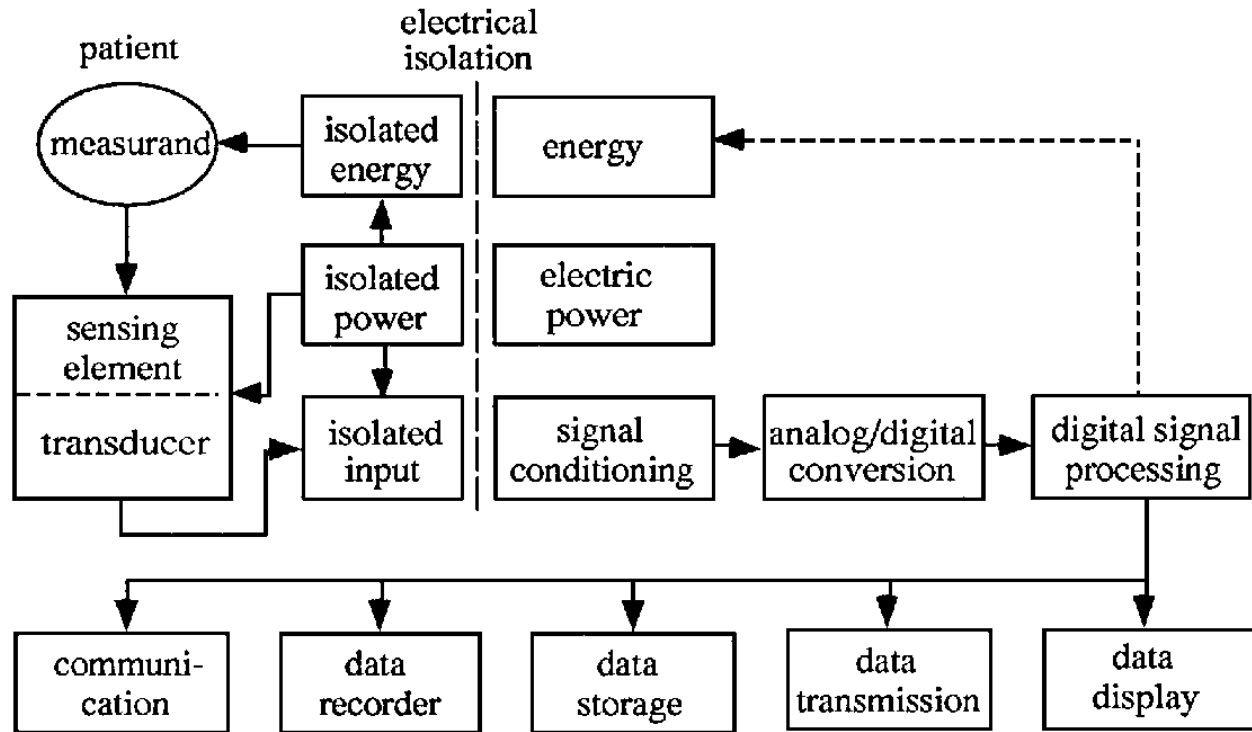

## 142.1 Basic Bioinstrumentation Systems

---

[Figure 142.1](#) shows the block diagram of a basic bioinstrumentation system. The physiological variable to be measured, the measurand, may be the result of a molecular, cellular, or systemic event and be mechanical, electrical, or chemical in nature. Blood pressure and blood flow, for instance, are important mechanical variables of the circulatory system. The electrocardiogram, electromyogram, and electroencephalogram provide information on the electrical activity of the heart, skeletal muscle, and brain, respectively. Partial pressures of oxygen or carbon dioxide reflect the status of the chemical balance in the blood. The sensing element in [Fig. 142.1](#) interacts with the measurand, directly or indirectly, and is designed with three main goals in mind: to minimize the unavoidable disturbance of the measurand and its environment, to avoid interference with life processes, and to provide an output signal sensitive primarily to the measurand and insensitive to other parameters.

**Figure 142.1** Schematic block diagram of a biomedical instrument.

The transducer takes the output of the sensing element and transforms it into an electrical signal. The most common analog signal-conditioning elements are amplifiers, filters, rectifiers, triggers, comparators, and wave shapers, just like in other instrumentation systems. Appropriate amplification and filtering prepare the analog signal for analog-to-digital conversion (ADC). Once in digital form, a microcomputer further processes the signal and displays it on a CRT screen or on an LCD panel, generates a hard copy on a recorder, sends it to another device, or stores it in a mass storage device. Some measurements require external energy or stimulation applied to the subject across an isolation barrier.

Medical instruments contain special circuits to safeguard patients and operators against electrical shock, to suppress interferences from the noisy hospital environment, and to protect sensitive input stages. The most important of these is the isolation barrier, made of transformers, capacitors, optocouplers, or a combination of these. The isolation barrier keeps current densities in the body below the safe level of  $100 \mu\text{A}/\text{cm}^2$ . Several national and international standards give limits for safe voltages and currents, describe methods to avoid potentially dangerous connections, and give detailed test procedures to ensure electrical safety [NFPA, 1990; AAMI, 1990; IEC, 1982].

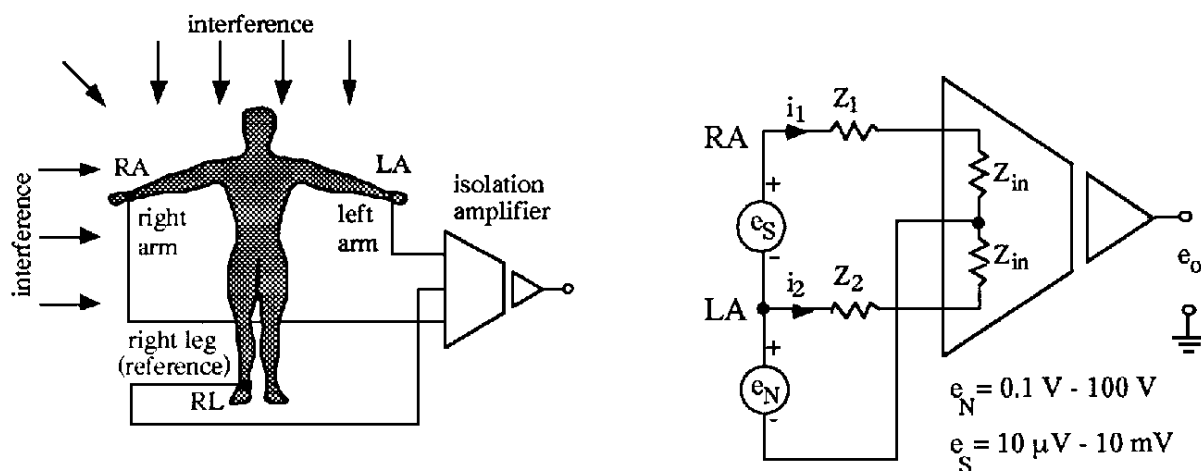

A single hospital room may contain electrocardiographs, blood pressure monitors, X-ray machines, cardiac output monitors, respirators, electrosurgery devices, defibrillators, and other devices. The useful and beneficial output of one device may severely interfere with another. To function in the same environment, these devices must contain special hardware circuits or software algorithms that suppress undesired outputs from other devices.

## 142.2 Applications and Examples

Action potentials of nerve and muscle cells inside the body manifest themselves on the surface of the skin as small voltages between  $10\ \mu\text{V}$  and  $100\ \text{mV}$  with high source impedances and high levels of interfering noise signals. These surface biopotentials are detected with surface electrodes that function as transducers between the ionic currents inside the body and electronic currents in wires and amplifiers. Electrodes represent complicated electrochemical systems, as described in many bioinstrumentation books [Aston, 1990; Bronzino, 1986; Geddes and Baker, 1989; Norman, 1988; Profio, 1993; Webster, 1992]. Most electrodes for recording surface biopotentials are made of silver or silver chloride because they provide stable and relatively noise-free recordings.

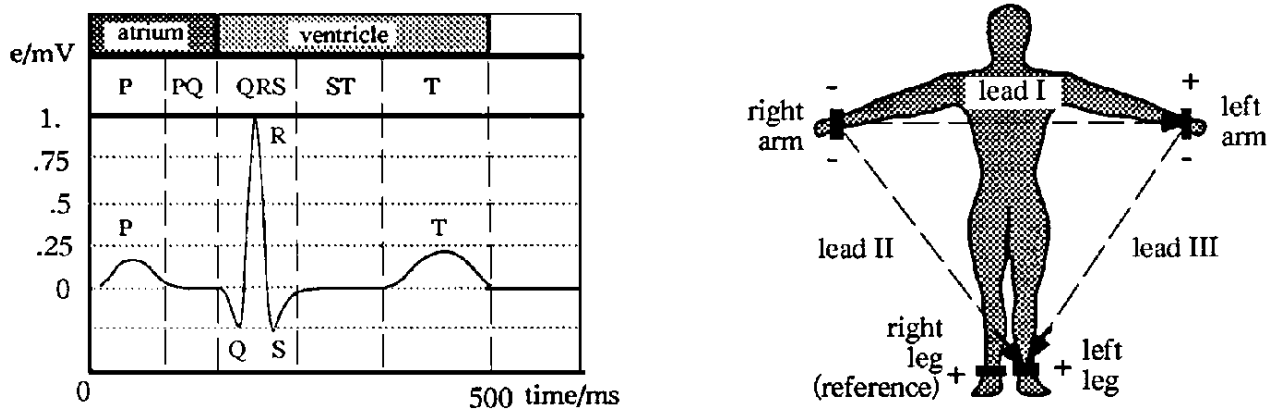

The diagram in Fig. 142.2 for obtaining a lead I electrocardiogram serves as an example of how to obtain a high-quality biopotential recording in general. Three electrodes attach to the subject—two for recording the biopotential and one for providing a reference potential. The electrodes on the left and right arms connect directly to the differential input of an isolated instrumentation amplifier; the reference electrode on the right leg connects to the floating ground terminal. This configuration separates the desired differential-mode biosignal  $e_S$  from the undesired common-mode noise  $e_N$ , as shown in the electric equivalent circuit of Fig. 142.2. The instrumentation amplifier provides a high differential-mode gain and a low common-mode gain to suppress power line interferences and electrode potentials. The ratio between these two gains is called common-mode rejection ratio (CMRR). Although the CMRR of a good instrumentation amplifier may be as high as 130 dB, the CMRR of the overall circuit is seldom greater than 80 dB or 10000:1. The primary cause for this large reduction in CMRR lies in the differences in electrode and skin impedances, represented by  $Z_1$  and  $Z_2$  in Fig. 142.2. Some bioinstrumentation systems use additional amplifiers that set the voltage on the right leg equal to the mean voltage between the left and right arm ("driven right leg"), thereby decreasing common-mode voltages.

**Figure 142.2** Left panel: schematic diagram for measuring biopotentials; right panel: electrical equivalent circuit.

The most important and most investigated biopotential waveform is the *electrocardiogram* (ECG) [Webster, 1992]. Since the electrocardiogram represents the heart's electrical activity associated with cardiac contraction, it provides diagnostic insight into many heart functions. The curve in the left panel of Fig. 142.3 represents a typical ECG waveform with the standard P, QRS, and T labels. The P wave and the QRS complex represent depolarization of cardiac muscle cells—the first one of atrial cells and the second one of ventricular cells. Although atrial repolarization cannot be seen in the ECG, the T wave represents ventricular repolarization. These P waves and QRS complexes precede cardiac contraction and the pumping of blood, first of the atria then of the ventricles.

**Figure 142.3** Left panel: typical lead II ECG recording; right panel: Einthoven triangle.

To enable comparisons of waveforms between subjects, certain standardized recording techniques have evolved. Einthoven, the pioneer of electrocardiography, developed an extremity lead system still in use today. As shown in the right panel of Fig. 142.3, the three recording electrodes of the Einthoven triangle are placed on the left arm, the right arm, and the left leg, whereas the reference electrode is placed on the right leg. The voltage differences between the three recording electrodes are known as lead I, lead II, and lead III recordings. The lead II recording from the right arm to the left leg runs almost in parallel to the main axis of the heart and is therefore the preferred recording of a single-channel ECG. In addition to Einthoven's recordings, physicians use augmented limb leads and unipolar chest leads.

Recordings of the electrical activities of the brain, called *electroencephalograms* (EEGs), are more difficult to obtain than recordings of the ECG. The skull is a poor electrical conductor and EEG voltages on the scalp are in the  $\mu\text{V}$  range, as opposed to ECG voltages in the mV range. Furthermore, it is difficult to relate EEG voltages to specific neuronal activities; they are the net result of many different neurons firing seemingly independently of each other. With a subject in a relaxed state with closed eyes, alpha waves are easily recorded between two electrodes on the scalp. As shown in Fig. 142.4, alpha waves are simple periodic waveforms in the frequency band of 8 to 13 Hz with slightly varying amplitudes. Alpha waves disappear when the subject's eyes are opened. The other waveforms shown in Fig. 142.4 have clinical significance, particularly in diagnosing epilepsy and sleep disorders or in providing feedback during general anesthesia. The low-frequency theta waves between 4 and 8 Hz indicate sleep, whereas the high-frequency beta waves between 14 and 22 Hz appear during high states of alertness.

**Figure 142.4** Left panel: typical EEG waveforms; right panel: typical EMG waveform.

Recordings of the electrical activities of skeletal muscles are called *electromyograms* (EMGs). They can be obtained with surface electrodes similar to ECG electrodes or needle electrodes. The latter puncture the skin and are positioned close to the muscle group, from which they record. The mean amplitude and mean frequency of the EMG power spectrum reveal both muscle strength and muscle fatigue, which can provide feedback information in rehabilitation engineering and functional electrical stimulation [Phillips, 1991]. Table 142.1 summarizes amplitudes and frequency ranges of ECG, EEG, and EMG. Similarly, other biopotentials originating from other nerve or muscle cells can be recorded from the surface of the body.

**Table 142.1** Amplitude and Frequency Ranges of ECG, EEG, and EMG

Origin of Electrical Activity	Name	Amplitude (mV)	Frequency Band(Hz)
Cardiac muscle	ECG	1–10	0.01–150
Skeletal muscle	EMG	5–100	10–5000
Brain	EEG	<0.2	1–30
	$\beta$	0.01	14–30
	$\alpha$	0.03	8–13
	$\theta$	0.05–0.1	4–7
	$\delta$	0.1–0.15	1–4

Bioelectric impedance measurements provide qualitative and quantitative information about volume changes in the heart and in peripheral arteries and determine body characteristics such as percent body fat, total body fluid volume, and cell volume. They are also used in sleep apnea monitoring, especially in infants, and in the detection of venous thrombus. Multiple bioelectric impedance measurements lead to computed cross-sectional images of the body, so-called *computed impedance tomograms*.

## DIAGNOSTIC X-RAY SYSTEMS

*Robert S. Ledley*

*Patented November 25, 1975*

*#3,922,522*

An excerpt:

It is the principal objective of this invention to improve the state of the prior art in contributing a tomographic scanning instrument having a degree of efficiency, practicality, and flexibility heretofore unknown.

Another principal objective of this invention is to provide a tomographic scanner having a capability of scanning any portion of the human body with equal efficiency and accuracy.

Another important object of the invention is to provide a medical diagnostic apparatus of the type described in which the plane of the scanner can be tilted over a relatively wide range of attitudes.

Taking X-ray images of organs in slices (tomography) had been known as a valuable (and cumbersome) diagnostic tool for some time, but Ledley developed in one neat package a machine for capturing these whole-body image slices and reconstructing them for interpretation by physicians. This technique is now known as Computer Aided Tomography or CAT scanning. (©1992, DewRay Products, Inc. Used with permission.)

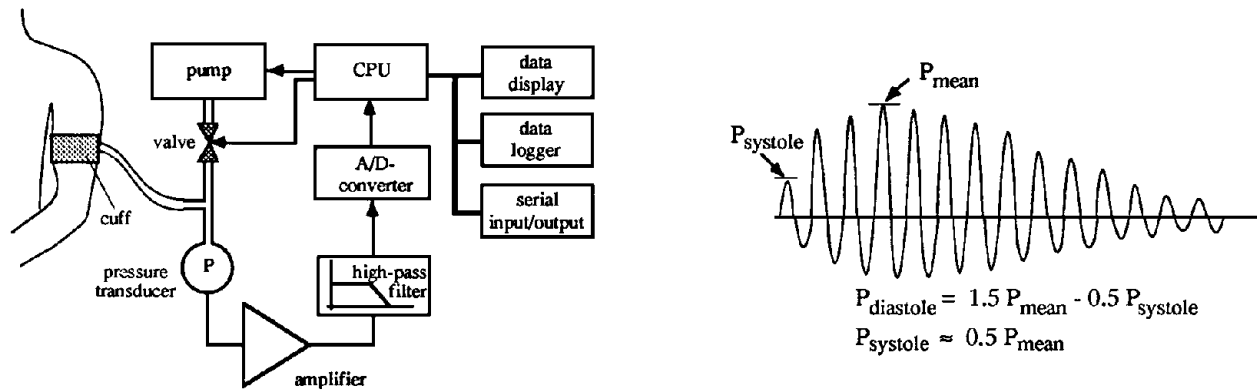

Figure 142.5 shows four band electrodes for the measurement of respiration, stroke volume, and cardiac output. A constant sinusoidal current with an amplitude in the range of 0.5 to 4 mA and a frequency between 50 and 100 kHz flows from the top electrode through the thorax to the bottom electrode. This current is maintained independent of skin or tissue impedances. The voltage drop between the two middle electrodes is amplified by a voltage amplifier with a high input impedance. The output voltage  $e_o$  is proportional to impedance changes  $\Delta Z$  that arise from thoracic volume changes due to respiration and from blood volume changes due to the pumping heart. Figure 142.4 shows the curves for  $\Delta Z$  and  $dZ/dt$ —the former being proportional to respiratory volume changes and the latter to blood flow.

**Figure 142.5** Electrode positions and typical waveforms of electrical impedance of thorax measurements.

The noninvasive measurement of blood pressure is important in the diagnosis of many cardiovascular problems. Blood pressure varies—often within seconds—to meet the physiological demands of organs and muscles. Although single blood pressure readings are valuable for entry-level screening, they do not provide as much information as monitoring over a specified length of time, usually 24 hours. The most common body-worn instrument for monitoring blood pressure noninvasively is a battery-powered oscillometric blood pressure monitor. In this monitor an inflatable cuff fits snugly around the upper or lower arm and connects to a pump and pressure transducer. The microcontroller (CPU) triggers the pump periodically to inflate the cuff up to a pressure slightly greater than systolic arterial pressure. It then controls the valve to release the cuff pressure at a rate of about 4 mmHg/s and measures the cuff pressure. The resulting cuff pressure curve consists of a descending curve superimposed by small periodic oscillations. These oscillations start just before the cuff pressure equals systolic pressure, increase rapidly, reach the maximum amplitude at mean arterial pressure, and then gradually decrease. A special algorithm suppresses motion artifacts, extracts systolic and mean pressure ( $P_s$  and  $P_m$ ) from the pressure curve, and calculates the diastolic arterial pressure. The oscillations also permit the calculation of heart rate. Blood pressure data, heart rate, date, and time are displayed on an LCD panel and stored in a data logger. The serial output permits up-loading data to another computer for further evaluations. Figure 142.6 shows the block diagram of this device and an annotated typical oscillometric waveform.

**Figure 142.6** Block diagram and waveforms of noninvasive oscillometric blood pressure monitor.

## 142.3 Summary

This chapter has focused primarily on electrical measurement techniques and examples thereof. Many interesting subjects and instruments could not be covered, such as blood flow and blood volume, partial pressures of oxygen and carbon dioxide, oxygen saturation, glucose, and enzyme concentrations, to mention only a few. The emerging technologies related to home care could not even be mentioned. For further reading the interested reader is referred to the texts listed at the end of the chapter.

## Defining Terms

**Action potential:** The reversible depolarization of the membrane potential of an excitable cell in response to a mechanical, electrical, or chemical stimulus. The peak action potential of a single cell is about 70 mV.

**Common-mode rejection ratio (CMRR):** The ratio of difference-mode gain over common-mode gain in a difference amplifier. It is a measure of the degree to which common-mode signals are suppressed in relation to difference-mode signals.

Global positioning system (GPS) technology is revolutionizing the way people survey and collect geographic data. Originally developed as a navigation and timing system for military applications, GPS has

emerged as a leading technology for geographic information system (GIS) data collection and general mapping. GPS is quickly becoming one of the preferred ways to collect and update information for GIS, CAD-based mapping applications, automated mapping and facilities management (AM/FM) systems, and land information systems (LIS).

The Trimble® GPS Pathfinder Pro XL is a global positioning system that can compute a location in less than a second. The process called differential GPS (DGPS) provides the capability of obtaining accuracies within decimeters. Shown above, a utility crew member uses the Pathfinder Pro XL to record the position of a transmission tower. The GPS receiver automatically records the position data while the crew member records attributes about the tower. With this system, the operators could log the position and attributes of one pole every two minutes, including the travel time between poles. For additional information on GIS basics and how GPS works, see page 1598. (Photo courtesy of Trimble Navigation.)

DURING MOST OF THE 20TH CENTURY there has been a gradual improvement in the quality of surveying equipment. Not only have better steel tapes been manufactured, but also better and better instruments have been made for determining elevation differences and measuring angles or directions. In the last few decades there has been an amazing acceleration in the improvement of instruments.

Electronic distance measuring instruments (EDMIs) were developed with which the surveyor

can precisely measure distances of a few feet or many miles almost instantaneously. Devices called total stations were developed with which distances, directions, and elevations can be determined with equal facility and the values read digitally and recorded electronically.

In the last few years another tremendous change has occurred in the surveying field: the development of the global positioning system (GPS). With this system points on the earth's surface can be located in three dimensions with speed and accuracy by means of radio signals sent out from artificial satellites.

The chapters to follow describe the recent, almost unbelievable changes in the surveying profession and its equipment. Two topics closely related to surveying are also described: remote sensing and geographic information systems (GISs).

Since the mid-1960s the term *remote sensing* has been used to describe images of the earth's surface produced by electronic sensing devices or aerial photographs made from aircraft or satellites. Their purpose is to inventory and monitor the earth's resources. Geographic information systems are computer-based systems which enable users to store, recall, and display data relating to natural and human-made features of the earth's surface such as elevations, property boundaries, streams, forests, agricultural uses, zoning regulations, soil types, utilities, and so on.

Surveyors collect measurements that are often crucial in supporting the needs of others. They serve the public by providing information about property lines, and they serve the civil engineer by providing a proper stakeout of a subdivision or the distances between pillars of a bridge. They may provide a state department with an accurate location for a global positioning system (GPS) base station, to which the department ties all its geographic information system (GIS) surveys. A surveyor may provide the scientific community with the proper distance between two monuments on each side of a fault zone, in order to monitor movement along that fault zone, or may provide the Federal Aviation Agency with proper coordinates of GPS beacons, which aid automated landings of commercial aircraft. In addition, a surveyor provides the Department of Natural Resources with proper heights for the mapping of flood plains.

The importance of the positions, heights, or distances resulting from such measurements makes the surveyor very careful about the quality of the measurement data, let alone the quality of the results computed from those measurements.

### 143.1 Errors

---

Even the most careful surveyor, like anybody else, makes errors—errors in judgment and, not necessarily more important, measurement errors. Some errors cannot be controlled or known about at the moment of measurement collection. Some errors cannot be avoided but should be foreseen and a measurement plan designed accordingly. To distinguish among a variety of classes (and this is not a game of semantics), one speaks of the precision of a measurement, the accuracy of a measurement, the reliability of a measurement, and, last but not least, the "up-to-dateness" of a

measurement. In this respect we have to view a measurement in a very loose manner: we may want to address the accuracy of the measurement itself or the accuracy of the variable directly or indirectly related to the actual measurement. In subsequent sections, each type will be addressed.

A classification which will be addressed in passing is often found in the statistical literature [see Papoulis, (1985), among many others]:

- Stochastic or random errors
- Systematic errors, including periodic errors
- Blunders

Stochastic errors and blunders first come to mind when talking about precision. Systematic errors are often viewed as an issue of accuracy. Reliability addresses all three types of errors. There are cases where a measurement is very precise but not accurate. In other cases the measurement or related outcome may be very precise and accurate, but not reliable. In still other cases a measurement or the resulting parameter may be very precise, very accurate, and very reliable, but not up to date, so that the overall quality is still low.

## 143.2 Precision

---

Precision in the classical sense deals with the repeatability of an experiment. A surveyor measures a distance over and over again, and the outcome differs each time. These are errors of a stochastic nature, which the surveyor does not have any control over. If readings give the same outcome, the surveyor can make them a little more precise, for instance by reading the tape not to the nearest centimeter but to the nearest millimeter, to make the errors (deviations) look random. The surveyor may compute the arithmetic mean of ten distance measurements, according to

$$\hat{\mu} = \frac{\sum_{i=1}^n l_i}{n} \quad (143.1)$$

where  $\hat{\mu}$  is the estimate of the average  $\mu$  based on the sample of  $n$  observations  $l_i$ .

Based on this sample of ten distance measurements  $l_i$ , with  $i = 1, \dots, 10$  ( $n = 10$ ), the surveyor gets an estimate of the average  $\hat{l}$ . Collecting an additional ten distance measurements would undoubtedly give a different average. This is why we say that the calculated average  $\hat{l}$  is just an estimate of the average based on that sample. So, for this example, we have

$$\hat{l} = \frac{\sum_{i=1}^{10} l_i}{10} = \frac{l_1 + l_2 + l_3 + \dots + l_{10}}{10} \quad (143.2)$$

In statistics this average is known as the first moment.

A second interesting quantity to look at is the spread of the  $n$  observations. If the  $n$  observations are close together, we may call our measurement procedure precise. If the  $n$  values vary over a large range, we tend to think of them as the result of a less precise measurement scheme. To

compute the spread, we compute the variations with respect to the estimated mean  $\hat{l}$ . We subtract the estimated average from each individual observation to get a residual  $v_i$ :

$$v_i = l_i - \hat{l} \quad (143.3)$$

If we counted how many observations happen to fall within a specified range, we would obtain an histogram, as in [Fig. 143.1](#).

**Figure 143.1** Histogram of  $n$  observations  $l_i$ .

If we add all the squared residuals and divide the sum by  $n - 1$ , we obtain an estimate of the standard deviation  $\hat{\sigma}$ . [We do not divide by  $n$  since we already extracted one piece of information from the sample of  $n$  observations: the estimate of the mean (and we used this estimate to compute the spread).] The sample variance  $\hat{\sigma}^2$  is the square of the sample standard deviation. We have for the sample standard deviation

$$\hat{\sigma} = \sqrt{\frac{\sum_{i=1}^n v_i^2}{n - 1}} \quad (143.4)$$

and for the sample variance

$$\hat{\sigma}^2 = \frac{\sum_{i=1}^n v_i^2}{n - 1} \quad (143.5)$$

In statistics the variance is also known as the second moment.

### 143.3 Law of Propagation of Errors

Often one is interested not so much in the standard deviation of the individual observations (say, those ten distance measurements), but in the standard deviation of the variable  $x$  computed from

those  $n$  observations. Differentially small errors will propagate according to the rules of total and partial derivatives of multivariate calculus. An error  $dl_i$  in an observation  $l_i$  will propagate into the vector of variables  $x_j$  as an error  $dx_j$  according to

$$dx_j = \sum_{i=1}^n \frac{\partial x_j}{\partial l_i} dl_i \quad (143.6)$$

For all  $u$  variables  $x_j$  ( $j = 1, \dots, u$ ), we have

$$\begin{aligned} dx_1 &= \frac{\partial x_1}{\partial l_1} dl_1 + \dots + \frac{\partial x_1}{\partial l_n} dl_n \\ dx_2 &= \frac{\partial x_2}{\partial l_1} dl_1 + \dots + \frac{\partial x_2}{\partial l_n} dl_n \\ &\vdots \\ dx_u &= \frac{\partial x_u}{\partial l_1} dl_1 + \dots + \frac{\partial x_u}{\partial l_n} dl_n \end{aligned} \quad (143.7)$$

or, in matrix form,

$$\vec{dx} = \mathbf{J}_{ji} \vec{dl} \quad (143.8)$$

where the matrix  $\mathbf{J}_{ji}$  is the so-called Jacobian.

If we collect all standard deviations of the observations into a matrix  $\Sigma$ , the standard deviations of the variables  $x_j$  are computed from

$$\begin{aligned} \Sigma_x &= \vec{dx} \vec{dx}^T \\ &= \mathbf{J}_{ji} \vec{dl} (\mathbf{J}_{ji} \vec{dl})^T \\ &= \mathbf{J}_{ji} \vec{dl} \vec{dl}^T \mathbf{J}_{ij} \\ &= \mathbf{J} \Sigma_l \mathbf{J}^T \end{aligned} \quad (143.9)$$

where  $\mathbf{J}^T$  is the transpose of the Jacobian in Eq. (143.8).

$\Sigma$  represents the variance/covariance matrix of the variables. Consequently, for the observations  $l_i$ , the matrix  $\Sigma_l$  is

$$\Sigma_l = \begin{bmatrix} \sigma_{l_1 l_1} & \sigma_{l_1 l_2} & \cdots & \sigma_{l_1 l_n} \\ \sigma_{l_2 l_1} & \sigma_{l_2 l_2} & \cdots & \sigma_{l_2 l_n} \\ \vdots & \vdots & \cdots & \vdots \\ \sigma_{l_n l_1} & \sigma_{l_n l_2} & \cdots & \sigma_{l_n l_n} \end{bmatrix} \quad (143.10)$$

In Eq. (143.10)  $\sigma_{l_i l_i}$  is the variance, as in Eq. (143.5). So we have

$$\sigma_{l_i l_i} = \sigma_{l_i}^2 \quad (143.11)$$

In Eq. (143.11)  $\sigma_{l_i l_j}$  is the covariance. From the covariance, the so-called correlation coefficient  $\rho_{l_i l_j}$  can be computed:

$$\rho_{l_i l_j} = \frac{\sigma_{l_i l_j}}{\sqrt{\sigma_{l_i}^2 \sigma_{l_j}^2}} \quad (143.12)$$

The values of the correlation coefficient will range between  $-1$  and  $1$ . Values close to  $1$  indicate high positive correlation, or that an error in quantity  $l_i$  will cause an error of equal sign and size in quantity  $l_j$ . Likewise, values close to  $-1$  indicate that an error in  $l_i$  will cause an error with opposite sign in quantity  $l_j$ . In general, we have

$$-1 \leq \rho_{l_i l_j} \leq +1 \quad (143.13)$$

In surveying we strive for uncorrelated observations, meaning that  $\sigma_{l_i l_j}$  is equal to zero. This results in a diagonal variance/covariance matrix  $\Sigma_l$  for the observations.

**Example: Standard Deviation of the Sample Mean.** To compute the standard deviation of the sample mean  $\hat{\mu}$ , we have to apply the law of propagation of errors. For the error in the sample mean, we have from Eq. (143.1)

$$d\hat{\mu} = \sum_{i=1}^n \frac{\partial \hat{\mu}}{\partial x_i} dx_i = \frac{1}{n} \sum_{i=1}^n dx_i \quad (143.14)$$

This leads to the variance of the sample mean

$$\hat{\sigma}_{\hat{\mu}}^2 = n \frac{1}{n^2} \hat{\sigma}_{x_i}^2 = \frac{1}{n} \hat{\sigma}_{x_i}^2 \quad (143.15)$$

or, for the standard deviation of the sample mean,

$$\hat{\sigma}_{\hat{\mu}} = \sqrt{\frac{\sum_{i=1}^n v_i^2}{n(n-1)}} \quad (143.16)$$

## 143.4 Statistical Testing

---

We can test the individual observation against an arbitrary number or against the sample mean. Since the possible outcomes of an experiment, including the values of their sample means and sample standard deviations, are limitless, we work with normalized observations  $l_i^n$ :

$$l_i^n = \frac{l_i - \hat{\mu}}{\hat{\sigma}} \quad (143.17)$$

The advantage of the normalized observations is that the expected outcome of the mean is equal to zero, and the standard deviation of the normalized observations is equal to 1. Tables are available in the statistical literature to test any normalized observation against any value.

The probability that an observation lies in the interval  $[a, b]$  is readily computable:

$$\begin{aligned} P(a \leq l_i \leq b) &= P\left(\frac{a - \hat{l}}{\hat{\sigma}} \leq \frac{l_i - \hat{l}}{\hat{\sigma}} \leq \frac{b - \hat{l}}{\hat{\sigma}}\right) \\ &= P\left(\frac{a - \hat{l}}{\hat{\sigma}} \leq l_i^n \leq \frac{b - \hat{l}}{\hat{\sigma}}\right) \\ &= P\left(l_i^n \leq \frac{b - \hat{l}}{\hat{\sigma}}\right) - P\left(l_i^n \leq \frac{a - \hat{l}}{\hat{\sigma}}\right) \end{aligned} \quad (143.18)$$

Assuming that the standard deviation of a distance measurement is 5 cm and the sample mean is 38.95 m, the probability that an individual observation will fall between 38.90 and 39.10 m is

$$\begin{aligned} P(38.90 \leq l_i \leq 39.05) &= P\left(\frac{38.90 - 38.95}{0.05} \leq \frac{l_i - 38.95}{0.05} \leq \frac{39.05 - 38.95}{0.05}\right) \\ &= P(-1 \leq l_i^n \leq +2) \\ &= P(l_i^n \leq +2) - P(l_i^n \leq -1) \\ &= 0.9772 - 0.1587 = 0.8185 \\ &= 81.85\% \end{aligned} \quad (143.19)$$

Similarly, the probability that the sample mean lies in an interval  $[a, b]$  is computed according to Eqs. (143.16) and (143.18):

$$\begin{aligned}
 P(a \leq \mu_i \leq b) &= P\left(\frac{a - \hat{\mu}}{\sigma_{\hat{\mu}}} \leq \frac{\mu_i - \hat{\mu}}{\sigma_{\hat{\mu}}} \leq \frac{b - \hat{\mu}}{\sigma_{\hat{\mu}}}\right) \\
 &= P\left(\frac{a - \hat{\mu}}{\sigma_{\hat{\mu}}} \leq \mu_i^n \leq \frac{b - \hat{\mu}}{\sigma_{\hat{\mu}}}\right) \\
 &= P\left(\mu_i^n \leq \frac{b - \hat{\mu}}{\sigma_{\hat{\mu}}}\right) - P\left(\mu_i^n \leq \frac{a - \hat{\mu}}{\sigma_{\hat{\mu}}}\right)
 \end{aligned} \tag{143.20}$$

Given the example of ten distance measurements, we first realize that the standard deviation of the mean is, using Eq. (143.15),

$$\sigma_{\hat{\mu}} = \frac{\sigma_{l_i}}{\sqrt{n}} = \frac{5 \text{ cm}}{\sqrt{10}} = 1.6 \text{ cm} \tag{143.21}$$

Knowing that the standard deviation of the mean of the ten distance measurements is 1.6 cm and the sample mean is 38.95 m, the probability that the mean will fall between 38.94 and 38.97 m is

$$\begin{aligned}
 P(38.94 \leq \mu_i \leq 38.97) &= P\left(\frac{38.94 - 38.95}{0.016} \leq \frac{\mu_i - 38.95}{0.016} \leq \frac{38.97 - 38.95}{0.016}\right) \\
 &= P(-0.625 \leq \mu_i^n \leq +1.250) \\
 &= P(\mu_i^n \leq +1.250) - P(\mu_i^n \leq -0.625) \\
 &= 0.8944 - 0.2659 = 0.6285 \\
 &= 62.85\%
 \end{aligned} \tag{143.22}$$

Actually, various tests have to be distinguished, depending on the type of variable investigated and whether its standard deviation is considered to be known or unknown [Hamilton, 1964]. When the standard deviation is known, we invoke a normalized test, as in the example above. For tests of variables with unknown sample standard deviation, we use the Student's  $t$ -test. Under these circumstances the mean would fall within the specified limits with a probability of

$$\begin{aligned}
P(38.94 \leq \mu_i \leq 38.97) &= P\left(\frac{38.94 - 38.95}{0.016} \leq \frac{\mu_i - 38.95}{0.016} \leq \frac{38.97 - 38.95}{0.016}\right) \\
&= P(-0.625 \leq \mu_i^t \leq +1.250) \\
&= P(\mu_i^t \leq +1.250) - P(\mu_i^t \leq -0.625) \\
&= 0.877 - 0.274 = 0.603 \\
&= 60.3\%
\end{aligned} \tag{143.23}$$

To test individual observations and errors attached to them, two tests are available: the normalized residual test, as part of the B-method of statistical testing [Baarda, 1968], and the  $\tau$ -test, as proposed by Pope [1976].

## Normalized Residual Test

The first test computes the normalized residual according to

$$w_i = -\frac{v_i}{\sigma_{v_i}} \tag{143.24}$$

At a specified significance level  $\alpha_0$ , the residuals  $v_i$  of the observations  $l_i$  are tested in the following standardized way:

$$|w_i| < \sqrt{F_{1-\alpha_0;1,\infty}} \tag{143.25}$$

with  $F$  the related critical value of the  $F$ -statistic for one degree of freedom. It should be noted that Eq. (143.24) only holds for uncorrelated observations. For the more general case of correlated observations, one is referred to Baarda [1968]. The multidimensional test on the sum of the squared residuals is

$$\frac{\hat{\sigma}_0}{\sigma_0} < \sqrt{F_{1-\alpha_0;r,\infty}} \tag{143.26}$$

where  $\sigma_0$  and  $\hat{\sigma}_0$  are the a priori and a posteriori variances of unit weight, respectively, and where

- $r$  = the number of degrees of freedom (generally the difference between the number of observations and the number of parameters to be estimated from the observations)
- $\alpha$  = the significance level of testing for  $r$  degrees of freedom

For the estimation of the mean (one parameter) from ten distance measurements, we would have  $r = n - 1 = 10 - 1 = 9$  .

## Tau-test

The  $\tau$ -test avoids the cumbersome computations of the variance/covariance matrix of the residuals [Pope, 1976] needed in the denominator in Eq. (143.24). The standard deviation of the residual  $\sigma_{v_i}$  is approximated by

$$\sigma_{v_i} \cong \sqrt{\frac{n-u}{n}} \sigma_{l_i} = \sqrt{\frac{r}{n}} \sigma_{l_i} \quad (143.27)$$

## Testing of Variances

For tests of variables of a quadratic nature, such as the variance, we use the so-called  $\chi^2$ -test. The probability that the standard deviation lies in the interval  $[a, b]$  is readily computable from

$$\begin{aligned} P(a \leq \sigma_{l_i}^2 \leq b) &= P\left(\frac{1}{a} \geq \frac{1}{\sigma_{l_i}^2} \geq \frac{1}{b}\right) \\ &= P\left(\frac{r\hat{\sigma}^2}{a} \geq \frac{r\hat{\sigma}^2}{\sigma_{l_i}^2} \geq \frac{r\hat{\sigma}^2}{b}\right) \\ &= P\left(\chi_{r;\alpha_0/2}^2 \geq \chi^2 \geq \chi_{r;1-\alpha_0/2}^2\right) \\ &= 1 - \alpha_0 \end{aligned} \quad (143.28)$$

In our example, we compute that our standard deviation falls, with a probability of 95%, in the interval

$$\left[ \sqrt{\frac{r\hat{\sigma}^2}{\chi_{r;\alpha_0/2}^2}} \leq \sigma \leq \sqrt{\frac{r\hat{\sigma}^2}{\chi_{r;1-\alpha_0/2}^2}} \right] \quad (143.29)$$

with the substituted values

$$\left[ \sqrt{\frac{9 \cdot 25}{19.02}} \leq \sigma \leq \sqrt{\frac{9 \cdot 25}{2.70}} \right] \quad (143.30)$$

or

$$[3.44 \text{ cm} \leq \sigma \leq 9.13 \text{ cm}] \quad (143.31)$$

For testing ratios of two squared estimates of the same (squared) variable we use the  $F$ -test.

Consult **Chapter 148** and the statistical literature for more details.

From statistical tables for normally distributed data (see the statistical literature for the definition of a normal distribution), it can be seen that, for instance, 95% of the observations fall in the region  $[-1.96\sigma, +1.96\sigma]$ . However, in 2.5% of the cases we may expect to have an observation which is more than  $1.96\sigma$  away from its mean. This is a good observation (it belongs to the distribution just described) but will likely be removed from the data set. If we make such an "error," we speak of an *error of the first kind*, or the so-called producer's error (e.g., a TV manufacturer erroneously rejects a good although deviating specimen). However, if this data set contained a systematic error, such an outlier may be an observation belonging to a set of observations for which the systematic error had been removed. The surveyor is, in this sense, a producer as well: a producer of survey results who does not want to erroneously reject good data. On the other hand, the erroneous acceptance of false data is an *error of the second kind*, or the consumer's error (e.g., a person purchasing a TV accepts a faulty specimen that erroneously slipped through the manufacturer's testing procedures). The client of the surveyor should be most worried about this type of error. However, the surveyor generally serving the public or any other client has to design the measurements in such a way as to minimize these types of errors, or at least the effect of errors of the second kind. The latter type of error brings us to the notions of accuracy and reliability.

## 143.5 Accuracy

---

Assume that a surveyor measures a distance very diligently (the proper tension is applied, temperature corrections are being applied, and so forth), but because of an earlier breakage the tape was repaired, resulting in an even 50 millimeters missing. All distances (assuming that all distances measured are shorter than one tape length) will have outcomes which are highly repeatable (the  $\hat{\sigma}_{\hat{\mu}}$  is very small); however, all distances will be 50 millimeters too long. The surveyor got inaccurate results despite a very precise measurement procedure. Inaccuracy is the deviation of the measurement outcomes from the "real" or "true" value of the quantity the surveyor tried to measure. (The adjectives *real* and *true* are in quotes because it can be easily argued that the true value of, say, a distance will never be known, since any measurement process will only provide us with a sample mean, never the true value.)

A dangerous but widespread practice is to increase the standard deviations of the measurements (remember, the standard deviations reflect precision or repeatability, not accuracy) by a factor of 2 to 10 in order to catch any inaccuracies caused by mismodeling, uncalibrated instrumental errors, setup errors, warming-up effects on a tripod that cause it to torque, personal errors, and so on. So we have

$$\sigma_{\text{accuracy}} = c \cdot \sigma_{\text{precision}} \quad (143.32)$$

with

$$2 \leq c \leq 10 \text{ or larger} \quad (143.33)$$

The preferred procedure is to apply any correction to the observations, such as the personal

equation of the surveyor who experiences a consistent delay in the triggering of a chronometer between the moment a star crosses a cross wire and the moment of an audible time signal. Similarly, it is better to strive for the correct atmospheric setting on a total station, rather than increasing the standard deviation of the directional/angular measurements.

Despite all the precautions, the surveyor wants, on behalf of the client, to have insight into the size of any inaccuracies that may be avoided by following certain measurement procedures as part of an overall network of measurements. This leads us to the notion of reliability.

## 143.6 Reliability

---

Having calibrated the survey equipment, having applied temperature corrections, and so on, the surveyor is able to assure himself and the client about the size of the error (inaccuracies) that can be detected with a certain probability under the given circumstances. This is often subject to a cost-versus-effect analysis.

### Internal Reliability

To be able to detect distance measurement errors of 10 cm with a probability of 80%, one has to evaluate the distance measurements as an intricate part of the overall network design. Increasing the probability from 80% to 90% will increase the cost of the survey. Similarly, the ability to detect errors smaller than 10 cm with a probability of 80% will also considerably increase the cost of the survey. This is an issue of *internal reliability*: what size measurement error is detectable with what probability? Such errors are referred to as *marginally detectable errors* (MDE). The marginally detectable error is denoted by a nabla ( $\nabla$ ).

$\lambda_0$  denotes the distance between the normal distribution under the hypothesis ( $H_0$ ) that the observation belongs to this distribution, and the distribution corresponding to the alternative hypothesis ( $H_a$ ) (see Fig. 143.2). In the statistical literature one can find tables or graphs depicting  $\lambda_0$  as a function of the level of significance  $\alpha_0$  and the power of the test  $\beta_0$  [Baarda, 1968, p. 21–26]. Common values for  $\alpha_0$  and  $\beta_0$  are 5% and 80%, respectively. It can be shown that for uncorrelated observations the marginally detectable error is

$$\nabla_o l_i = \frac{\sigma_{l_i}^2}{\sigma_{v_i}} \sqrt{\lambda_0(\alpha_0, \beta_0)} \quad (143.34)$$

Following are three sets of examples for values of  $\alpha_0$  and  $\beta_0$ :

1.  $\lambda_0 = 11.70[(2.58 + 0.84)^2]$  for  $\alpha_0 = 0.01$  (1%) and  $\beta_0 = 0.80$  (80%). The alternative distribution is shifted by  $\sqrt{11.70} = 3.42$  units.
2.  $\lambda_0 = 7.84[(1.96 + 0.84)^2]$  for  $\alpha_0 = 0.05$  (5%) and  $\beta_0 = 0.80$  (80%). The alternative distribution is shifted by  $\sqrt{7.84} = 2.80$  units.
3.  $\lambda_0 = 10.50[(1.96 + 1.28)^2]$  for  $\alpha_0 = 0.05$  (5%) and  $\beta_0 = 0.90$  (90%). The alternative distribution is shifted by  $\sqrt{10.50} = 3.24$  units.

**Figure 143.2** The one-dimensional test of the normal standardized variable  $w$ , shown for hypothesis  $H_0$  and alternative hypothesis  $H_a$ .

If we apply Eq. (143.34) to the example of section 143.2 (ten uncorrelated distance measurements), we may be able to detect an error of 17.5 cm ( $= 25 \cdot 2.8/4$ ) with a probability of 80% (and level of significance 5%) if  $\sigma_l = 5$  cm and the standard deviation of the residuals is  $\sigma_v = 4$  cm.

## External Reliability

Rather than the size of the marginally detectable error, we are more interested in the effect of the MDE on the actual results computed from the measurements. Repeating Eq. (143.8), we assume that variables  $x_j$  depend on the measurements  $l_i$  according to

$$d\vec{x} = J_{ji} d\vec{l} \quad (143.35)$$

The influence of a marginally detectable error of the size of  $\nabla l_{(i)}$  on the variables  $x_j$  can be computed from

$$\nabla \vec{x} = J_{ji} \nabla \vec{l}_{(i)} \quad (143.36)$$

It should be noted that the parentheses around the subscript  $i$  denote that the vector  $\nabla l_{(i)}$  in Eqs.

(143.34) and (143.36) contains all zeros except for the  $i$ th observation for which the influence on all variables  $x_j$  is computed.

Surveyors design networks to minimize the influence of MDEs in the observations. For classical terrestrial networks this leads to designs avoiding triangles with small angles. Survey resection problems with small top angles lead to large MDEs with large negative effects on the positional accuracy for the point to be resected. In modern surveying using the global positioning system (GPS), bad DOPs (see **Chapter 149** for an explanation) lead similarly to large MDEs in the GPS observables. In these cases precise and accurate measurements may lead to highly unreliable results because of the system's incapability to flag errors of small magnitudes. Large errors in the GPS network positions may go undetected as a result [see (FGCC, 1984) and (FGCC, 1989)].

## 143.7 Actuality

---

Precise, accurate, and reliable measurements and the resulting maps may be worthless if they tend to represent locations of a network in a highly dynamic environment. Leveled heights referring to some vertical datum in an area of large annual subsidence may be worthless. Maps showing property boundaries or a GIS land use database for an area where the land use rapidly changes soon become worthless also.

The vector  $\vec{x}_j$  of results should be time-tagged and reflect the epoch  $t_0$  at which the situation is reflected:

$$\vec{x}_j = \vec{x}_j(t_0) \quad (143.37)$$

Models may be available to represent the time history of the vector  $\vec{x}_j$ . Transformation parameters are capable of expressing the current result vector  $\vec{x}_j(t)$  as a function of the result vector at reference epoch  $t_0$ . In this case, a Jacobian matrix  $\Phi$  will relate the state of  $x_j(t)$  at  $t$  to the state of  $x_j(t_0)$  at  $t_0$ :

$$\begin{aligned} d\vec{x}(t) &= \frac{\partial \vec{x}(t)}{\partial \vec{x}(t_0)} d\vec{x}(t_0) \\ &= \Phi_{t,t_0} d\vec{x}(t_0) \end{aligned} \quad (143.38)$$

with the state transition matrix being

$$\Phi(t, t_0) = \begin{pmatrix} \frac{\partial x_1(t)}{\partial x_1(t_0)} & \frac{\partial x_1(t)}{\partial x_2(t_0)} & \cdots & \frac{\partial x_1(t)}{\partial x_u(t_0)} \\ \frac{\partial x_2(t)}{\partial x_1(t_0)} & \frac{\partial x_2(t)}{\partial x_2(t_0)} & \cdots & \frac{\partial x_2(t)}{\partial x_u(t_0)} \\ \vdots & \vdots & \cdots & \vdots \\ \frac{\partial x_u(t)}{\partial x_1(t_0)} & \frac{\partial x_u(t)}{\partial x_2(t_0)} & \cdots & \frac{\partial x_u(t)}{\partial x_u(t_0)} \end{pmatrix} \quad (143.39)$$

Analytic expressions for the behavior of a set of coordinates as a function of time may be available. These functions may have the character of polynomials or may reflect more realistic (geo)physically or geometrically oriented time behavior.

## Journals and Organizations

The latest results from research of statistical applications in geodesy, surveying, mapping, and photogrammetry are published in a variety of journals.

The following are two international magazines under the auspices of the International Association of Geodesy, both published by Springer-Verlag (Berlin/Heidelberg/New York):

*Bulletin Géodésique*

*Manuscripta Geodetica*

Geodesy- and geophysics-related articles can be found in:

American Geophysical Union, Washington, DC: *EOS* and *Journal of Geophysical Research*

Royal Astronomical Society, London: *Geophysical Journal International*

Statistical articles related to kinematic GPS can be found in:

Institute of Navigation: *Navigation*

Many national mapping organizations publish journals in which recent statistical applications in

geodesy/surveying/mapping/photogrammetry are documented:

American Congress of Surveying and Mapping:

*Surveying and Land Information Systems*

Cartography and Geographic Information Systems

American Society of Photogrammetry and Remote Sensing: *Photogrammetric Engineering & Remote Sensing*

American Society of Civil Engineers: *Journal of Surveying Engineering*

Deutscher Verein für Vermessungswesen: *Zeitschrift für Vermessungswesen*, Konrad Wittwer Verlag, Stuttgart

The Canadian Institute of Geomatics: *Geomatica*

The Royal Society of Chartered Surveyors: *Survey Review*

Institute of Surveyors of Australia: *Australian Surveyor*

Worth special mention are the following trade magazines:

*GPS World*, published by Advanstar Communications, Eugene, OR

*P.O.B. (Point of Beginning)*, published by P.O.B. Publishing Company, Canton, MI

*Professional Surveyor*, published by American Surveyors Publishing Company, Arlington, VA

*Geodetical Info Magazine*, published by Geodetical Information & Trading Centre bv., Lemmer, the Netherlands

National mapping organizations such as the U.S. National Geodetic Survey (NGS) regularly make software available (free and at cost). Information can be obtained from:

National Geodetic Survey

**Elevation** is the distance above or below a specified reference surface. In engineering and surveying the surface most commonly used to reference elevation is the geoid. The geoid is defined as an equipotential surface that closely approximates **mean sea level**. However, the geoid and mean sea level surfaces are not coincident. They may be separated by a meter or more at any specific location.

By definition, the potential due to gravity is equal at all points on the geoid, and the force of gravity is perpendicular to the geoid at all points. The geoid is an undulating, irregular surface that is affected by density variations within the earth. The geoid is not readily defined by mathematical equations. The mathematical ellipsoid used as a **datum** surface for geodetic position can approximate the geoid, but the ellipsoid and geoid will be separated by up to 100 meters or more for a mean global fit. [Figure 144.1](#) illustrates the general relationship between the geoid and some approximating geodetic ellipsoid.

**Figure 144.1** Relationship between geoid and approximating geodetic ellipsoid.

## 144.1 Measures of Elevation and Height

The vertical distance referenced to the geoid is called an orthometric **height** (elevation),  $H$ . Orthometric height is measured along the plumb line. A height referenced to the ellipsoid is called an *ellipsoidal height*,  $h$ . Ellipsoidal height is measured along the normal to the ellipsoid. Geoid height,  $N$ , is the distance between the geoid and the ellipsoid measured along the normal to the ellipsoid. Neglecting the deviation between the plumb line and the ellipsoidal normal, the geoid height is related to the orthometric and ellipsoidal heights by the equation

$$h = H + N$$

Thus, Fig. 144.2 shows a negative geoid height, which is typical in the U.S.

**Figure 144.2** Illustration of negative geoid height.

Equipotential surfaces (level surfaces) are not parallel to another. The distance between the surfaces decreases toward the earth's north pole. Each level surface has a different gravity potential relative to the geoid that can be expressed as a geopotential number measured in terms of geopotential units: 1 geopotential unit (gpu) = 1000 gal-meters. As an expression of height, the geopotential number (a potential) is constant for a given level surface, whereas the orthometric height decreases for a given level surface proceeding toward the pole. The change in orthometric height can be calculated using the formula found at the end of this chapter. Geopotential numbers can be converted to distance units of height. One possible type of height is defined by dynamic height,  $H_d$ , given as

$$H_d = \frac{\text{GPN}}{g_n}$$

where GPN is the geopotential number of the point and  $g_n$  is the value of gravity calculated on the ellipsoid at  $45^\circ$  latitude using a standard gravity formula.

## 144.2 Deflection of the Vertical

A **vertical** or plumb line is perpendicular to the geoid and therefore parallel to the direction of gravity. A normal line is perpendicular to the ellipsoid. Because the geoid and ellipsoid are generally not parallel, a vertical line and a normal line are not coincident for most points on the earth's surface. The deflection of the vertical is the angle between these two lines at a point on the earth's surface. Figure 144.3 illustrates the definition of the deflection of the vertical. The deflection of the vertical is generally resolved into two components:  $\xi$  in the N-S direction and  $\eta$  in the E-W direction.

**Figure 144.3** Definition of the deflection of the vertical.

The geoid has been modeled regionally for the U.S. by the National Geodetic Survey (NGS). The model is known as GEOID93, and it is distributed as a computer program by NGS. The program estimates geoid height differences with a reported accuracy of 10 cm (one standard deviation) over lengths of approximately 100 km.

### 144.3 Vertical Datums

Vertical datums are defined for the purpose of specifying the elevation of points with respect to the geoid. There are two relevant continental vertical datums within the U.S.: the National Geodetic Vertical Datum of 1929 (NGVD 29) and the North American Vertical Datum of 1988 (NAVD 88).

The National Geodetic Vertical Datum of 1929 (NGVD 29) is a long-used reference for mean sea level in the U.S. NGVD 29 was the product of a 1929 general adjustment of the U.S. and Canadian vertical control networks. The 1929 adjustment was based, in part, upon the assumption

that the local mean sea level at the tide stations used in the adjustment was equal (same equipotential surface). This is not a valid assumption since the elevation of mean sea level varies from the Atlantic coast to the Pacific coast of the U.S. This distortion of the vertical datum caused the official name of the 1929 datum to change from "Sea Level Datum of 1929" to "National Geodetic Vertical Datum of 1929" in 1976. Other distortions, including those from upheaval and subsidence of the earth's crust, are present in the NGVD 29; however, it remains a datum of reference for the U.S.

A new adjustment of the vertical datum for North America has been completed recently. This project, known as the North American Vertical Datum of 1988 (NAVD 88), is a least-squares readjustment of over 600 000 **benchmarks** across the North American continent, resulting in a better approximation of the geoid. The project includes re-leveling of approximately 83 000 km of first-order vertical control within the U.S. Leveling data from Canada, Mexico, and Central America is included in the adjustment. The result of the NAVD 88 adjustment is a computer database of vertical control stations and elevations across the U.S. This improved model of the geoid is beneficial for the determination of orthometric heights using Global Positioning System (GPS)–derived heights above the ellipsoid.

The change in elevations from NGVD 29 to NAVD 88 varies, depending upon the area of the country involved. The relative elevation between existing benchmarks will change only by a few millimeters. The absolute elevation of benchmarks may change by as much as a few decimeters. An elevation correction constant between the two datums will suffice for most project areas.

## 144.4 Elevation Measurement

---

Elevation may be measured by several methods. Some of these methods measure elevation directly, for example, GPS satellite ranging, photogrammetric aerotriangulation, inertial surveying methods, and barometric altimetry. Some of these methods measure the difference in elevation from a reference benchmark to the point to be determined, for example, ordinary and precise differential leveling and trigonometric leveling. It should be noted that the direct methods typically must also be referenced to benchmarks so that translations and rotations can be performed to establish the proper relationship to the elevation datum. Thus the difference in elevation is, fundamentally, the important value to be measured.

### Ordinary Differential Leveling

Differential leveling is a very simple process based on the measurement of vertical distances from a horizontal line. Elevations are transferred from one point to another through the process of using a leveling instrument to read a rod held vertically on, first, a point of known elevation and, then, on the point of unknown elevation.

A single-level setup is illustrated in [Fig. 144.4](#). The known elevation of the backsight point is transferred vertically to the line of sight by adding the known elevation and the backsight rod reading. The elevation of the line of sight is the height of instrument, HI. By definition, the line of sight generates a horizontal plane at the instrument location when the telescope is rotated on the

vertical axis. The line-of-sight elevation is transferred down to the unknown elevation point by turning the telescope to the foresight, subtracting the rod reading from the height of instrument. Note that the difference in elevation from the backsight station to the foresight station is determined by subtracting the foresight rod reading from the backsight rod reading.

**Figure 144.4** Using differential leveling to measure elevation.

A level route consists of several level setups, each one carrying the elevation forward to the next foresight using the differential leveling method. A level route is typically checked by closing on a second known benchmark or by looping back to the starting benchmark. At the closing benchmark, closure = computed elevation – known elevation. Since differential leveling is usually performed with approximately equal setup distances between turning points, the level route is adjusted by distributing the closure equally to each setup:

$$\text{Adjustment} = \left( -\frac{\text{Closure}}{n} \right) \text{ per setup}$$

where  $n$  is the number of setups in the route. When a network of interconnected routes is surveyed, a least-squares adjustment is warranted.

## Precise Leveling

Precise leveling methods are used when the highest accuracy is required for engineering and surveying work. Instruments used in precise leveling are specifically designed to obtain a high degree of accuracy in leveling. Improved optics in the telescope, improved level sensitivity, and carefully calibrated rod scales are all incorporated into the differential leveling process.

Typically when performing precise leveling, a method of leveling called *three-wire leveling* is used. This involves reading the center cross hair as well as the upper and lower "stadia" cross hairs.

The basic process of leveling is the same as ordinary differential leveling, except that the three cross hair readings are averaged to improve the precision of each backsight and foresight value.

Another method that can be used to improve the precision of the level rod reading is to use an optical micrometer on the telescope. The optical micrometer is a rotating parallel-plate prism attached in front of the objective lens of the level. The prism enables the observer to displace the line of sight parallel with itself and set the horizontal cross hair exactly on the nearest rod graduation. The observer adds the middle cross hair rod reading and the displacement reading on the micrometer to obtain a precise rod reading to the nearest 0.1 millimeter.

## Trigonometric Leveling

Trigonometric leveling is a method usually applied when a total station is used to measure the slope distance,  $S$ , and the vertical angle,  $\alpha$ , to a point. Assuming the total station is set up on a station of known elevation and the height of instrument, HI, and reflector, HR, are measured, the elevation of the unknown station is

$$V = S \sin \alpha$$
$$P_{\text{Elev}} = A_{\text{Elev}} + \text{HI} + V - \text{HR}$$

The precision of trigonometric elevations is determined by the uncertainty in the vertical angle measurement and the uncertainty caused by atmospheric refraction effects. For long lines the effects of earth curvature and atmospheric refraction must be included.

## Instruments

### Altimeters

Surveying altimeters are precise aneroid barometers that are graduated in feet or meters. As the altimeter is raised in elevation, the barometer senses the atmospheric pressure drop. The elevation is read directly on the face of the instrument. Although the surveying altimeter may be considered to measure elevation directly, best results are obtained if a difference in elevation is observed by subtracting readings between a base altimeter kept at a point of known elevation and a roving altimeter read at unknown points in the area to be surveyed. The difference in altimeter readings is a better estimate of the difference in elevation, since the effects of local weather changes, temperature, and humidity that affect altimeter readings are canceled in the subtraction process. By limiting the distance between base and roving altimeters, accuracies of 3 to 5 feet are possible. Other survey configurations utilizing low and high base stations or leap-frogging roving altimeters can yield good results over large areas.

### Level Bubble Instruments

Level bubble instruments, or spirit levels, contain a level vial with a bubble that must be centered to define a horizontal plane. Field instruments consist of three main components: a telescope to

define a line of sight and magnify the object sighted, a level vial attached to the telescope to define the orientation of the instrument with respect to gravity, and a leveling head to tilt and orient the instrument.

All level bubble instruments are designed around the same fundamental relationships. These relationships are as follows:

- The axis of the level bubble (or compensator) should be perpendicular to the vertical axis.
- The line of sight should be parallel to the axis of the level bubble.

When these instrument adjustment relationships are true and the instrument is properly set up, the line of sight will sweep out a horizontal plane that is perpendicular to gravity at the instrument location.

Instruments that use a level bubble to orient the axes to the direction of gravity depend on the bubble's sensitivity for accuracy. Level bubble sensitivity is defined as the central angle subtended by an arc of one division on the bubble tube. The smaller the angle subtended is, the more sensitive the bubble is to dislevelment. A bubble division is typically 2 millimeters long, and bubble sensitivity typically ranges from 60 seconds to 1 second.

### **Builder's Level**

The builder's level typically is less precise than other instruments in this category, but it is one of the most inexpensive and versatile instruments that is used by field engineers for construction layout. In addition to being able to perform leveling operations, it can be used to turn angles, and the scope can be tilted for inclined sights.

### **Transit**

Although the primary functions of the transit are for angle measurement and layout, it can also be used for leveling because it has a bubble attached to the telescope. However, the field engineer should be aware that the transit may not be as sensitive and stable as a quality level.

### **Dumpy Level**

The engineer's dumpy-type level has been the workhorse of leveling instruments for more than 150 years. Even with advancements in other leveling instruments, such as the automatic level and the laser, the dumpy may still be the instrument of choice in a construction environment because of its stability.

### **Automatic Compensator Levels**

Compensators were developed about 50 years ago and incorporated into field levels. The compensator is a free-swinging pendulum arrangement in the optical path that maintains a fixed relationship between the line of sight and the direction of gravity. If the instrument is in adjustment, the line of sight will be maintained as a horizontal line. Compensator instruments are extremely fast to set up and level.

## **Laser Levels**

A laser level uses a laser beam directed at a spinning optical reflector. The reflector is oriented so that the rotating laser beam sweeps out a horizontal reference plane. The level rod is equipped with a sensor to detect the rotating beam. By sliding the detector on the rod, a vertical reading can be obtained at the rod point. Laser levels are especially useful on construction sites. The spinning optics can also be oriented to produce a vertical reference plane.

## **Digital Levels**

Digital levels are electronic levels that can be used to more quickly obtain a rod reading and make the reading process more reliable. The length scale on the level rod is replaced by a bar code. The digital level senses the bar code pattern and compares it to a copy of the code held in its internal memory. By matching the bar code pattern, a rod reading length can be obtained. Digital levels are available for ordinary and precise leveling applications.

## **Level Rods**

In addition to the chosen leveling instrument, a level rod is required to be able to transfer elevations from one point to another. The level rod is a graduated length scale affixed to a rod and held vertically on a turning point or benchmark. The scale is read to obtain the vertical distance from the point to the line of sight.

Level rods are graduated in feet, inches, and fractions; feet, tenths, and hundredths; or meters and centimeters. Rods used in ordinary leveling may be multipiece extendable rods with graduations marked directly on the rod material or on a metal strip affixed to the rod for support. Rods used in precise leveling are one-piece rods with a stable invar metal graduated scale supported under constant tension by the rod. A precise rod can be calibrated for changes in length caused by temperature.

Accurate field leveling work is also aided by the use of rod targets, rod levels, and stable turning point pins when required.

# **144.5 Systematic Errors**

---

## **Earth Curvature**

The curved shape of the earth results in the equipotential surface through the telescope departing from the horizontal plane through the telescope as the line of sight proceeds to the horizon. This effect makes actual level rod readings too large by the following approximate relation,

$$C = 0.0239D^2$$

where  $D$  is the sight distance in thousands of feet.

## **Atmospheric Refraction**

The atmosphere refracts the horizontal line of sight downward, making the level rod reading

smaller. The typical effect of refraction is equal to about 14% of the effect of earth curvature. Thus, the combined effect of curvature and refraction is approximately

$$(C - r) = 0.0206D^2$$

## Instrument Adjustment

If the geometric relationships defined in the preceding discussion are not correct in the leveling instrument, the line of sight will slope upward or downward with respect to the horizontal plane through the telescope. The test of the line of sight of the level to ensure that it is horizontal is called the "two-peg test." If the line of sight is inclined, the difference in elevation obtained from the two setups will not be equal. Either the instrument must be adjusted, or the slope of the line of sight must be calculated. The slope is expressed as a collimation factor,  $C$ , in terms of rod reading correction per unit of sight distance. It may be applied to each sight by the following:

$$\text{Corrected rod reading} = \text{Rod reading} + (C_{\text{Factor}} \cdot D_{\text{Sight}})$$

In ordinary differential leveling, these effects are canceled in the field procedure by always setting up so that the backsight distance and foresight distance are equal. The errors are canceled in the subtraction process. If long unequal sight distances are used, the rod readings should be corrected for curvature and refraction and for collimation error.

## Orthometric Correction

When long, precise level routes are surveyed, it is necessary to account for the fact that the equipotential surfaces converge as the survey proceeds north. The correction to be applied for convergence of equipotential surfaces at different elevations can be calculated by

$$\text{Correction} = -0.0053 \sin 2\phi H \Delta\phi_{\text{rad}}$$

where  $\phi$  is the latitude at the beginning point,  $H$  is the elevation at the beginning point, and  $\Delta\phi$  is the change in latitude from the southerly station to the northerly station expressed in radians.

## Defining Terms

**Benchmark (BM):** A benchmark is a permanent object having a mark of known elevation, for example, a cross chiseled on a boulder or a concrete monument with an embedded brass disk.

**Datum:** Any quantity or set of such quantities that may serve as a reference or basis for calculation of other quantities.

**Datum sea level:** An equipotential surface passing through a specified point at mean sea level that is used as a reference for elevations; a surface passing through mean sea level at certain specified points to which elevations determined by leveling are referred. Note that, in general, the latter surface is not an equipotential surface.

**Elevation:** The distance, measured along the direction of gravity (plumb line), between a point and a reference equipotential surface, usually the geoid.

**Height:** The distance, measured along a perpendicular, between a point and a reference surface, for example, the ellipsoidal height; the distance, measured along the direction of gravity, between a point and a reference surface of constant geopotential, for example, the orthometric height. Note that the term *elevation* is preferred when the geoid is used as the reference surface.

**Mean sea level:** The arithmetic mean of elevations (heights) of the water's surface observed hourly over a specific 19-year cycle.

**Vertical:** The direction in which gravity acts.

Taping • Stadia • Subtense Bar • Electronic Distance Measurements

#### **R. Ben Buckner**

*Surveying Education Consultant*

When the word **distance** is used in surveying without qualification, it is usually construed to mean *horizontal distance*<sup>3/4</sup>that is, a distance either measured directly along a horizontal line or measured along a slope and then mathematically projected to the horizontal. If linear measurements along other alignments are being discussed, they are given specific designations, such as *slope distance* or *vertical distance* (elevation difference).

Since ancient times, direct distance measurements have been made using lines, cords, ropes, rods, chains, tapes, and other such devices. Distances have also been measured indirectly, employing stadia and other tacheometric methods, as well as trigonometrically, using a combination of distance and angle measurements and calculations. Technological advances during the second half of the 20th century have created changes in the methods used to measure many distances. During the 1960s and 1970s most surveyors made a gradual shift from the chain and tape to electronic distance systems that measure distances with light waves or microwaves. During the 1980s this trend continued into using *total station* systems, which measure both distances and angles electronically and process the combined measurements into a Cartesian coordinate form for the survey points. Thus, many distances are determined by computations from the coordinate positions rather than by direct measurements. Most recently, there has been a trend toward using the global positioning system (GPS) for precise determination of positions of points, and these positions are then used to indirectly determine the distances between survey points. Eventually, GPS may replace both the tape and electronic distance instruments (including the total station) for most surveying measurements, including angles, elevations, and distances. GPS is covered in **Chapter 149**.

An overview of the concepts of direct and indirect distance measurements will be given here. The geometric, electronic, and other physical principles of the measurement systems will not be discussed—only the basic measuring procedures and the appropriate corrections needed to achieve optimum accuracy.

## 145.1 Fundamentals of Distance Measurement

---

### The Need for Corrections

Measurements, whether of distance or any other quantity, are but estimates of the magnitude of the quantity. Few initial readings (observations) in surveying contain the accuracy desired without some correction for systematic errors. Much of the consideration regarding measurements is not so much of how to operate the instruments and perform the calculations to reduce the data, but of how to identify and evaluate the magnitude of the corrections that must be applied to the readings. The "true value," theoretically, is always equal to the reading plus the corrections. That is,  $T = R + \sum C$ . If the true value is known and the reading is needed to achieve this,  $R = T - \sum C$ . Application of this basic concept will be illustrated subsequently. The following sections discuss the typical methods of determining survey distances.

### Taped Measurements

Most **taped** measurements are made using a steel tape, usually of 100 ft length. The tape is laid along a line between points and stretched tight. If the distance desired is longer than the length of the tape, more than one tape length is employed, the ends of the tape being marked with taping pins (sometimes called "arrows"). Alignment of the ends of the tape, to keep the tape on a straight line, is achieved either by hand signals from a rear tapeman or by a transit or theodolite centered over one of the two ends of the line.

The tape is either (1) allowed to rest on the ground surface ("fully supported"), or (2) suspended throughout its length ("end supported"), with the distance mark on the tape being transferred to the ground using plumb bobs at one or both ends. In the former case corrections for ground slope must be made, the slope having been measured using other instruments, such as hand levels, clinometers, or theodolites. In the latter case the two ends of the tape are usually held near the same elevation as determined by hand levels or clinometers. End-supported taping requires corrections for the sag of the tape, but not the slope. In either type of taping, corrections must usually be made (depending on the accuracy desired) for calibrated length, changes from calibration temperature to field temperature, and tension (if different from that used when calibrated).

Steel tapes are made in various lengths other than 100 feet, for example, 25 meters, 50 meters, 200 feet, and so forth. The principles in the use and correction of readings is much the same for various tapes, regardless of length.

Tapes are also made of other materials, including woven fiber and invar (a nickel-steel alloy). The fiber ("cloth") tapes are used only for rough measurements, and there is usually no attempt to apply corrections to the readings. In contrast, invar tapes are used for precise surveys, such as the establishment of calibration base lines for electronic distance measurements, and all applicable corrections must be made. The use of these more precise tapes and the less precise "cloth" tapes will not be covered here.

## Tacheometric Measurements

The most common method in the **tacheometry** category uses the stadia. Such measurements are made through the telescope of a transit, theodolite, or level instrument. The measurement is achieved by observing where the two horizontal stadia hairs, viewed through the telescope, strike a graduated rod held vertically on a survey point. The difference between the two readings is a function of the separation of the stadia hairs, the focal length of the telescope, and the distance between the instrument and the rod. When the line of sight is other than horizontal, the vertical or zenith angle must also be considered. Stadia distances are generally accurate to only about one or two feet for normal sight distances, and thus there is little need to be concerned about corrections to the data.

The subtense bar is another tacheometric instrument. The principle employs the measurement of a precise horizontal angle between two distinct targets at the two ends of the bar. The bar is erected on a tripod to lie horizontally and perpendicular to the line of sight, centered over a survey point. The theodolite is centered over the other end of the line. The separation between the two targets defining the bar is a known length (commonly two meters). Using this known length and the measured angle, the horizontal distance is computed by trigonometry. For relatively short distances (up to perhaps 150–200 feet) this method can exceed the accuracy of both taping and electronic measurements, and thus it is very useful for measurements across busy streets or other small, inaccessible places. Because this method lacks error due to slope corrections, it is useful for measuring to high places, such as to tops of buildings. Its application is probably overlooked nowadays because of the ease of using electronic instruments—even though it is more accurate for short measurements, has advantages similar to those of electronic distance measurement, and avoids slope corrections.

## Electronic Distance Measurements

The most common of **electronic distance instruments** (EDMs) employs a visible light beam reflected off a system of reflectors called *retroprisms*. The light beam is reflected onto the instrument for interpretation of the wavelengths and partial wavelengths comprising the double-slope distance between the instrument and the reflector. Older EDMs are individual units, measuring distance only. The most modern version is part of the aforementioned total station system, which also measures angles. Whether an individual unit or part of a more complete survey system, the principle of EDM operation is much the same.

A common fallacy, particularly when using total station systems, is that the measurements are free of errors. As has been mentioned, there is error in any measuring system. When measuring with an EDM, the surveyor must be concerned with calibration, just as with any distance-measuring system. For example, the electronic center of the instrument may not be located precisely along the same vertical line as the geometric center plumbed over the ground station. The instrument will usually have this small, constant instrument error, as well as an error that is proportional to the distance measured (often called the *parts per million* or *PPM correction*). Also, the reflector has a "constant," and the optical plummets in the tribrach mounting systems can be out of adjustment. The magnitude and sign of these errors should be determined by field tests for best accuracy. EDMs are also affected by variations in atmospheric pressure and temperature. Microwave measurements are also affected by humidity.

All measurements made with EDMs are "slope" measurements between the center of the EDM and the reflector, and thus must be corrected to horizontal using measured vertical or zenith angles, and also instrument heights.

## Indirect Computational Methods

Distances are commonly determined by **indirect measurement** using trigonometric principles. The most common of these methods are *intersection* and the coordinate *inverse*. Using intersection, a distance is measured (or computed from other measurements) and angles measured to a common point from the two ends of this *base line*, which forms an oblique triangle. The unknown sides of the triangle are solved using the sine law. Using the inverse, the computation starts with determination of the departure (difference in  $x$  coordinates) and the latitude (difference in  $y$  coordinates) of the line defined by the two coordinate points. The distance is the hypotenuse of a right triangle whose sides are the departure and latitude of the line; it is determined using the Pythagorean theorem. Many variations of these indirect methods occur in practice and usually involve some variation of an oblique triangle solution or the coordinate inverse. Some of these concepts are discussed in section 145.2.

Photogrammetry is another such method for determining distances. After proper orientation of a stereomodel, coordinates can be read from it, from which distances can be determined by the same inverse computation as discussed earlier. The science of photogrammetry is briefly explained in **Chapter 147**.

## Approximate Methods

As mentioned, all measurements are estimates of an unknown quantity. The method used to determine a distance is chosen as dictated by the accuracy needed. The above methods are typical for measurements where accuracies of a few millimeters to a fraction of a meter are desired. If less accuracy is needed, a range finder, a measuring wheel, pacing, the odometer on a bicycle or vehicle, map scaling, digitizing coordinates from maps (with subsequent "inverse" computations), or even visual estimation can be used. Range finders are optical instruments that might be considered under the classification of tachymetric methods. These instruments and the calibrated measuring wheel or an odometer on a bicycle have accuracy comparable to the stadia method. A car odometer can yield an accuracy of perhaps 50 to 100 feet in a mile, if calibrated. The accuracies of the other approximate methods depend on several factors, particularly the map scale and the map accuracy. It must be emphasized that digitizing from maps cannot yield high accuracy of positions or distances. Even for a fairly large-scale map, the accuracy of such methods is seldom better than 10 feet.

## 145.2 Applications and Calculations

---

### Taping

The variables affecting a horizontal distance using a tape, with their correction equations, are as

follows:

1. *Calibration.*  $C_l = l_t - l_r$  . The correction per tape length is the actual ("true") length of the tape minus the nominal length (reading between end marks). The actual length is determined by calibration at some observed temperature, tension, and support condition, comparing the tape's length with an accurate base line.
2. *Temperature.*  $C_t = K_t l (t_f - t_s)$  . Temperature correction is given by the coefficient of thermal expansion multiplied by the nominal length of the tape times the difference between the field temperature and the calibration temperature. The correction is positive when  $t_f > t_s$  , since the tape expands when the temperature is warmer. The value for  $K_t$  is 0.00000645 units per unit per °F (the constant is 0.0000116 if °C is used).
3. *Pull (tension).*  $C_p = (P_f - P_s) l \div AE$  . This is the correction for tension if the field tension is different from the standardization tension. In this equation  $A$  is the cross-sectional area of the tape and  $E$  is the modulus of elasticity, which is 29000000 lb/in.<sup>2</sup>. Care should be taken that the field tension appears first in the equation, subtracting the standardization tension from it.
4. *Sag.*  $C_s = -(w^2 l) / (24 P^2)$  . This is the correction for sag, where  $w$  and  $l$  are the weight and length of the portion of the tape suspended between supports. The pull,  $P$ , is the actual tension on the tape. It has no relationship to the standardization pull.
5. *Slope.*  $C_g = -(v^2) / (2l)$  . This is the correction for grade or slope, which, when added to the slope length, yields the horizontal distance. This correction is applied when the tape ends are not at the same elevation. In this equation  $s$  is the slope distance being corrected and  $v$  is the elevation difference between the two tape ends at this length. This equation is inexact but is accurate for slopes less than about 10%. The Pythagorean theorem can be used in any case, solving the equation  $h^2 + v^2 = s^2$  for the horizontal distance,  $h$ .

Slope corrections can also be made trigonometrically if the vertical angle (slope angle) is measured with a clinometer or theodolite. For a line of any length  $H = S \cos \gamma$  , where  $H$  is the horizontal distance,  $S$  is the slope distance, and  $\gamma$  is the vertical angle. ( $H = S \sin \gamma$  if the zenith angle is used.)

The alignment error is generally not corrected in practice, but instead rendered negligible by the process of careful tape alignment.

For many errors the correction can usually be made for one tape length and then multiplied by the number of tape lengths, as long as the condition causing the error does not vary between tape lengths. This generally always applies to the calibration, temperature, and tension errors, and sometimes to the sag and slope errors.

Taping problems are of two types: (1) calculation of the horizontal distance between two established points, and (2) calculation of the reading to be observed to establish a given distance. The theory of systematic errors is applicable in making taping corrections. Solving for the true value  $T = R + \sum C$  is the first type of problem. If "layout" is required, then the reading  $R = T - \sum C$  is solved from the given value and the corrections.

The following problems will utilize a calibrated 100 ft tape, found to be 99.992 feet long at 70°F, 15 lb tension, fully supported. It has a cross-sectional area of 0.006 in.<sup>2</sup> and weighs 2.2 lb. In the solutions TL is the number of tape lengths.

**Example 145.1.** A reading of 458.97 feet is observed between two points when the field temperature is 40°F, along a 4% slope. Find the correct horizontal distance.

**Solution.** There are three systematic errors to consider: calibration, temperature, and slope.

$$C_L = (l_t - l_r)TL = (99.992 - 100.000)4.59 = -0.037 \text{ ft}$$

$$C_t = K_t l(t_f - t_s)TL = 0.00000645(100)(40 - 70)4.59 = -0.089 \text{ ft}$$

$$C_g = -\frac{v^2}{2l}TL = [4^2 \div (2 \times 100)](4.59) = -0.367 \text{ ft}$$

$$\sum C = -0.493 \text{ ft} , \text{ from which } T = 458.97 - 0.49 = 458.48 \text{ ft} .$$

**Example 145.2.** A distance of 200.00 feet is to be laid out along a horizontal alignment. The tape must be suspended for 60 feet of one of its tape lengths. A tension of 30 lb is used for this portion of the layout; otherwise, 15 lb is used. Temperature is 70°F.

**Solution.** There are three systematic errors to consider: calibration, tension, and sag.

$$C_L = (l_t - l_r)TL = (99.992 - 100.000)2.00 = -0.016 \text{ ft}$$

$$C_p = (P_f - P_s)l \div AE = (30 - 15)60 \div (0.006 \times 29 \times 10^6) = 0.005 \text{ ft}$$

$$C_s = -\frac{w^2 l}{24P^2} = -(2.2 \times 0.6)^2 60 \div (24 \times 30^2) = -0.005 \text{ ft}$$

$$\sum C = -0.016 \text{ ft} \quad \text{and} \quad R = 200.00 - (-0.016) = 200.016 = 200.02 \text{ ft}$$

It is seen in this example that the added tension for the end-supported part of the taping compensated for the sag effect.

## Stadia

Stadia hairs or lines are placed in most telescopes so that the *stadia interval factor*,  $K$ , equals 100. This makes it convenient to measure distance, merely subtracting the two stadia hair readings and multiplying by 100 to get the distance between the rod and the theodolite. Since the stadia hairs are each read with a precision of approximately  $\pm 0.01$  feet at ordinary distances, the precision of a stadia distance is no better than  $\pm 1.0$  feet, with variation according to how clearly the rod is seen and how carefully it is read.

Old *external focusing* telescopes had a *stadia constant*,  $C$ , of about one foot. The instruments of recent generations, however, being *internally focusing*, eliminate this constant.

For a horizontal sighting  $H = KI + C$ , where  $K$  and  $C$  are as defined earlier and  $I$  is the rod intercept (difference between the upper and lower rod readings). When vertical angles are involved,  $H = KI \cos^2 \gamma + C \cos \gamma$ , where  $\gamma$  is the vertical angle.

**Example 145.3.** A theodolite has a stadia interval factor of 100. The reading on the upper stadia hair is 7.54 ft and on the lower hair it is 3.66 ft. The zenith angle to the center crosshair is  $96^{\circ}36'30''$ . What is the horizontal distance, to the nearest foot?

**Solution.** Assuming the stadia constant to be zero and converting the zenith angle to vertical angle, the appropriate values in the preceding equation are as follows:

$$H = 100(7.54 - 3.66) \cos^2(-6^{\circ}36'30'') = 383 \text{ ft}$$

## Subtense Bar

After the horizontal angle is measured between the two end targets on the bar, the horizontal distance is computed from  $H = \frac{1}{2}b \cot \alpha/2$ , where  $b$  is the bar length and  $\alpha$  is the horizontal angle. Using a bar of the usual 2-meter length, the value of  $H$  is in meters, since half the bar length is 1 meter.

Note that the distance is *always* horizontal, since the horizontal angle is the same regardless of the relative elevation of the two points. Thus, no slope corrections are ever required.

In practice, a 1" theodolite is generally used and several angles are measured, in order to achieve adequate precision.

**Example 145.4.** A 1" theodolite is used to measure the angle between the targets on the ends of a 2-meter subtense bar. The mean of six independent readings of the angle is  $0^{\circ}45'46''$ . Compute the horizontal distance between the theodolite and the bar.

$$H = \frac{1}{2}b \cot \alpha/2 = \frac{1}{2}(2 \text{ meters}) \cot (0^{\circ}45'46''/2) = 75.110 \text{ m}$$

## Electronic Distance Measurements

Although the instrument constant is in practice, usually adjusted to zero whenever the instrument is serviced, calibration can discover a small instrument constant. Similarly, the reflector constant is usually keyed into the instrument by the surveyor and thus compensated, but a field test of reflector constants can discover slight discrepancies between what the manufacturer states the constant to be and what it actually is. Likewise, the atmospheric errors are generally keyed into the instrument after reading the temperature and pressure but are sometimes overlooked, and an old setting remains in the instrument. The surveyor should be aware of these possible error sources. The following example assumes that the atmospheric errors and reflector constant have been handled properly.

**Example 145.5.** An EDM has been calibrated using a four-station NGS base line, and errors are found as follows:  $C = +0.003$  meters and  $P = +0.000\,004\,56$ , where  $C$  is the constant correction and  $P$  is the "scale" correction, which may be expressed as 4.56 PPM. The zenith angle along the line is  $88^{\circ}34'42''$ . The observed slope distance is 1789.783 meters. What is the corrected

horizontal distance?

**Solution.** The PPM correction is  $+0.00000456(1789.8 \text{ m}) = +0.0082 \text{ m}$ . The constant correction is  $+0.003 \text{ m}$ . The corrected slope distance is

$$\begin{aligned} 1789.783 + 0.008 + 0.003 &= 1789.794 \text{ m} \\ H &= 1789.794 \sin 88^\circ 34' 42'' = 1789.243 \text{ m} \end{aligned}$$

An additional correction might be necessary if the reflector is not set at the same height as the EDM because, if so, the measured slope angle does not correspond to the slope of a line connecting the two ground points. The correction involves adjusting the measured zenith angle before calculating the horizontal distance as done previously.

## Defining Terms

**Distance:** A linear value, either measured or computed. Unless qualified otherwise, it is understood to lie along the horizontal. The observed distance is considered inaccurate until corrected for systematic errors caused by instruments, nature, or other sources.

**Electronic distance instrument:** An instrument that measures distances using reflected light waves or microwaves.

**Indirect measurement:** A measurement that has been computed from other measurements, usually employing trigonometric principles.

**Tacheometry:** A distance-measuring procedure that involves measuring intervals between cross hairs on a rod or angles subtended between marks on a bar of known length, or a similar indirect method.

**Tape:** A surveying instrument used to measure distance by stretching it, end for end, along a line between points.

## Directions

---

- 146.1 Angles
- 146.2 Meridians
- 146.3 Direction
- 146.4 Back Bearing and Back Azimuth
- 146.5 Applications

**Bon A. Dewitt**  
*University of Florida*

In surveying, direction is the term used to denote the course or heading of a line. Here, a line is defined by its end points, giving it a magnitude (length) and direction, much like a vector. By convention, direction is specified in terms of angles and is separated into horizontal and vertical components. This chapter deals primarily with the horizontal component of direction within the context of **plane surveys**. In **geodetic surveys**, where the earth's curvature is taken into account, the fundamental concepts of direction still apply, though their use in subsequent calculations is far more complex.

Traditionally, direction has been established through astronomic observations or compass readings. Although these traditional approaches may still be applicable in certain situations, the **Global Positioning System** is now preferred due to its accuracy and convenience.

### 146.1 Angles

---

Angles form the basis for quantification of direction. There are several conventions available for specification of angular units. In the U.S., the sexagesimal system is currently the most commonly used for surveying applications. In this system a full circle is divided into 360 degrees, with further subdivisions into minutes and seconds. Sixty minutes is equivalent to one degree and sixty seconds is equivalent to one minute. Thus, an angle can be expressed in degrees ( $^{\circ}$ ), minutes ( $'$ ), and seconds ( $''$ ), much like time is expressed in terms of hours, minutes, and seconds. As an alternative, angles can be expressed in terms of degrees and a decimal fraction thereof, though this is not conventional surveying notation.

Other angular units are available, such as radians, grads, or mils [see Eq. (146.1) for unit equivalents]. The radian is a dimensionless unit that utilizes the ratio of the length of a circular arc to its radius to express the magnitude of the subtended angle. The grad (or *gon*) is a unit of measure in the centesimal system (widely used in Europe) that corresponds to 1/400 of a full circle. The mil is an angular unit corresponding to 1/6400 of a full circle and is used by the U.S. military,

primarily in artillery applications. These three alternate systems are decimal based, as opposed to the base-sixty approach of the sexagesimal system.

$$\text{Right angle} = 90 \text{ degrees} = 100 \text{ grads} = 1600 \text{ mils} = \pi/2 \text{ radians} \quad (146.1)$$

**Horizontal angles** are measured in a plane perpendicular to the direction of gravity. There are many types of horizontal angles, such as angles to the right (clockwise) or left (counterclockwise), interior angles, exterior angles, and deflection angles. Figure 146.1 shows the various types of angles. Angles to the right—with the backsight, occupied, and foresight points specified—are recommended for modern surveys due to their applicability to electronic data collectors and computer software. An illustration of this notation is given in Fig. 146.1(a), where point A is the backsight, B is occupied, and C is the foresight point.

**Figure 146.1** Illustration of various types of horizontal angles.

**Vertical angles** are measured in a plane perpendicular to the horizontal. There are two fundamental types of vertical angles: zenith angles and altitude angles. A zenith angle (or zenith distance), illustrated in Fig. 146.2 (a), is the angle from the observer's zenith direction to the target. Zenith angles range from  $0^\circ$  to  $360^\circ$ , with  $90^\circ$  and  $270^\circ$  corresponding to the direction of the horizon in the direct and reverse position, respectively. An altitude angle, illustrated in Fig. 146.2 (b), is the angle from the observer's horizon to the target. Altitude angles above the horizon are called *elevation angles* and are considered positive by convention, whereas those below the

horizon are called *depression angles* and are considered negative.

**Figure 146.2** Profile view illustrating two types of vertical angles.

Surveyors determine angles with instruments known as *transits* or *theodolites*. Both instruments enable the user to perform the same basic functions, that is, to measure or establish horizontal and vertical angles. Generally, theodolites are more accurate and precise than transits, though this is not always the case. Some modern theodolites have electronic angle-reading systems and are incorporated into **total stations**, which also have the capability of measuring distances electronically. Total stations are particularly convenient due to their ability to feed recorded data directly to a field computer.

## 146.2 Meridians

In order to specify the horizontal component of direction, it is first necessary to specify the reference meridian. A meridian is an imaginary line that is selected as the nominal north-south indicator in the observer's horizon plane. It can be based on any one of several references: geodetic, astronomic, magnetic, grid, or assumed.

A geodetic (also called *geographic*) meridian is based on the north and south poles as defined by a particular latitude and longitude reference or graticule. It has been demonstrated that the rotational axis of the earth changes slightly over time, so in essence the geographic graticule is a "snapshot" in time. This reference becomes standardized by virtue of published coordinates for a network of monumented points, based on its definition.

An astronomic meridian is based on the rotational axis of the earth and the direction of gravity. It derives its name from the means by which it is typically established: astronomic observations. The angular difference between astronomic and geodetic meridians is expressed in terms of the Laplace equation. For most practical purposes in plane surveying, this difference is negligible and both meridians are collectively referred to as the "true" meridian.

A magnetic meridian is based on the magnetic north and south poles of the earth. These poles are

distinct from the geographic poles and change appreciably over time. The angle from true north to magnetic north is called the *magnetic declination* and is a function of the observer's location with respect to the poles. The effect of magnetic declination can be quite large—for example, in parts of Alaska, magnetic declination is greater than  $30^\circ$  east.

A map projection is a distorted rendition of a portion of the curved earth's surface on a surface that can be laid out flat. The projection has an inherent  $x, y$  coordinate system, with  $y$  in the general direction of north. In the projection any line parallel to the  $y$  axis is a grid meridian. They are different from the three meridians previously mentioned, in that grid meridians are parallel to each other, whereas the others are not.

Assumed (arbitrary) meridians are chosen for convenience. Here, a direction is arbitrarily specified for a line connecting two survey points. This direction is often chosen so as to approximate some specific meridian; however, no actual observation of a meridian is performed. There is an inherent risk associated with assumed meridians. If one or both of the survey points is lost, the assumed meridian becomes unrecoverable.

## 146.3 Direction

---

In mathematics, polar coordinates are often used to specify the position of a point. Here, the direction of the line from the origin to the point is based on the angle from the positive  $x$  axis, with counterclockwise angles being positive. In surveying, the direction of a line can be expressed either in terms of **bearing** or **azimuth**. Both forms depend on the meridian definition mentioned earlier. No matter which approach is used, it is important to clearly specify the meridian upon which the direction is based.

Bearing of a line is specified as an acute horizontal angle between the line and meridian, along with letters specifying the proper quadrant. It is expressed in the form of the letter N or S, followed by an angle (less than or equal to  $90^\circ$ ), followed by the letter E or W.

Azimuth is specified as the clockwise horizontal angle from the meridian to the line. The angular value is positive and less than  $360^\circ$ . Azimuths are commonly specified from north, though this is not a universally accepted standard. Some applications use azimuths that are referenced from south. Due to this possible ambiguity, one should clearly indicate whether a north or south reference is implied. [Figure 146.3](#) gives examples of bearings and azimuths (from north) for selected lines.

**Figure 146.3** Examples of bearings of selected lines and their equivalent azimuths.

## 146.4 Back Bearing and Back Azimuth

Back bearings are expressions of the opposite direction of a line. The expression is formed by starting with the original (forward) bearing and then changing the "sense" of the letters. An N is changed to an S (or vice versa), and an E is changed to a W (or vice versa); however, the angular value remains the same. For example, if the bearing from point 1 to point 2 is N47°15' W, its back bearing (i.e., the bearing from point 2 to point 1) is S47°15' E.

Back azimuths are also expressions of the opposite direction of a line. The expression is formed by adding 180° to or subtracting 180° from the original (forward) azimuth, keeping in mind that the result must be in the range of 0 to 360°. For example, if the azimuth from point 1 to point 2 is 312°45' , its back azimuth (i.e., the azimuth from point 2 to point 1) is 132°45' .

The foregoing simple relations for back bearings and back azimuths are applicable only to plane surveys of a limited extent, where it can be assumed that all meridians are parallel. In surveys covering a large area, earth curvature and meridian convergence are appreciable factors and therefore a more complicated relation must be used.

## 146.5 Applications

There are many applications in surveying that call for the use of directions. Property surveys, geodetic control surveys, transportation corridor (route) surveys, and topographic surveys are but a few. Most applications involving directions utilize plane trigonometry in the solution.

Computations involving addition and subtraction of angles, sine and cosine laws, right triangle relationships, and sum of angles in a closed polygon are routinely performed.

### Defining Terms

**Azimuth:** An expression for the direction of a line consisting of the clockwise horizontal angle ( $\geq 0^\circ$  and  $< 360^\circ$ ) from one end of the meridian. Azimuths from north are generally used;

however, some conventions employ azimuth from south.

**Bearing:** An expression for the direction of a line consisting of the horizontal angle ( $\leq 90^\circ$ ) that the line makes with the meridian in conjunction with prefixed and postfixed letters that specify the quadrant.

**Geodetic survey:** A survey in which the earth's true three-dimensional shape and gravity field are taken into account.

**Global Positioning System:** A system of satellites and ground receivers that enables users to determine geodetic coordinates of points to a high degree of accuracy. The system is under the control of the U.S. Department of Defense but has been used for civilian applications since the early 1980s.

**Horizontal angle:** An angle that is defined in a plane perpendicular to the direction of gravity.

**Meridian:** In a global context a meridian is the intersection of the plane containing the north pole, the south pole, and the observer's position with the spheroidal figure that approximates the earth. In a local context a meridian is a reference line that defines the north-south direction. This reference can be on a geodetic, astronomic, magnetic, grid, or assumed basis.

**Plane survey:** A survey of limited extent and accuracy in which the earth's surface is assumed to be a plane. This assumption permits the use of plane trigonometry in computations involving coordinates and other parameters.

**Total station:** A device used in surveying that incorporates an electronic theodolite with an electronic distance-measuring instrument and a computer. The device can automatically read and record horizontal and vertical angles and slope distances.

**Vertical angle:** An angle that is defined in a plane parallel to the direction of gravity.

## 147.1 Basic Concepts

---

The term *photogrammetry* refers to the measurement of photographs and images for the purpose of determining the size, shape, position, and other spatial attributes of features appearing in the images. The most common application of this technique is aerial photogrammetry, in which nominally vertical photographs are used to produce topographic maps, which are often used for engineering design and land development. Aerial cameras are made to very exacting tolerances, and whatever small systematic errors may be present in the resulting photographs can be modeled mathematically so that very accurate ground positions and elevations can be inferred from photograph measurements. The mathematical basis of the imaging equations which relate object points (3-D) to image points (2-D) is that of a perspective projection, with a point (actually two points) in the lens assembly serving as the perspective center(s). A terrain point projected into two adjacent frame photographs is shown in [Fig. 147.1](#). The geometric relationship between the image and object spaces may be modeled in *analog* fashion by optical rays or by mechanically gimbaled steel rods. Today it is more commonly modeled mathematically in an *analytical* instrument or possibly in a *softcopy* workstation. Stereo data extraction instruments and systems are shown schematically in [Fig. 147.2](#).

**Figure 147.1** Terrain point projected into two frame photographs.

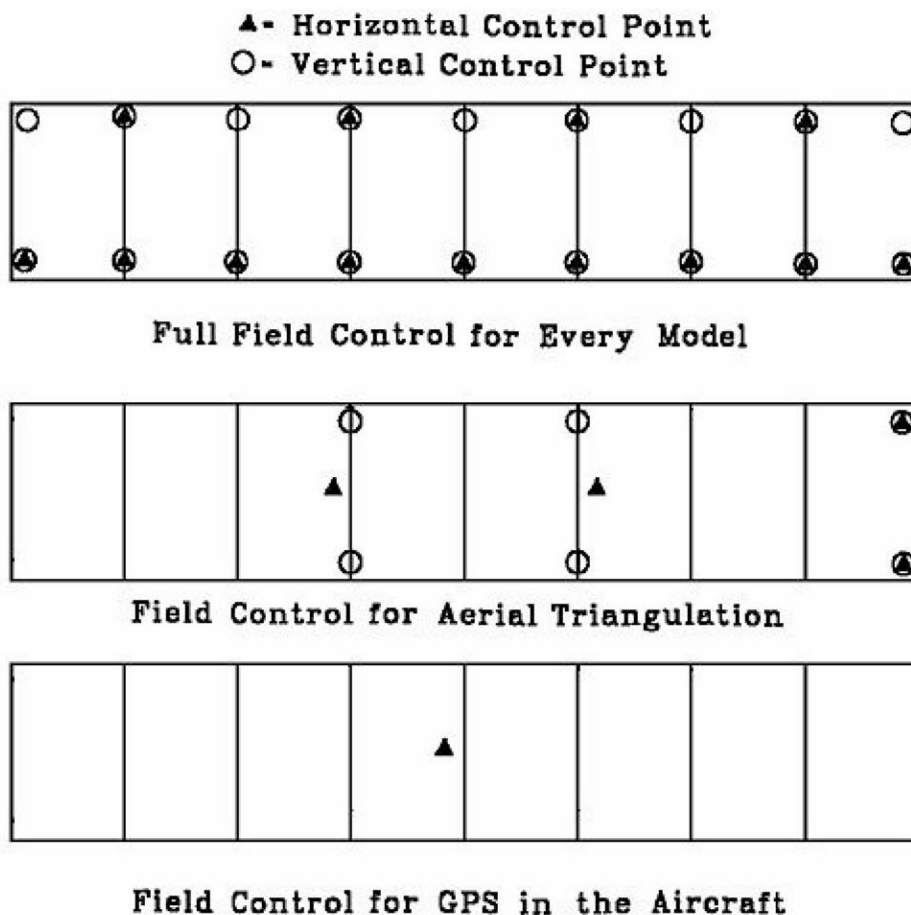

**Figure 147.2** Photogrammetric stereo data extraction systems.

Historically, the production of topographic maps from aerial photographs has been a very labor-intensive operation, beginning with the establishment of *ground control points*, proceeding through *aerial triangulation* to densify the ground control, and culminating in the meticulous tracing of planimetric features from adjacent *stereo pairs* and the tracing of contour lines to depict the shape of the landforms. Control point requirements for several scenarios are shown in [Fig. 147.3](#). In recent years, several trends have emerged which promise to make the mapping process more efficient. The use of GPS, the *global positioning system*, for ground control as well as for

direct observation of the *exposure stations* in the aircraft, is greatly simplifying the preliminary steps in the photogrammetric mapping process. High-level image processing of photographs converted to digital form is also beginning to replace the sometimes tedious operations of point selection, orientation, and even feature extraction.

**Figure 147.3** Variations of control requirements for a strip.

## 147.2 Orientation and Model Setup

Since photographs are inherently two-dimensional representations of a three-dimensional world, it takes a minimum of two photographs of the region of interest, taken from different points of view, to reconstruct the 3-D scene including the topographic landforms. Having the same scene viewed from two different locations gives rise to *parallax*, which our eyes interpret as a depth cue, much the same as in normal binocular vision. In order to position the two photographs of such a stereo pair, they must be aligned in the viewing instrument so that the flight paths coincide. Also, any tilts present in the camera at the instant of exposure must be reintroduced. This process is called *relative orientation*. When the *stereo model* is so oriented, then viewing of the entire overlap area

can be made without misalignments in the "cross-flight" direction, that is, without *y-parallax*.

Following relative orientation, one usually wishes to tie the "local" model coordinates to the object or ground coordinate system. Such a system is either a local (project-specific) Cartesian system, or one of the common map projection systems such as the state plane systems in the U.S. State plane systems are either transverse mercator projections or Lambert conic projections, depending on the shape and orientation of the zone. The process of relating the local model space to the object space with a given coordinate system is referred to as *absolute orientation*.

### 147.3 Data Collection for Topography

---

Terrain data for constructing a topographic map can be collected either in the field or from aerial photographs or other imagery. There is a certain threshold project size, below which it is more economical to collect data directly in the field, and above which it is more economical to first acquire aerial photographs and then collect the terrain data from the stereo photographs. This threshold project size is around 8 hectares (20 acres).

In previous decades, field procedures might have involved a *plane table*. Today field procedures most likely involve a *total station* with an electronic data collector. Such a system can record either raw angles and distances, or point coordinates, along with a point identification and a feature code. Using a total station, data points can be distributed as a *grid*, as points along a series of *cross sections*, or as a collection of random points dictated by the terrain. In both the cross section method and the random point method, field judgment is exercised to collect only significant planimetric or topographic features, or points that represent slope discontinuities. In addition, *break lines* may be collected to enforce sharp breaks in the slope continuity.

Not surprisingly, similar strategies are employed by the photogrammetrist in collecting terrain data on a *stereoplotter* or *digital (softcopy) stereo workstation*. Grids, cross sections, and random point collection are widely used in photogrammetric practice. Such data often take the form of a *digital terrain model (DTM)*, *digital elevation model (DEM)*, *digital height model (DHM)*, or *digital terrain elevation data (DTED)*. The photogrammetrist has other options as well. With the stereo view from above, direct tracing of contour lines is possible. In fact, until recently, this was the principal means of collecting topographic data from aerial photographs. A manually compiled contour map is shown in [Fig. 147.4](#). Another approach involves the collection system analyzing the data on the fly and interacting with the stereo operator to densify regions until all high-spatial-frequency terrain features are determined. This process is referred to as *progressive sampling* and, while intriguing, has never achieved wide acceptance. With the emerging dominance of digital imagery, automated methods of terrain surface extraction by image-processing techniques are gaining widespread use and acceptance. Such *matching* techniques, intended to duplicate the function of the human operator, may need to be tuned and adapted to different scales, terrain types, and image types.

**Figure 147.4** Manually compiled contour map.

Matching techniques often begin by aggregating the fine-resolution digital image into a coarser-resolution image, stopping the process when the aggregated image may be only a few *pixels* on a side. Such a progressive series of image resolutions is called an *image pyramid*. Matching at the coarse resolutions is effectively operating on a low-pass-filtered image, and thus reveals the low-spatial-frequency components of the terrain shape. Operating on the successively finer-resolution images, all the way down to the finest resolution, will reveal successively higher-spatial-frequency components of the terrain shape. Matching can be done by features or by raw grey levels or colors. It can be constrained by known image orientation data, or it can be unconstrained. It can take place in one dimension, as in *epipolar* resampled imagery, or it can take place with areas or area elements, as in *least squares* matching or *vertical line locus (VLL)* matching.

As automated terrain extraction from digital imagery becomes increasingly robust and reliable, other sources of digital imagery, besides scanned aerial photographs, may become very important. In particular, the recent relaxation of security concerns toward former Soviet Union countries has allowed the U.S. government to permit the dissemination of satellite imagery with a pixel size as small as 1 meter for civilian applications. Three commercial systems are currently planned to begin providing such data in the 1- to 3-meter range during 1996 and 1997. Such systems could have an enormous impact on the generation of DEM data in the years ahead. One caution is that the image geometry from such systems will be dynamic and time dependent and will therefore be much more difficult to model mathematically than simple frame aerial photographs. Thus digital softcopy workstations will become a necessity for handling such imagery rather than the relatively simple photogrammetric stereoplotters in wide use today.

A final note on data collection regarding GPS. Up to now field-collected elevations from GPS have been of only limited use. This is because engineers and land developers wish to have elevations in a system referenced to *mean sea level (MSL)*, whereas GPS height data is referenced

to the *ellipsoid* surface. The difference between the ellipsoid surface and the *geoid* surface is referred to as the *geoid undulation* or *geoid separation*. As our maps of geoid undulation become denser and more accurate, it will become increasingly possible to reduce GPS height data to MSL data. Thus another option will emerge for the rapid field collection of elevation data.

## 147.4 Data Processing for Topography

---

Data points collected either by field methods or by photogrammetric methods can be processed in a number of ways to make them useful for design engineers and others. Some systems are designed to work with a grid arrangement of the data points. If the raw data were not collected on such a grid, then the heights at the grid locations must be interpolated. This interpolation may be accomplished by *linear prediction*, by patchwise polynomials, or by a "moving-surface" method. If the data are in grid form, or have already been converted to grid form, then another interpolation task is necessary to generate heights at arbitrary locations. This could also be a moving-surface method, but grids are particularly well suited to techniques such as bilinear interpolation. If the data points are not in a grid, then they are often organized into a *triangulated irregular network (TIN)*. Representing the terrain surface by a TIN usually requires fewer data points than a grid, but there is a penalty in terms of access time. A small set of measured data points is shown in [Fig. 147.5](#), and the generated TIN is shown in [Fig. 147.6](#). The interpolated contours are shown in [Fig. 147.7](#).

**Figure 147.5** Sample random point data set.

**Figure 147.6** TIN generated from points in Fig. 147.5.

**Figure 147.7** Interpolated contours from TIN.

The usual criterion for generating the triangular mesh in a TIN is that the triangles be as nearly equilateral as possible. For any given set of points there is a unique network of triangles, with the points as vertices, that most closely satisfies this criterion. This is called the *Delaunay*

*triangulation*. It may be generated from the data points by several algorithms. One of the simplest is the Watson algorithm outlined on the next page.

1. Create three fictitious points such that the defined triangle includes all of the data points.
2. Pick a data point.
3. Find all existing triangles (in the first pass there is only one, from step 1 above) whose circumscribed circle contains the point.
4. Make the union of all triangles from step 3, forming an "insertion polygon."
5. Destroy all internal edges in the insertion polygon, and connect the current point to all vertices of the polygon.
6. Go back to step 2, pick another point, and proceed until all points have been processed.
7. When done, eliminate any triangle containing a vertex from the three "artificial" points from step 1.

To enforce a break line, one can overlay the break line on the preliminary TIN and introduce new triangles as required to keep the break line continuous.

## 147.5 Data Presentation

---

Topographic data have traditionally been presented as contour lines on a hardcopy map. For engineering design work, presentation scales (i.e., map scales) in the U.S. have been 1:600 (1 inch = 50 feet), 1:1200 (1 inch = 100 feet), or 1:2400 (1 inch = 200 feet). In current practice such data might become a layer in a *geographic information system (GIS)*, and thus there may never be an archival document containing the topographic data. Many GIS systems are able to integrate DEM data, either grid or TIN, better than contour data. This is so because DEM data are more amenable to interpolation and manipulation than contour data. Derived information and products which can be produced from DEM data include volumes and earthwork quantities, flood levels, drainage patterns, arbitrary profiles, unobstructed line-of-sight diagrams, wireframe and shaded perspective views, image draped perspective views, and *orthophotographs*, or differentially rectified images.

Photogrammetry provides the most efficient way to generate topographic data for all but very small projects, where direct measurement in the field may be used. Photogrammetric techniques are undergoing a transition from strictly manual methods to increasingly automated methods. Likewise, there is a trend toward digital softcopy stereo workstations as opposed to the older hardcopy-based analog or analytical stereoplotter. Finally, it seems likely that a new generation of high-resolution commercial satellite imaging systems will gradually supplant film-based photographic methods, at least for small- and medium-scale mapping.

Surveyors collect measurements (observations, data, etc.) for the purpose of determining a wide variety of variables (parameters, unknowns, etc.). These measurements may be distances, directions, angles, look angles, azimuths, elevation angles, height differences, time, and so on. From these observations the surveyor deduces results in terms of parameters, such as coordinates of an intersection point of two boundary lines or the height of a marker on a bridge. Rather than identifying a variety of (classical) survey problems such as point positioning through traversing or height determinations through spirit leveling, this chapter follows a more general approach by discussing a general relationship between observational data and parameters. In section 148.6 an example is presented.

## 148.1 Principles of Multivariate Calculus

---

A general relationship between two classes of variables may exist. One class of variables is denoted by  $l$  and the other by  $x$ . The two classes of variables refer to the two main classes a surveyor deals with: observations or the input data ( $l$ ) and the results or output data ( $x$ ). The variable  $l$  represents a group of  $n$  variables  $l_i$  with  $i = 1, \dots, n$ . The other variable  $x$  represents a group of  $u$  variables  $x_j$  with  $j = 1, \dots, u$ . There exists a functional relationship  $F$  between these two groups of variables. This functional relationship is nothing else than the mathematical model which expresses the assumed interdependency between the variables in question. Realize, though, that it is the surveyor who makes this enormously important judgment call on this mathematical relationship: like a car driver engages a gear, the surveyor engages at a certain moment a

mathematical model, or at least follows the spiritual father of the model provided in terms of some survey software package. The number of functional relationships does not need to be equal to  $n$  or  $u$ ; we may have  $F_k (k = 1, \dots, r)$  relationships. Summarizing, we have

$$F_k = F(l_i, x_j) \quad (148.1)$$

with

$$k = 1, \dots, r \quad (148.2)$$

$$i = 1, \dots, n \quad (148.3)$$

$$j = 1, \dots, u \quad (148.4)$$

A simple example will illustrate. Suppose we observe four pairs of coordinates  $\{X_l, Y_l\}$ , which we assume lie on a circle. So the model  $F_k$  is the equation of a circle, centered at an arbitrary coordinate  $\{X_c, Y_c\}$  with an arbitrary radius  $R$ :

$$F_k = (X_k - X_c)^2 + (Y_k - Y_c)^2 - R^2 \quad (148.5)$$

Geometry dictates that a circle is defined through three points (six coordinates), provided that those three points are not on a line. So four sets of coordinates will not quite fit the "circle" model. Small adjustments to the eight coordinates will be necessary to end up with one unique circle. In addition, we may have to slightly adjust the unknown circle centered at  $\{X_c, Y_c\}$  and its unknown radius  $R$ . We will probably have to slightly adjust any initial guess of these three variables  $\{X_c, Y_c, R\}$  to find the optimum circle passing through those four pairs of coordinates. These small adjustments to the variables  $l$  and  $x$ , which we call  $dl$  and  $dx$ , will make the variables fit the circle model just right. Adding the small corrections  $dl$  and  $dx$  to  $l$  and  $x$  will make the equations  $F_k$  become equal to zero:

$$F_k = F(l_i + dl_i, x_j + dx_j) = 0 \quad (148.6)$$

The problem of finding these hopefully small corrections  $dl_i$  and  $dx_j$  will be made much easier if we linearize the model according to the rules of multivariate calculus:

$$F_k(l_i + dl_i, x_j + dx_j) = F_k(l_i, x_j) + \frac{\partial F_k}{\partial l_i} dl_i + \frac{\partial F_k}{\partial x_j} dx_j + \dots = 0 \quad (148.7)$$

With the wealth of variables in Eq. (148.7),

- $r$  equations  $F_k$
- $n$  variables  $l_i$
- $u$  variables  $x_j$

at hand, it is much more practical to use the tools (vectors and matrices) of linear

algebra.

## 148.2 Principles of Linear Algebra

---

Equation (148.7) can be rewritten in terms of vectors and matrices. Defining the vectors (shown below in transposed form)  $\mathbf{L}$ ,  $\mathbf{X}$ , and  $\mathbf{W}$  and the matrices  $\mathbf{A}$  and  $\mathbf{B}$  according to

$$\mathbf{L}^T = [l_1, l_2, \dots, l_i, \dots, l_n]^T \quad (148.8)$$

$$\mathbf{X}^T = [x_1, x_2, \dots, x_j, \dots, x_u]^T \quad (148.9)$$

$$\mathbf{W}^T = [F_1, F_2, \dots, F_k, \dots, F_r]^T \quad (148.10)$$

and

$$\mathbf{A} = \begin{bmatrix} \frac{\partial F_1}{\partial l_1} & \dots & \frac{\partial F_1}{\partial l_n} \\ \vdots & \dots & \vdots \\ \frac{\partial F_r}{\partial l_1} & \dots & \frac{\partial F_r}{\partial l_n} \end{bmatrix} \quad (148.11)$$

$$\mathbf{B} = \begin{bmatrix} \frac{\partial F_1}{\partial x_1} & \dots & \frac{\partial F_1}{\partial x_u} \\ \vdots & \dots & \vdots \\ \frac{\partial F_r}{\partial x_1} & \dots & \frac{\partial F_r}{\partial x_u} \end{bmatrix} \quad (148.12)$$

Matrix  $\mathbf{A}$  is the Jacobian of the model equations  $F$  with respect to the variables  $l$ , and consists of  $r$  rows and  $n$  columns. Similarly, the matrix  $\mathbf{B}$  is the Jacobian of the model equations  $F$  with respect to the variables  $x$ , and consists of  $r$  rows and  $u$  columns. The vector/matrix notation enables us to shorten Eq. (148.7) to

$$\mathbf{W} + \mathbf{B} d\mathbf{L} + \mathbf{A} d\mathbf{X} + \dots = 0 \quad (148.13)$$

Referring back to our circle fitting example, we have, for instance,

$$d\mathbf{L}^T = [dX_1, dY_1, dX_2, dY_2, dX_3, dY_3, dX_4, dY_4]^T \quad (148.14)$$

$$d\mathbf{X}^T = [dX_c, dY_c, dR]^T \quad (148.15)$$

The matrix element  $A_{3,2}$  (third row, second column) is equal to

$$A_{(\text{row}=3, \text{col}=2)} = \frac{\partial F_3}{\partial Y_c} = -2 \times (Y_3 - Y_c) \quad (148.16)$$

The matrix element  $B_{3,5}$  (third row, fifth column) is equal to

$$B_{(\text{row}=3, \text{col}=5)} = \frac{\partial F_3}{\partial X_3} = 2 \times (X_3 - X_c) \quad (148.17)$$

Matrix **A** is a full matrix; however, the **B** matrix is of the nature

$$\mathbf{B} = \begin{bmatrix} X & X & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & X & X & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & X & X & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & X & X \end{bmatrix} \quad (148.18)$$

with the  $X$ s denoting nonzero elements.

In this example, the running indices  $i, j, k$  [see Eqs. (148.3), (148.4), and (148.2), respectively] have ranges

$$\begin{aligned} i &= 1, \dots, 8 \\ j &= 1, \dots, 3 \\ k &= 1, \dots, 4 \end{aligned} \quad (148.19)$$

denoting eight observations and three parameters to be estimated, all being part of four equations.

### 148.3 Model of Two Sets of Variables, Observations, and Parameters: The Mixed Model

---

The linearized version of Eq. (148.6), Eq. (148.7), demands closer inspection of the definition of all variables involved. The surveyor has the benefit of observed values and approximate values for the parameters; however, they should not be mixed. With subscripts we indicate the nature of the variable. Subscript  $b$  denotes "observed value," subscript 0 denotes "approximate value," and subscript  $a$  denotes the value of the observable quantity or the (unknown) parameter which perfectly fits the model  $F$ .  $\mathbf{V}$  denotes the residual, which is the value that must be added to the observed value  $\mathbf{L}_b$  to obtain the value for  $\mathbf{L}_a$  which perfectly fits the model  $F$ . Similarly,  $\mathbf{X}$  denotes the correction which needs to be added to the approximate values of the parameter  $\mathbf{X}_0$  to obtain the value for the parameter  $\mathbf{X}_a$  which perfectly fits the model  $F$ .

The following steps need to be taken to arrive at the linearized model [Eq. (148.7) or (148.26)], starting from Eq. (148.6) or (148.20), with the linearization around the Taylor point  $\{\mathbf{L}_0, \mathbf{X}_0\}$  :

$$F(\mathbf{L}_a, \mathbf{X}_a) = 0 \quad (148.20)$$

or

$$F(\mathbf{L}_b + \mathbf{V}, \mathbf{X}_0 + \mathbf{X}) = 0 \quad (148.21)$$

$$F(\mathbf{L}_0, \mathbf{X}_0) + \frac{\partial F}{\partial \mathbf{L}}(\mathbf{L}_a - \mathbf{L}_0) + \frac{\partial F}{\partial \mathbf{X}}(\mathbf{X}_a - \mathbf{X}_0) = 0 \quad (148.22)$$

$$\mathbf{W}_0 + \mathbf{B} \times (\mathbf{L}_a - \mathbf{L}_b + \mathbf{L}_b - \mathbf{L}_0) + \mathbf{A} \times (\mathbf{X}_a - \mathbf{X}_0) = 0 \quad (148.23)$$

$$\mathbf{W}_0 + \mathbf{B} \times (\mathbf{V} + \mathbf{L}) + \mathbf{A} \times \mathbf{X} = 0 \quad (148.24)$$

$$\mathbf{A}\mathbf{X} + \mathbf{B}\mathbf{V} + (\mathbf{W}_0 + \mathbf{B}\mathbf{L}) = 0 \quad (148.25)$$

or, arriving at the linearized form of Eq. (148.20),

$$\mathbf{A}\mathbf{X} + \mathbf{B}\mathbf{V} + \mathbf{W} = 0 \quad (148.26)$$

with

$$\begin{aligned} \mathbf{A} &= \frac{\partial F}{\partial \mathbf{X}} \\ \mathbf{B} &= \frac{\partial F}{\partial \mathbf{L}} \\ \mathbf{X} &= \mathbf{X}_a - \mathbf{X}_0 \\ \mathbf{V} &= \mathbf{L}_a - \mathbf{L}_b \\ \mathbf{L} &= \mathbf{L}_b - \mathbf{L}_0 \\ \mathbf{W} &= \mathbf{W}_0 + \mathbf{B}\mathbf{L} \end{aligned} \quad (148.27)$$

In words, the variables denote

$\mathbf{L}_a$  : adjusted observations

$\mathbf{L}_b$  : observed values

$\mathbf{V}$  : residuals

$\mathbf{L}_0$  : approximate observations

$\mathbf{L}$  : residual observations

$\mathbf{X}_a$  : adjusted parameters

$\mathbf{X}_0$  : approximate parameters (initial guess)

$\mathbf{X}$  : unknown correction to parameters

$W_0$  : misclosure vector

$W$  : misclosure vector

$A$  : design matrix (partial derivative matrix for the parameters)

$B$  : partial derivative matrix for the observations

Equation (148.26) is a set of  $r$  equations with  $u$  unknowns. This is an inconsistent set of equations and cannot be solved since often  $r > u$ . The method of Lagrangian multipliers provides a set of  $u$  equations with  $u$  unknowns under the conditions that the sum of the squared residuals is minimum. This leads to a minimum variance estimate for the vector  $\mathbf{X}$  [see, e.g., (Hamilton, 1964; Strang, 1986; and Strang, 1988)]. The unknown vector  $\mathbf{X}$  can be computed from the  $u$  equations with  $u$  unknowns, also known as the "normal equations." Without derivation, the normal equations are

$$\mathbf{A}^T \mathbf{M}^{-1} \mathbf{A} \mathbf{X} + \mathbf{A}^T \mathbf{M}^{-1} \mathbf{W} = 0 \quad (148.28)$$

or, in short,

$$\mathbf{N} \mathbf{X} + \mathbf{U} = 0 \quad (148.29)$$

with

$$\mathbf{N} = \mathbf{A}^T \mathbf{M}^{-1} \mathbf{A} \quad (148.30)$$

$$\mathbf{U} = \mathbf{A}^T \mathbf{M}^{-1} \mathbf{W} \quad (148.31)$$

and

$$\mathbf{M} = \mathbf{B} \mathbf{B}^T \quad (148.32)$$

The model which mixes the observations  $L_a$  and the parameters  $X_a$  can be further generalized, assuming a statistical model (variance/covariance matrix for the observations; see also **Chapter 143**):

$$\Sigma_{L_b} = \begin{bmatrix} \sigma_{l_1 l_1} & \sigma_{l_1 l_2} & \cdots & \sigma_{l_1 l_n} \\ \sigma_{l_2 l_1} & \sigma_{l_2 l_2} & \cdots & \sigma_{l_2 l_n} \\ \vdots & \vdots & \cdots & \vdots \\ \sigma_{l_n l_1} & \sigma_{l_n l_2} & \cdots & \sigma_{l_n l_n} \end{bmatrix} \quad (148.33)$$

Factoring a common (standard unit weight) constant out, we get

$$\Sigma_{L_b} = \sigma_0^2 \mathbf{Q}_{L_b} = \begin{bmatrix} q_{l_1 l_1} & q_{l_1 l_2} & \cdots & q_{l_1 l_n} \\ q_{l_2 l_1} & q_{l_2 l_2} & \cdots & q_{l_2 l_n} \\ \vdots & \vdots & \cdots & \vdots \\ q_{l_n l_1} & q_{l_n l_2} & \cdots & q_{l_n l_n} \end{bmatrix} \quad (148.34)$$

The  $\mathbf{Q}$  matrix is called the weight coefficient matrix. In terms of the weight matrix  $\mathbf{P}$ , we get

$$\Sigma_{L_b} = \sigma_0^2 \mathbf{P}_{L_b}^{-1} = \begin{bmatrix} p_{l_1 l_1} & p_{l_1 l_2} & \cdots & p_{l_1 l_n} \\ p_{l_2 l_1} & p_{l_2 l_2} & \cdots & p_{l_2 l_n} \\ \vdots & \vdots & \cdots & \vdots \\ p_{l_n l_1} & p_{l_n l_2} & \cdots & p_{l_n l_n} \end{bmatrix}^{-1} \quad (148.35)$$

For weighted observations, the matrix  $\mathbf{M}$ , Eq. (148.32), is simply replaced by

$$\mathbf{M} = \mathbf{B} \mathbf{P}^{-1} \mathbf{B}^T = \frac{1}{\sigma_0^2} \mathbf{B} \Sigma_{L_b} \mathbf{B}^T \quad (148.36)$$

The least squares estimate for the solution vector can be obtained from

$$\begin{aligned} X_a &= X_0 + X \\ &= X_0 - [\mathbf{A}^T \mathbf{M}^{-1} \mathbf{A}]^{-1} \mathbf{A}^T \mathbf{M}^{-1} \mathbf{W} \\ &= X_0 - [\mathbf{A}^T (\mathbf{B} \mathbf{P}^{-1} \mathbf{B}^T)^{-1} \mathbf{A}]^{-1} \mathbf{A}^T (\mathbf{B} \mathbf{P}^{-1} \mathbf{B}^T)^{-1} \mathbf{W} \end{aligned} \quad (148.37)$$

The variance/covariance matrix of the parameter vector  $\mathbf{X}$  or  $X_a$ , after applying the law of propagation of errors, can be shown to be equal to

$$\Sigma_{X_a} = \Sigma_X = \sigma_0^2 (\mathbf{A}^T \mathbf{M}^{-1} \mathbf{A})^{-1} \quad (148.38)$$

The relationship between the a priori variance of unit weight  $\sigma_0^2$  and the a posteriori variance of unit weight  $\hat{\sigma}_0^2$ , the latter being computed from

$$\hat{\sigma}_0^2 = \frac{\mathbf{V}^T \mathbf{P} \mathbf{V}}{r-u} \quad (148.39)$$

can be tested according to

$$\frac{\chi_{r-u;1-\alpha/2}^2}{r-u} < \frac{\hat{\sigma}_0^2}{\sigma_0^2} < \frac{\chi_{r-u;\alpha/2}^2}{r-u} \quad (148.40)$$

Equation (148.40) reflects the probability that the ratio of the variances will fall within the specified bounds, and is equal to  $1 - \alpha$  ( = 95% if  $\alpha = 0.05$  or 5%). This test gives insight between the expected observational precision and the overall behavior of the residuals once a model has

been "engaged." Rejection of the test may also lead to rejection of the particular model—for instance, in our example, if the observations were actually to lie on an ellipse rather than a circle.

From the "mixed model"  $F(L_a, X_a) = 0$ , two special models can be derived, which will be treated in the following two sections.

## 148.4 Observations as a Function of Parameters Only: The Model of Observation Equations

---

From the  $r$  (linearized) equations with  $u$  unknowns, a special case results if it so happens that each individual observation can be expressed as a function of the unknowns only. In this case we have  $L_a = F(X_a)$ , which can be derived directly by rewriting Eq. (148.26) as

$$-BL - BV = AX + W_0 \quad (148.41)$$

If  $B$  is assumed to be equal to a negative unit matrix (a square matrix with zeros and  $-1$  as diagonal elements), Eq. (148.41) becomes simply, with  $W_0$  being absorbed in the  $L$  vector [see Eqs. (148.44) and (148.45)],

$$L + V = AX \quad (148.42)$$

with

$$\begin{aligned} A &= \frac{\partial F}{\partial X} \\ X &= X_a - X_0 \\ V &= L_a - L_b \\ L &= L_b - L_0 \\ L_0 &= F(X_0) \end{aligned} \quad (148.43)$$

When you start from the unlinearized model  $L_a = F(X_a)$ , we find similarly

$$\begin{aligned} L_a &= F(X_a) \\ L_b + V &= F(X_0 + X_a - X_0) \\ L_b + V &= F(X_0) + \frac{\partial F}{\partial X} \cdot (X_a - X_0) \\ L_b + V &= L_0 + A \cdot X \end{aligned} \quad (148.44)$$

Bringing the  $L_0$  vector to the left-hand side,

$$\begin{aligned} L_b - L_0 + V &= A \cdot X \\ L + V &= A \cdot X \end{aligned} \quad (148.45)$$

In words, the variables denote

$L_a$  : adjusted observations

$L_b$  : observed values

$V$  : residuals

$L_0$  : approximate observations

$L$  : residual observations

$X_a$  : adjusted parameters

$X_0$  : approximate parameters (initial guess)

$X$  : unknown correction to parameters

$A$  : design matrix (partial derivative matrix for the parameters)

The normal equations simplify to

$$NX + U = 0 \quad (148.46)$$

with

$$N = A^T P A \quad (148.47)$$

$$U = -A^T P L \quad (148.48)$$

The solution vector  $X_a$  is equal to

$$\begin{aligned} X_a &= X_0 + X \\ &= X_0 + [A^T P A]^{-1} A^T P L \end{aligned} \quad (148.49)$$

The variance/covariance matrix of the parameter vector  $X$  or  $X_a$ , applying the law of propagation of errors, can be shown to be equal to

$$\Sigma_{X_a} = \Sigma_X = \sigma_0^2 (A^T P A)^{-1} \quad (148.50)$$

The relationship between the a priori variance of unit weight  $\sigma_0^2$  and the a posteriori variance of unit weight  $\hat{\sigma}_0^2$ , the latter being computed from

$$\hat{\sigma}_0^2 = \frac{V^T P V}{n-u} \quad (148.51)$$

Note that the denominator of Eq. (148.51) represents the degrees of freedom, which are equal to  $n - u$  since we deal with  $n$  (linearized) equations with  $u$  unknowns.

The method of observation equations is also known as "adjustment of indirect observations"

[see, e.g., (Mikhail, 1976)].

## Notation

The linearized observation equation, Eq. (148.45),

$$L + V = AX \quad (148.52)$$

appears under a variety of notations in the literature. For instance, Mikhail [1976] and Mikhail and Gracie [1981] use

$$l + \nu = -B\Delta \quad (148.53)$$

In the statistics literature one often finds

$$y - \varepsilon = X\beta \quad (148.54)$$

or, as in Gelb [1974],

$$z - \nu = Hx \quad (148.55)$$

Also, a more tensor-oriented notation may be found, as in Baarda [1967]:

$$x^i + \varepsilon^i = a_{\alpha}^i Y^{\alpha} \quad (148.56)$$

## 148.5 All Parameters Eliminated: The Model of Condition Equations

---

From the  $r$  (linearized) equations with  $u$  unknowns, another special case may be derived by eliminating the  $u$  unknowns from the linearized model, Eq. (148.26):

$$AX + BV + W = 0 \quad (148.57)$$

After elimination, we obtain  $r - u$  equations which reflect the mathematical relationship between the observations only. The equations are of the type

$$B'V + W' = 0 \quad (148.58)$$

They reflect the existing conditions between the observables—hence the name of the method. The classical example in surveying is that in a (not too large) triangle, the three measured angles have to sum to  $\pi$ . Another example concerns the loop closures between the leveled height differences, which have to sum to zero in each loop.

Starting from the nonlinearized model  $F(\mathbf{L}_a) = 0$ , we find

$$\begin{aligned}
 F(\mathbf{L}_a) &= 0 \\
 F(\mathbf{L}_b + \mathbf{V}) &= 0 \\
 F(\mathbf{L}_0 + \mathbf{L}_b - \mathbf{L}_0 + \mathbf{V}) &= 0 \\
 F(\mathbf{L}_0 + \mathbf{L} + \mathbf{V}) &= 0 \\
 F(\mathbf{L}_0) + \frac{\partial F}{\partial \mathbf{L}} \cdot (\mathbf{L} + \mathbf{V}) &= 0 \\
 \mathbf{W}_0 + \mathbf{B} \cdot \mathbf{L} + \mathbf{B} \cdot \mathbf{V} &= 0 \\
 \mathbf{W} + \mathbf{B}\mathbf{V} &= 0
 \end{aligned} \tag{148.59}$$

with

$$\begin{aligned}
 \mathbf{B} &= \frac{\partial F}{\partial \mathbf{L}} \\
 \mathbf{V} &= \mathbf{L}_a - \mathbf{L}_b \\
 \mathbf{L} &= \mathbf{L}_b - \mathbf{L}_0 \\
 \mathbf{W}_0 &= F(\mathbf{L}_0) \\
 \mathbf{W} &= \mathbf{W}_0 + \mathbf{B}\mathbf{L}
 \end{aligned} \tag{148.60}$$

In words, the variables denote

$\mathbf{L}_a$ : adjusted observations

$\mathbf{L}_b$ : observed values

$\mathbf{V}$ : residuals

$\mathbf{L}_0$ : approximate observations

$\mathbf{L}$ : residual observations

$\mathbf{W}_0$ : misclosure vector

$\mathbf{W}$ : misclosure vector

$\mathbf{B}$ : partial derivative matrix for the observations

## 148.6 An Example: Traversing

Various methods are presented in the survey literature [see, e.g., [Wolf and Brinker \(1995\)](#), chapters 12 and 13] to adjust data collected as part of a traverse. The (two-dimensional) least squares example discussed illustrates the formation of observation equations and can be adapted to reflect any traverse method. The example here involves the measurements of directions and distances along a traverse which stretches between two known points  $A$  and  $B$ , in coordinates  $\{x_A, y_A\}$  and  $\{x_B, y_B\}$ . In these terminal points two closing directions are measured to two known azimuth

markers, the points  $P$  and  $Q$ , respectively. The traverse is to solve for parameters such as the unknown coordinates of points 1 through  $n$ , the orientation unknowns for each point where directional measurements took place. Finally we assume the existence of an unknown scale factor  $\lambda$  between the distance measurement equipment and the distances implied by the known coordinates of points  $A$ ,  $B$ ,  $P$ , and  $Q$ .

## Directional Measurements $r_{ij}$

In point  $A$  two directions are measured, a backsight direction to  $P$  and a foresight direction to point 1. In point 1 two directions are measured, to the previous point  $A$  and to point 2; in point 2 directions are measured to 1 and 3; and so on. In the next to last point  $n$  a backsight direction is measured to point  $n - 1$  and a foresight direction to point  $B$ . In point  $B$  two directions are measured, to  $n$  and to the azimuth marker  $Q$ . The directional measurements can be written as a function of differences of azimuths  $Az_{ij}$  between points  $i$  and  $j$  and the unknown azimuths of the directional zero orientations  $o_i$ . The latter refer to the (unknown) azimuths of the "zero" reading on the horizontal circle of the theodolite. This so-called zero "reading" is not a reading on the circle at all, but the result of an analysis of a series of directional measurements taken in the point in question. The azimuths  $Az_{ij}$  are in turn a function of the coordinate unknowns  $\{x_i, y_i\}$  and  $\{x_j, y_j\}$ .

The first two observation equations, Eqs. (148.61) and (148.62), generated by the two directional measurements in point  $A$  are

$$r_{AP} = Az_{AP} - o_A = \arctan \left( \frac{x_P - x_A}{y_P - y_A} \right) - o_A \quad (148.61)$$

Note that  $o_A$  in Eq. (148.61) is the only unknown since we adopted the coordinates of  $A$  and  $P$ . However, the second (forward) direction in  $A(r_{A1})$  is dependent of three unknowns,  $o_A, x_1, y_1$ :

$$r_{A1} = Az_{A1} - o_A = \arctan \left( \frac{x_1 - x_A}{y_1 - y_A} \right) - o_A \quad (148.62)$$

The next two directional measurements, Eqs. (148.63) and (148.64), in point 1 are dependent of five unknowns,  $o_1, x_1, y_1, x_2$ , and  $y_2$ :

$$r_{1A} = Az_{1A} - o_1 = \arctan \left( \frac{x_A - x_1}{y_A - y_1} \right) - o_1 \quad (148.63)$$

For the foresight direction,

$$r_{12} = Az_{12} - o_1 = \arctan \left( \frac{x_2 - x_1}{y_2 - y_1} \right) - o_1 \quad (148.64)$$

In point  $i$ , in the middle of the traverse, we have the backsight direction

$$r_{i,i-1} = Az_{i,i-1} - o_i = \arctan \left( \frac{x_{i-1} - x_i}{y_{i-1} - y_i} \right) - o_i \quad (148.65)$$

and the foresight direction

$$r_{i,i+1} = Az_{i,i+1} - o_i = \arctan \left( \frac{x_{i+1} - x_i}{y_{i+1} - y_i} \right) - o_i \quad (148.66)$$

In the last point of the traverse, point  $B$ , we have

$$r_{Bn} = Az_{Bn} - o_B = \arctan \left( \frac{x_n - x_B}{y_n - y_B} \right) - o_B \quad (148.67)$$

and the foresight direction to azimuth marker  $Q$ ,

$$r_{BQ} = Az_{BQ} - o_B = \arctan \left( \frac{x_Q - x_B}{y_Q - y_B} \right) - o_B \quad (148.68)$$

So far, these directional measurements have generated  $2(n + 2)$  observational equations with  $(n + 2)$  directional unknowns and  $2n$  unknown coordinates, totaling  $3n + 2$  unknown parameters. The problem would not be solvable:  $2n + 4$  equations with  $3n + 2$  unknowns, a fact known to a surveyor because of geometric considerations alone. The addition of distance measurements will make traversing an efficient survey tool.

Note that one may have to add or subtract multiples of 360 degrees to keep the directional measurements  $r_{ij}$  between 0 and 360 degrees.

## Distance Measurements $s_{ij}$

The distance measurements with unknown (common) scale  $\lambda$  can be written in terms of the following functions. Since no distance measurements between point  $A$  and the azimuth marker  $P$  were assumed, we have in point  $A$  only one (forward) distance measurement

$$s_{A1} = \lambda[(x_1 - x_A)^2 + (y_1 - y_A)^2]^{1/2} \quad (148.69)$$

In point 1 we have a backsight distance  $s_{1A}$  and a foresight distance  $s_{12}$ , generating the following two observation equations:

$$s_{1A} = \lambda[(x_A - x_1)^2 + (y_A - y_1)^2]^{1/2} \quad (148.70)$$

and

$$s_{12} = \lambda[(x_2 - x_1)^2 + (y_2 - y_1)^2]^{1/2} \quad (148.71)$$

In point  $i$ , in the middle of the traverse, we have for the backsight distance

$$s_{i,i-1} = \lambda[(x_{i-1} - x_i)^2 + (y_{i-1} - y_i)^2]^{1/2} \quad (148.72)$$

and the foresight distance,

$$s_{i,i+1} = \lambda[(x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2]^{1/2} \quad (148.73)$$

In the last point of the traverse, in point  $B$ , we have for the backsight distance

$$s_{Bn} = \lambda[(x_n - x_B)^2 + (y_n - y_B)^2]^{1/2} \quad (148.74)$$

We assumed that no foresight distance measurement to azimuth marker  $Q$  took place.

The distance measurements added  $2(n + 1)$  observation equations and only one additional unknown, the scale factor  $\lambda$ . The  $2n$  coordinates  $\{x_i, y_i\}$  were already included in the previous directional observation equations. Summing the equations for both the directions and distances, we have for this particular traverse  $2(n + 2) + 2(n + 1) = 4n + 6$  observations with  $(3n + 2) + 1 = 3n + 3$  unknowns. The degrees of freedom are in this case  $(4n + 6) - (3n + 3) = n + 3$  for the traverse under mentioned measurement conditions.

## 148.7 Dynamical Systems

---

Modern survey techniques incorporate the element *time* in two different aspects: first of all, in classical survey systems the assumption is made that we deal with stationary systems. That is, the random behavior of, say, the residuals is invariant of time. Secondly, during a kinematic survey—for instance, having an aircraft make aerial photographs equipped with a GPS receiver—we have to deal with estimating a vector of unknowns, say the position of the GPS antenna fixed on top of the airplane's fuselage, which is not independent of time anymore. We get for the variance/covariance matrix of the observations, Eq. (148.33), and the linearized version of Eq. (148.52), respectively

$$\Sigma_{L_b} = \Sigma_{L_b(t)}(t) \quad (148.75)$$

and

$$L(t) + V(t) = A(t)X(t) \quad (148.76)$$

The vector  $X(t)$  reflects the state of the parameters at epoch  $t$ . At the same time, a different model may be at hand which describes the rate of change of this vector (vector velocity),

$$\dot{\mathbf{X}}(t) = F(t)\mathbf{X}(t) + \varepsilon' \quad (148.77)$$

One may similarly be able to write the state of the vector  $\mathbf{X}$  at epoch  $(t + dt)$  as a function of the state at  $t$ , according to

$$\mathbf{X}(t + dt) = \Phi(t + dt, t)\mathbf{X}(t) + \varepsilon \quad (148.78)$$

The (Jacobian) matrix  $\Phi$  (see also section 143.7 elsewhere in this book) is called the state transition matrix. A new estimate  $\mathbf{X}(t + dt)$  is computed from a new measurement through Eq. (148.76) and through the use of the previous estimate  $\mathbf{X}(t)$  through Eq. (148.77) or (148.78).

Equations (148.75) through (148.78) lead to dynamical estimation models. One of the better-known estimation (filtering) models has been developed by Kalman and others. These models are developed in the so-called time domain (as opposed to the frequency domain). The reader is referred to the vast literature in this area [see, e.g., (Gelb, 1974) and others].
